## Abstract

Stratosphere-troposphere exchange (STE) is an important source of tropospheric ozone, affecting all of atmospheric chemistry, climate, and air quality. The study of impacts needs STE fluxes to be resolved by latitude and month, and for this we rely on global chemistry models, whose results diverge greatly. Overall, we lack guidance from model-measurement metrics that inform us about processes and patterns related to the STE flux of ozone ( $O_3$ ). In this work, we use modeled tracers ( $N_2O$ ,  $CFCl_3$ ) whose distributions and budgets can be constrained by satellite and surface observations, allowing us to follow stratospheric signals across the tropopause. The satellite derived photochemical loss of  $N_2O$  on annual and quasi-biennial cycles can be matched by the models. The STE flux of  $N_2O$ -depleted air in our chemistry transport model drives surface variability that closely matches observed fluctuations on both annual and quasi-biennial cycles, confirming the modeled flux. The observed tracer correlations between  $N_2O$  and  $O_3$  in the lowermost stratosphere provide a hemispheric scaling of the  $N_2O$  STE flux to that of  $O_3$ . For  $N_2O$  and  $CFCl_3$ , we model greater southern hemispheric STE fluxes, a result supported by some metrics, but counter to prevailing theory of wave-driven stratospheric circulation. The STE flux of  $O_3$ , however, is predominantly northern hemispheric, but evidence shows that this is caused by the Antarctic ozone hole reducing southern hemispheric  $O_3$  STE by 14%. Our best estimate of the current STE  $O_3$  flux based on a range of constraints is 400 Tg( $O_3$ )/yr with a one-sigma uncertainty of  $\pm 15\%$  and with a NH:SH ratio ranging from 50:50 to 60:40. We identify a range of observational metrics that can better constrain the modeled STE  $O_3$  flux in future assessments.

## 1. Introduction & Background

The influx of stratospheric ozone ( $O_3$ ) into the troposphere affects its distribution, variability, lifetime, and thus its role in driving climate change and surface air pollution (Zeng et al., 2010; Hess et al., 2015; Williams et al., 2019). The net stratosphere-to-troposphere exchange (STE) flux of  $O_3$  has a regular seasonal cycle in each hemisphere that is an important part of the tropospheric  $O_3$  budget (Stohl et al., 2003). Such fluxes are not directly observable, and we rely on observational estimates using trace-gas ratios, in particular the  $O_3:N_2O$  ratio in the lower stratosphere (Murphy and Fahey, 1994; McLinden et al., 2000), or dynamical calculations using measured/modeled winds and  $O_3$  abundances (Gettelman et al., 1997; Olsen et al., 2004; Yang et al., 2016). The uncertainty in these estimates does not effectively constrain the wide range found in the models being used to project future ozone (Young et al., 2013, 2018; Griffiths et al., 2021). Here we present the case for using the observed variations in nitrous oxide ( $N_2O$ ) from the middle stratosphere to the surface in order to constrain the STE flux of  $O_3$ . A similar case

has been made for the radionuclide  $^7\text{Be}$  (Liu et al., 2016), but  $\text{N}_2\text{O}$  has a wealth of model-observation metrics on hemispheric, seasonal, and interannual scales that constrains its STE flux very well (Prather et al., 2015; Ruiz et al., 2021).

Ozone-rich stratospheric air has been photochemically aged and is depleted in trace gases such as  $\text{N}_2\text{O}$  and chlorofluorocarbons (CFCs). For these trace gases, the overall circulation from tropospheric sources to stratospheric destruction and back is part of the lifecycle that maintains their global abundance (Holton, 1990). For  $\text{N}_2\text{O}$  and CFCs, this cycle of (i) loss in the middle to upper stratosphere, (ii) transport to the lowermost stratosphere (Holton et al., 1995), and then (iii) influx into the troposphere produces surface variations not related to surface emissions (Hamilton and Fan, 2000; Nevison et al., 2004; Hirsch et al., 2006; Montzka et al., 2018; Ray et al., 2020; Ruiz et al., 2021). In this work we relate our modeled STE fluxes to variations at the surface and throughout the stratosphere, linking the fluxes of  $\text{N}_2\text{O}$  to  $\text{O}_3$  through stratospheric measurements. Our goal is to develop a set of model metrics founded on observations that are related to the STE  $\text{O}_3$  flux and can be used with an ensemble of models to determine a better, constrained estimate for the flux, including seasonal, interannual, and hemispheric patterns. This approach is similar to efforts involving the ozone depletion recovery time (Strahan et al., 2011) and projections of future warming (Liang et al., 2020; Tokarska et al., 2020).

In a previous work (Ruiz et al., 2021, hence R2021) we showed that historical simulations with three chemistry transport models (CTMs) were able to match the interannual surface variations observed in  $\text{N}_2\text{O}$ . These were clearly driven by the stratospheric quasi-biennial oscillation (QBO) which appears to be the major interannual signal in stratospheric circulation and STE (Kinnerson and Tung, 1999; Baldwin et al., 2001; Olsen et al., 2019). In this work, we calculate the monthly latitudinal STE fluxes of  $\text{O}_3$ ,  $\text{N}_2\text{O}$ , and  $\text{CFCl}_3$  (F11), establish a coherent picture relating fluxes to observed abundances, and summarize the methods in Section 2. In section 3, we examine the annual and interannual cycles as well as geographic patterns of modeled STE flux. In section 4, we relate the surface variability of  $\text{N}_2\text{O}$  to its STE flux. We find some evidence to support our model result that the STE flux of depleted- $\text{N}_2\text{O}$  air is greater in the southern hemisphere than in the northern, thus altering the asymmetry in surface emissions in the source inversions (Nevison et al., 2007; Thompson et al., 2014). In section 5, we examine the lowermost stratosphere to understand the large north-south asymmetry found in  $\text{O}_3$  STE versus  $\text{N}_2\text{O}$  or F11 STE, and find a clear signal of the Antarctic ozone hole in STE. In section 6, we examine the consistency of the model calculations of STE flux and derive a best estimate for the  $\text{O}_3$  flux from this and previous studies. We summarize a sequence of model metrics, primarily using  $\text{O}_3$  and  $\text{N}_2\text{O}$ , that can narrow the range in the tropospheric  $\text{O}_3$  budget terms for the multi-model intercomparison projects used in tropospheric chemistry and climate assessments.

## 2. Methods

The modeled STE fluxes here are calculated with the UCI (University of California Irvine) CTM driven by 3-hour forecast fields from the European Centre for Medium-range Weather Forecasts (ECMWF) Integrated Forecast System (IFS Cycle 38r1 T159L60) for years 1990-2017, as are the calculations in R2021. The CTM uses the IFS native  $160 \times 320$  Gauss grid ( $\sim 1.1^\circ$ ) with 60 layers, about 35 of which are in the troposphere. The stratospheric chemistry uses the linearized model Linoz v3 and includes  $\text{O}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}_y$ ,  $\text{CH}_4$ , and F11 as transported trace gases (Hsu and

Prather, 2010; Prather et al., 2015; Ruiz et al., 2021). There is no tropospheric chemistry, but rather a boundary-layer e-fold to a specified abundance, or a surface boundary reset to an abundance. Equivalent effective stratospheric chlorine levels are high enough to drive an Antarctic ozone hole, which is observed throughout this period. Thus, the ozone-hole chemistry in Linoz v3 is activated for all years, and the amount of O<sub>3</sub> depleted depends on the Antarctic meteorology of that year (Hsu and Prather, 2010).

The STE flux is calculated using the e90 definition of tropospheric grid cells (Prather et al., 2011) and the change in tropospheric tracer mass from before to after each tracer transport step as developed at UCI (Hsu et al., 2005; Hsu and Prather, 2009; Hsu and Prather, 2014). This method is precise and geographically accurate for O<sub>3</sub> and is self-consistent with a CTM's tracer-transport calculation (Tang et al., 2013; Hsu and Prather, 2014). Extensive comparisons with other methods of calculating STE are shown in Hsu and Prather (2014). Annual-mean STE fluxes are calculated from the full 28-year (336 month) time series as 12-month running means, and the annual cycle of monthly fluxes is the average of the 28 values for each month.

R2021 modeled the surface signal of stratospheric loss with the decaying tracers, N<sub>2</sub>OX and F11X (e.g., (Hamilton and Fan, 2000; Hirsch et al., 2006). These X-tracers have the identical stratospheric chemical loss frequencies as N<sub>2</sub>O and CFCl<sub>3</sub>, respectively, but no surface sources and are therefore affected only by the stratospheric sink and atmospheric transport. The multi-decade (F11X) to century (N<sub>2</sub>OX) decays are easily rescaled using a 12-month smoothing filter to give stationary results and a tropospheric mean abundance of 320 ppb. We treat F11X like N<sub>2</sub>OX with the same initial conditions and molecular weight. Budgets for N<sub>2</sub>OX are reported, as in N<sub>2</sub>O studies (Tian et al., 2020), as Tg of N as N<sub>2</sub>O. These rescaled N<sub>2</sub>OX and F11X tracers are designated simply as N<sub>2</sub>O (not N<sub>2</sub>O) and F11. Our F11 STE fluxes are thus unrealistically large compared to current CFCl<sub>3</sub> fluxes, but can be easily compared with our N<sub>2</sub>O results.

When trying to calculate the STE flux of N<sub>2</sub>O-depleted air across the tropopause, we found that the Hsu method was numerically noisy because the gradient across the tropopause, unlike that of O<sub>3</sub>, was negligible. Thus, for this work we created the complementary tracers cN<sub>2</sub>OX and cF11X: for each kg of the X-tracer (i.e., N<sub>2</sub>OX) destroyed by photochemistry, 1 kg of its complementary tracer (cN<sub>2</sub>OX) is created. Air parcels that are depleted in N<sub>2</sub>OX (F11X) are therefore rich in cN<sub>2</sub>OX (cF11X). After crossing the tropopause, cN<sub>2</sub>OX and cF11X are removed through rapid uptake in the boundary layer, thus creating sharp gradients at the tropopause in parallel with that of O<sub>3</sub>. As a check, we compared the boundary layer sinks of the c-tracers with their e90-derived STE fluxes and find that their sums are identical. The c-tracers and their STE fluxes are rescaled as are the X-tracers to give them a stationary time series corresponding to a tropospheric abundance of 320 ppb for their parallel X tracers. We designate these scaled tracers simply as cN<sub>2</sub>O and cF11.

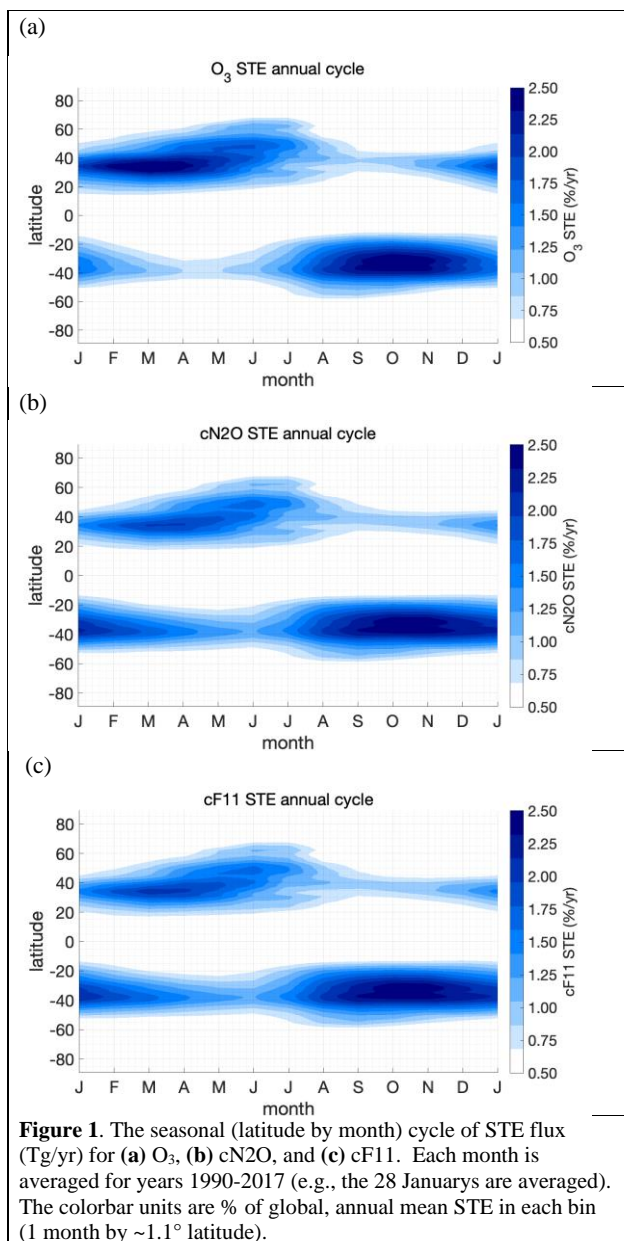

### 3. Modeled STE fluxes

#### 3.1 Global and hemispheric means

The 28-year mean of global O<sub>3</sub> STE is 390±16 Tg/yr (positive flux means stratosphere to troposphere, the ± values are the standard deviation of the 28 annual means and do not represent

uncertainty). This value is well within the uncertainty in the observation-based estimates (Murphy and Fahey, 1994; Olsen et al., 2001), and far from the extreme ranges of the 34 models in the latest Tropospheric Ozone Assessment Report (Young et al., 2018), 150 to 940 Tg/yr. The global STE flux of cN<sub>2</sub>O is  $11.5 \pm 0.7$  Tg/yr, and that of cF11 is  $23.5 \pm 1.5$  Tg/yr. These fluxes for cN<sub>2</sub>O and cF11 match the total long-term troposphere-to-stratosphere flux of N<sub>2</sub>O and F11 as derived from their stratospheric losses. The cF11 budget is about twice as large as cN<sub>2</sub>O, because F11 is photolyzed rapidly in the lower-middle stratosphere (~24 km) instead of the upper stratosphere like N<sub>2</sub>O (~32 km). The seasonal mean pattern of STE fluxes are shown in Figure 1. The large majority of STE flux enters the troposphere at 25°-45° latitude in each hemisphere, but there is a broadening of the northern flux to 65°N in Jun-Jul. The importance of this region about the sub-tropical jet for STE is supported by satellite data where stratospheric folding events (high O<sub>3</sub> in the upper troposphere) are found at the bends of the jet (Tang and Prather, 2010).

Given the small STE fluxes in the core tropics, the northern hemisphere (NH) and southern hemisphere (SH) fluxes are distinct. The annual mean of NH O<sub>3</sub> STE is  $208 \pm 11$  Tg/yr and is slightly larger than the SH mean of  $182 \pm 11$  Tg/yr. This NH:SH ratio of 53:47 is typically found in other studies (Gettelman et al., 1997; Hsu and Prather, 2009; Yang et al., 2016), although some have higher ratios like 58:42 (Hegglin and Shepherd, 2009; Meul et al., 2018). In contrast, for cN<sub>2</sub>O and cF11, the NH flux ( $5.1 \pm 0.4$  Tg/yr and  $10.6 \pm 0.8$  Tg/yr, respectively) is smaller than the SH flux ( $6.4 \pm 0.5$  Tg/yr and  $12.9 \pm 1.0$  Tg/yr, respectively), giving a NH:SH ratio of about 45:55. The established view on STE is that the flux is wave-driven and under downward control, and thus the NH flux is much greater than the SH flux (see Table 1 of Holton et al., 1995; also Appenzeller et al., 1996). Our unexpected results require further analysis including evidence for hemispheric asymmetry in observations which is shown in section 4 along with other model metrics.

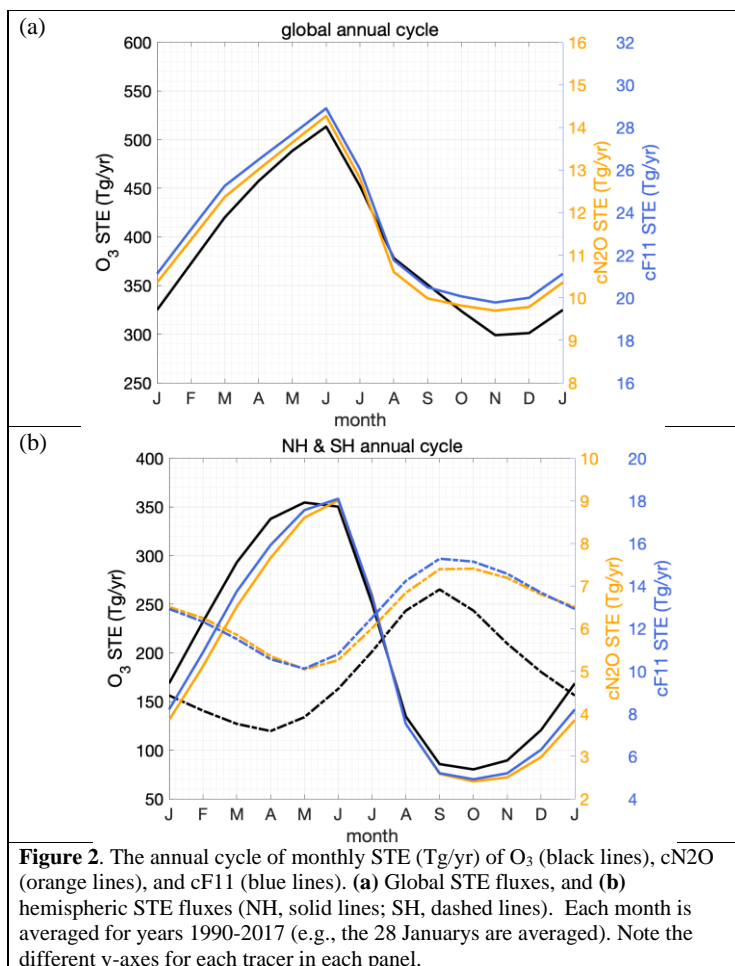

173  
174

### 3.2 Seasonal cycle

The seasonal cycles of STE fluxes summed over global, NH, and SH are shown in Figure 2. The scales are given as the annual rate (as if the monthly rate were maintained for the year), and each species has a different axis. The right y-axes are kept at a N<sub>2</sub>O:F11 ratio of 1:2. Despite large differences in the stratospheric chemistry across all three species, the seasonal cycle of STE is highly correlated (Pearson's correlation coefficient  $cc > 0.98$ , except for SH O<sub>3</sub>), indicating that all three enter the troposphere from a seasonally near-uniform mixture of O<sub>3</sub>:N<sub>2</sub>O:F11 in the lowermost stratosphere.

Global STE peaks in June and reaches a minimum in November. The two hemispheres have dramatically different seasonal amplitudes and somewhat opposite phases. NH peak STE for all 3 species occurs in the late boreal spring (May-June), while that in the SH occurs at the start of austral spring (September-October). In the NH O<sub>3</sub> STE peaks a month before the c-tracers, and in the SH the whole annual cycle of O<sub>3</sub> is shifted a month earlier. The NH STE seasonal amplitude is very large for all species (~ 4:1 ratio max-to-min) with exchange almost ceasing in the fall. In contrast, the SH STE is more uniform year-round with a 1.5:1 ratio for cN<sub>2</sub>O and cF11, and 2.2:1 for O<sub>3</sub>. Other models with similar NH and SH O<sub>3</sub> fluxes show different seasonal amplitudes and phasing (see Fig. 6 of Tang et al., 2021), which will affect tropospheric O<sub>3</sub> abundances. It is important to develop observational metrics that test the seasonality of the lowermost stratosphere related to STE fluxes, and to establish monthly STE fluxes as a standard model diagnostic.

An interesting result here is the very tight correlation of the monthly cN<sub>2</sub>O and cF11 STE while the O<sub>3</sub> STE is sometimes shifted. Loss of N<sub>2</sub>O and F11 occurs at very different altitudes in the tropical stratosphere (~32 km and ~24 km, respectively), but both have similar seasonality in loss, driven mostly by the intensity of sunlight along the Earth's orbit (N<sub>2</sub>O loss peaks in Feb and reaches a minimum in July, see Fig. 4 from Prather et al. (2015)). Photochemical losses of N<sub>2</sub>O and F11 drop quickly for air descending from the altitudes of peak loss in the tropics and hence the relative cN<sub>2</sub>O and cF11 STE fluxes are locked in. O<sub>3</sub>, however, continues to evolve photochemically from 24 km to 16 km (upper boundary of the lowermost stratosphere), through net photochemical production in the tropics and loss at mid- and high-latitudes that depends on sunlight and is thus seasonal. There may be observational evidence for the patterns modeled here in the correlation of these three tracers in the lower (16-20 km) and lowermost (12-16 km) extratropical stratosphere (see section 4).

### 3.3 Interannual variability

Interannual variability (IAV) of N<sub>2</sub>O loss and its lifetime is associated primarily with the QBO (most recently, R2021). When the QBO is in its easterly (westerly) phase the entire overturning circulation is enhanced (suppressed) (Baldwin et al., 2001). This results in more (less) air rich in N<sub>2</sub>O and F11 being transported from the troposphere to the lower or middle stratosphere, thereby increasing (decreasing) the N<sub>2</sub>O and F11 sinks (Prather et al., 2015; Strahan et al., 2015). From the tropical stratosphere, the overturning circulation transports air depleted in N<sub>2</sub>O and F11 into the lowermost extratropical stratosphere, where it enters the troposphere. R2021 showed that the

observed surface variability of N<sub>2</sub>O from this circulation can be modeled and has a clear QBO signal, but one that is not strongly correlated with the QBO signal in stratospheric loss.

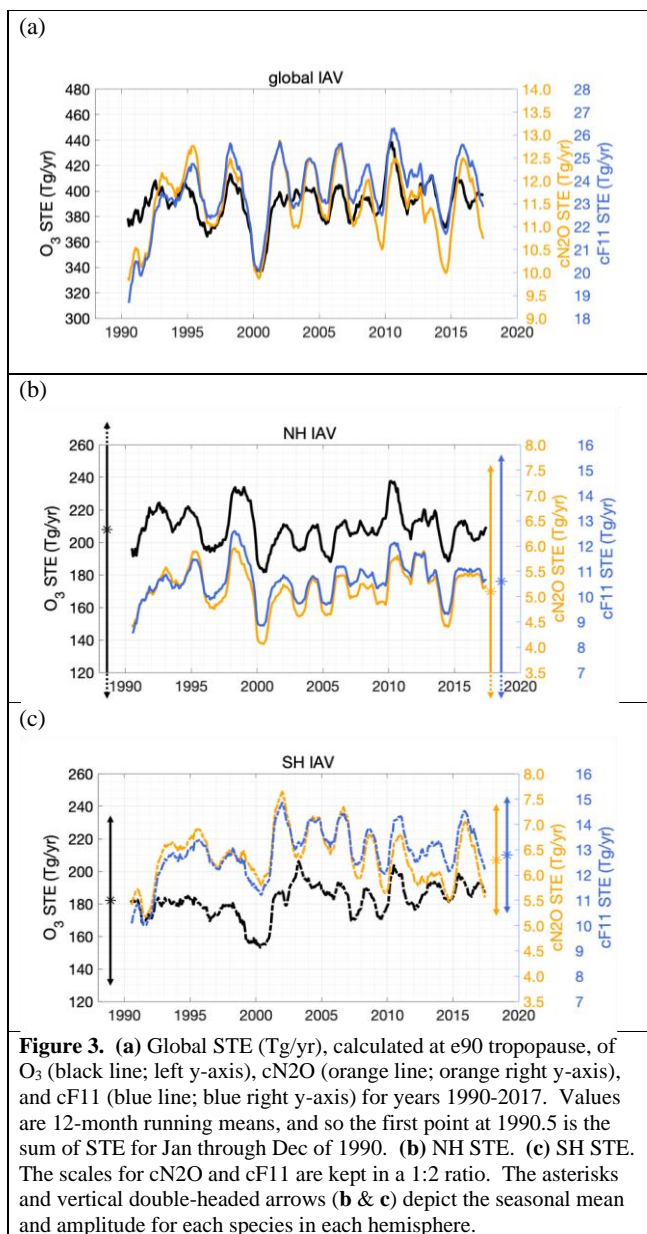

We generate the IAV of STE fluxes for O<sub>3</sub>, cN<sub>2</sub>O, and cF11 in Figure 3abc with panels for global, NH, and SH. Values are 12-month running means, and so the first modeled point at 1990.5 is the sum of STE for Jan through Dec of 1990. In Figures 3bc, we also show the seasonal amplitude of STE with double-headed arrows on the left (O<sub>3</sub>) and right (cN<sub>2</sub>O and cF11). In a surprising result, the large NH-SH differences in seasonal amplitude are not reflected in the IAV where NH and SH amplitudes are similar for all three tracers. The QBO modulation of the lowermost stratosphere and STE appears to be unrelated to the seasonal cycle in STE.

Global STE for all three tracers shows QBO-like cycling throughout the 1990-2017 time series: cN<sub>2</sub>O and cF11 are well correlated ( $cc \sim 0.9$ ), but either species with O<sub>3</sub> is much less so ( $cc < 0.7$ ). The hemispheric breakdown provides key information regarding O<sub>3</sub>. In the NH the STE IAV is similar across all three tracers with high correlation coefficients ( $cc = 0.82$  for O<sub>3</sub>-cN<sub>2</sub>O,  $0.83$  for O<sub>3</sub>-cF11, and  $0.94$  for cN<sub>2</sub>O-cF11). Conversely in the SH, O<sub>3</sub> STE diverges from the c-tracer fluxes, showing opposite-sign peaks in 2003 and 2016. The corresponding SH correlations are ( $cc = 0.38, 0.65, 0.85$ ). The loss of correlation between cN<sub>2</sub>O and cF11 is unusual: cN<sub>2</sub>O STE drifts downward relative to cF11 STE, particularly after 2007; nevertheless, the fine structure after 2007 is well matched in both tracers.

In the SH, the massive loss of O<sub>3</sub> within the Antarctic vortex, when mixed with the extra-polar lowermost stratosphere will systematically shift the O<sub>3</sub> STE to lower values, with less impact on the cN<sub>2</sub>O and cF11 STE. The IAV of the Antarctic winter vortex, in terms of the amount of O<sub>3</sub> that is depleted (see Fig. 4-4 of WMO, 2018), appears to drive the decorrelation of the SH STE fluxes and is analyzed in section 4.

In the NH, the high variability of the Arctic winter stratosphere can modulate the total O<sub>3</sub> STE flux (e.g., Hsu and Prather, 2009) but appears to maintain the same relative ratio with the cN<sub>2</sub>O and cF11 fluxes. Model results here indicate that in the NH, the IAV of O<sub>3</sub>, cN<sub>2</sub>O, and cF11 STE fluxes are synchronized, and thus the air masses entering the lowermost stratosphere have the same chemical mixtures from year to year. We know that cold-temperature activation of halogen-driven O<sub>3</sub> depletion in the Arctic winter at altitudes above 400 K (potential temperature) can produce large IAV in column ozone (Manney et al., 2011); but the magnitude is still much smaller than in the Antarctic; and it may not reach into the lowermost stratosphere ( $<380$ K potential temperature). This model accurately simulates Antarctic O<sub>3</sub> loss (section 4), but we have not evaluated it for Arctic loss, and the Arctic conditions operate closer to the thresholds initiating loss where Linoz v3 chemistry may be inadequate. The same meteorology and transport model with full stratospheric chemistry is able to simulate Arctic O<sub>3</sub> loss (Oslo's CTM2: Isaksen et al., 2012), and thus it will be possible to re-evaluate the NH IAV with such models or with lowermost stratosphere tracer measurements.

268  
269

### 3.4 The link from stratospheric loss to STE flux

What is unusual about the very tight correlation of cN<sub>2</sub>O and cF11 STE fluxes is that the photochemical loss of N<sub>2</sub>O and F11 occurs at very different altitudes in the tropical stratosphere, which are not in phase with respect to the QBO as shown in R2021 (their Fig. 2). The separate phasing of cN<sub>2</sub>O and cF11 production is lost, presumably by diffusive tracer transport, by the time they reach the extratropical lowermost stratosphere. The overall synchronization of the STE fluxes implies that the absolute STE flux is driven primarily by variations in venting of the lowermost stratosphere as expected (Holton et al., 1995; Appenzeller et al., 1996) rather than by variations in the chemistry of the middle stratosphere.

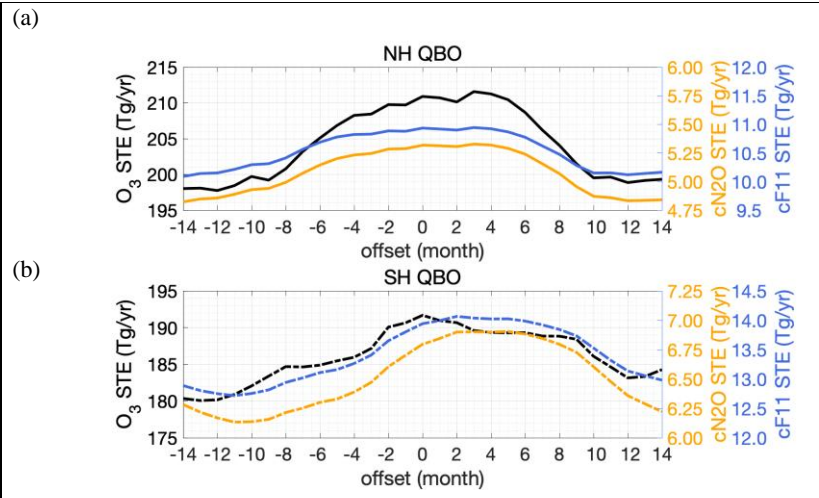

This disconnect between the chemical signals generated by the prominent QBO signature of wind reversals, upwelling in the tropical stratosphere, and the STE fluxes is also clear in the magnitude of the loss versus STE. For N<sub>2</sub>O, the IAV of cN<sub>2</sub>O production has a range of  $\pm 0.5$  Tg/yr, whether from Microwave Limb Sounder (MLS) observations or the model; whereas the IAV of cN<sub>2</sub>O STE flux is  $\pm 1.1$  Tg/yr. The same is true in relative terms for cF11. Thus, the modulation of the lowermost stratosphere by the QBO is clearly a part of the overall changes in stratospheric circulation related to the QBO (Tung and Yang, 1994a; Kinnersley and Tung, 1999) and is the dominant source of IAV for these three greenhouse gases.

### 3.5. The QBO signal

To examine the QBO cycle in STE flux, we build a composite pattern (see R2021, Fig. 3 of N<sub>2</sub>O surface variations), by synchronizing the STE IAV in Figure 2 with the QBO cycle. The sync point (offset = 0 months) is taken from one of the standard definitions of the QBO phase change, i.e., the shift in sign of the 40-hPa tropical zonal wind from easterly to westerly (Newman, 2020). The 1990-2017 model period has 12 QBO cycles, but we restrict our analysis here to years 2001-2016 to overlap with the observed surface N<sub>2</sub>O data. This period includes seven QBO phase transitions (01/2002, 03/2004, 04/2006, 04/2008, 08/2010, 04/2013, 07/2015), but the observed surface N<sub>2</sub>O is highly anomalous during the QBO centered on 08/2010 (R2021), so we remove it from our comparison for consistency with R2021 (see their Fig S4d). The resulting QBO composites for NH and SH in Figure 4 span 28 months.

In the NH, the QBO modulation of all three tracers is similar: STE flux begins to increase at an offset of -8 months and continues to increase slowly for a year, peaking at an offset of +4 months; thereafter it decreases more rapidly in about ½ year (offset = +10). The rise-and-fall cycle takes about 18 months. In the SH, the pattern for cN<sub>2</sub>O and cF11 is more sinusoidal and is shifted later by ~3 months. The SH amplitude of the c-tracers is slightly larger relative to the hemispheric mean flux than in the NH, and thus the SH QBO signal is larger than the NH by about 40%. Thus, over the typical QBO cycle centered on the sync point, more depleted N<sub>2</sub>O and F11 is entering the SH than in the NH. For O<sub>3</sub>, the SH modulation of STE is irregular and reduced compared with the NH. Our hypothesis here, consistent with the annual cycle of STE (Figure 1), is that the breakup of the Antarctic ozone hole has a major impact on STE, particularly that of O<sub>3</sub>, and that its signal has large IAV that does not synchronize with the QBO. Surprisingly, the large wintertime IAV in the NH Arctic, in the form of sudden stratospheric warmings, does not seem to have a major role in STE fluxes as noted above. This model may

miss some of the Arctic O<sub>3</sub> depletion, but it accurately simulates the warmings, which must have a small impact on STE because they do not disrupt the clear QBO signal in the c-tracers.

**Figure 4.** QBO composites of the STE of O<sub>3</sub> (black lines; left y-axes), cN2OX (orange lines; orange right y-axes), and cF11X (blue lines; blue right y-axes) for the (a) NH (0°-90°N; solid lines) and (b) SH (0°-90°S; dashed lines). These composites are averages centered on the QBO phase transition at 40 hPa throughout the period of surface observations (years 2001-2016, excluding the 08/2010 observed anomaly, for a total of 6 QBOs). Note: the y-axes limits are different for each panel, but the interval scale is consistent for each tracer.

#### 4. Surface variability of N<sub>2</sub>O related to STE flux

Surface variability of N<sub>2</sub>O is driven by surface emissions, stratospheric loss, and atmospheric transport that mixes the first two signals. R2021 explored the variability originating only from stratospheric chemistry using the decaying tracer N2OX. Here, we use surf-N2O to denote the surface abundances of N2OX when corrected to steady state. R2021 showed that three independent chemistry-transport models produced annual and QBO patterns in surface N<sub>2</sub>O simply from stratospheric loss. In this paper we link surf-N2O to the STE cN2O flux, which is linked above to the STE O<sub>3</sub> flux.

The observed surface N<sub>2</sub>O, denoted obs-N<sub>2</sub>O and taken from the NOAA network (Dlugokencky et al., 2019), shows a slowly increasing abundance (~0.9 ppb/yr) with a clear signal of annual and interannual variability at some latitudes (see R2021). We calculate annual and QBO-composite obs-N<sub>2</sub>O after de-trending and restrict analysis in this section to model years 2001-2016 to be consistent with the surface data. The latitude-by-month pattern of obs-N<sub>2</sub>O includes the impact of both stratospheric loss (~13.5 Tg/yr) and surface emissions (~17 TgN/yr), with the preponderance of emissions being in the NH (Tian et al., 2020). Total emissions are not

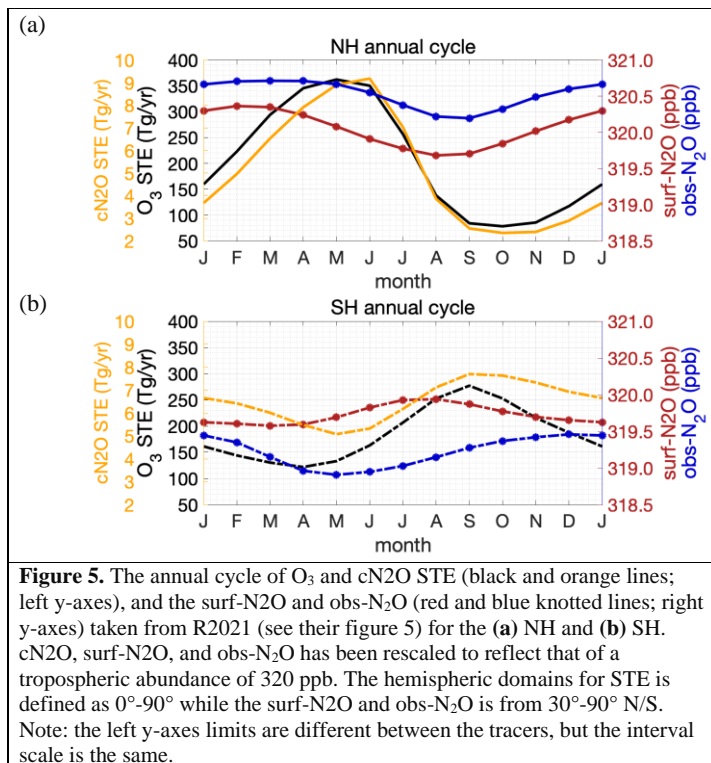

expected to have large IAV but may have a seasonal cycle. The seasonal variation of surface  $\text{N}_2\text{O}$  can also be driven by seasonality in the interhemispheric mixing of the NH-SH gradient ( $\sim 1$  ppb).

#### 4.1 Annual cycle

Figure 5 replots the hemispheric mean annual cycles of cN<sub>2</sub>O STE flux alongside the annual cycles of surf-N<sub>2</sub>O and obs-N<sub>2</sub>O. As noted above, the STE in each hemisphere is almost in opposite phase, as is the modeled surf-N<sub>2</sub>O (taken from Fig. 5 of R2021). The NH:SH amplitude ratio is about 2.4:1 for both STE and surf-N<sub>2</sub>O. The lag from peak STE flux of cN<sub>2</sub>O (negative N<sub>2</sub>O) to minimum surf-N<sub>2</sub>O is about 3 months. Such a 90° phase shift is expected for the seasonal variation of a long-lived tracer relative to a seasonal source or sink. The time lag between the signal at the tropopause and at the surface, the tropospheric turnover time, should be no more than a month. Surprisingly, the cN<sub>2</sub>O STE seasonal amplitude is much larger in the NH ( $\pm 3.4$  Tg/yr) than in the SH ( $\pm 1.3$  Tg/yr), although the SH mean (6.5 Tg/yr) is larger than the NH (5.2 Tg/yr). Essentially, there is more variability of air depleted in N<sub>2</sub>O entering the NH, but air entering the SH has a larger overall deficit. Thus in our model, the stratosphere creates a NH-SH gradient of +0.3 ppb at the surface, which is a significant fraction of the observed N-S difference of +1.3 ppb (R2021). This important result needs to be verified with other models or analyses because it constrains the NH-SH location of sources.

In the NH, as noted in R2021, the two surface abundances, surf-N<sub>2</sub>O and obs-N<sub>2</sub>O, have the same amplitude and phase, implying that, if the model is correct, the emissions-driven surface signal has no seasonality, although we know that some important emissions are seasonal (Butterbach-Bahl et al., 2013). In the SH, the surf-N<sub>2</sub>O signal is much smaller, in parallel with the small seasonal amplitude in cN<sub>2</sub>O STE, but it is out of phase with the obs-N<sub>2</sub>O. This result implies that the SH has some highly seasonal sources, or simply that the forcing of SH surf-N<sub>2</sub>O by the seasonal cycle of cN<sub>2</sub>O is weak. Indeed, this is what we might expect from Figure 3: In the NH the seasonal amplitude in N<sub>2</sub>O overwhelms the IAV amplitude and is driving the obs-N<sub>2</sub>O; but in the SH, both amplitudes are comparable. Given the quasi-regular nature of the QBO, it would interfere with the seasonal cycle and likely change its phase (as found for other models in R2021).

In the NH, the annual cycle of O<sub>3</sub> and cN<sub>2</sub>O STE are clearly linked. If we accept that the obs-N<sub>2</sub>O NH seasonal cycle is simply driven by the STE flux, then how will tropospheric O<sub>3</sub> respond seasonally? A mole-fraction scaling of the STE fluxes gives an O<sub>3</sub>:N<sub>2</sub>O ratio of  $\sim 25$ , and thus scaling the surf-N<sub>2</sub>O amplitude gives a large O<sub>3</sub> surface seasonality of  $\sim 18$  ppb. However, the residence time of a tropospheric O<sub>3</sub> perturbation is  $\sim 1$  month, and thus the peak surface abundance will lag the peak STE flux by only about a month and not by 3 months as for N<sub>2</sub>O. O<sub>3</sub> will equilibrate with the flux on monthly timescales and not accumulate. Thus, our estimate is that NH 30°-90° surface ozone might increase about 5 ppb, peaking in June, due to the STE flux. In the SH, seasonal patterns are weaker and not well defined, and thus no obvious STE O<sub>3</sub> signal is expected.

**Figure 5.** The annual cycle of O<sub>3</sub> and cN<sub>2</sub>O STE (black and orange lines; left y-axes), and the surf-N<sub>2</sub>O and obs-N<sub>2</sub>O (red and blue knotted lines; right y-axes) taken from R2021 (see their figure 5) for the (a) NH and (b) SH. cN<sub>2</sub>O, surf-N<sub>2</sub>O, and obs-N<sub>2</sub>O has been rescaled to reflect that of a tropospheric abundance of 320 ppb. The hemispheric domains for STE is defined as 0°-90° while the surf-N<sub>2</sub>O and obs-N<sub>2</sub>O is from 30°-90° N/S. Note: the left y-axes limits are different between the tracers, but the interval scale is the same.

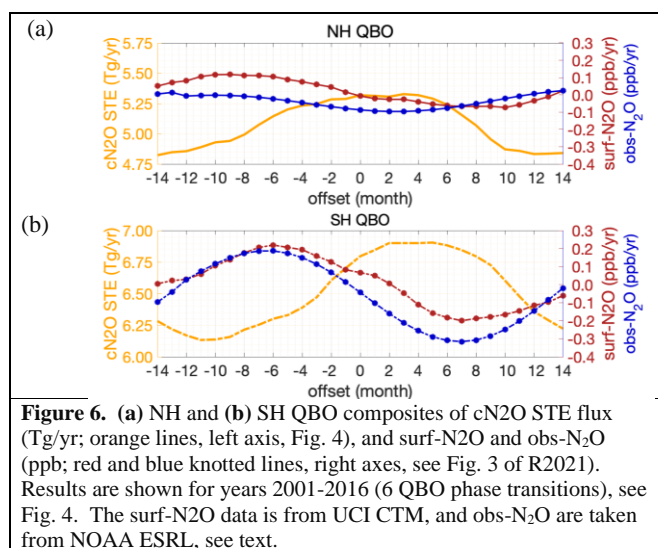

#### 4.2. QBO cycle

The QBO composite of hemispheric mean cN<sub>2</sub>O STE flux from Figure 4 is compared with the composite of surface abundances (surf-N<sub>2</sub>O and obs-N<sub>2</sub>O) in Figure 6. The peak in cN<sub>2</sub>O flux is broad and flat, but centers on +2 months for the NH and +4 months for the SH. Unlike the annual cycle, the QBO cycle in STE flux is almost in phase in both hemispheres, with the NH preceding the SH. This phasing of the QBO cycle in surface N<sub>2</sub>O was seen with the three models in R2021. In both hemispheres, the modeled surf-N<sub>2</sub>O peaks before the rise in cN<sub>2</sub>O and then decreases through most of the period with elevated cN<sub>2</sub>O flux as expected. The amplitude of the QBO STE flux is smaller in the NH than SH by about half, and the amplitude of surf-N<sub>2</sub>O is likewise smaller. The ratio of the amplitudes of surf-N<sub>2</sub>O to cN<sub>2</sub>O STE flux is similar in both hemispheres (~ 0.4 ppb per Tg/yr), which is encouraging. This ratio is larger than the corresponding one from the annual cycles (~ 0.1 ppb per Tg/yr) because the length of the QBO cycle leads to longer accumulation of N<sub>2</sub>O-depleted air from the cN<sub>2</sub>O flux.

In the SH, where the QBO cycle in cN<sub>2</sub>O flux has a large amplitude, the modeled surf-N<sub>2</sub>O matches obs-N<sub>2</sub>O in amplitude and phase as reported in R2021. In the NH, the comparison of

surf-N<sub>2</sub>O with obs-N<sub>2</sub>O is not so good: obs-N<sub>2</sub>O has a much smaller amplitude and a different phase. This QBO cycle pattern is similar, but reversed, to that of the annual cycle and can be understood in the same way. The NH QBO cycle has relatively small amplitude and thus the interference with the large-amplitude annual cycle adds noise, obscuring the QBO cycle. In the SH it is the opposite, with its weak annual cycle, the SH QBO cycle is clear. The modeled cN<sub>2</sub>O fluxes enable us to understand the large-scale variability of the observations.

Thus, for both annual and QBO fluctuations, when the variation in STE flux is dominated by either cycle, the surface variations are clearly seen and modeled for that cycle. This further supports the findings in R2021 and other studies, that hemispheric surface N<sub>2</sub>O variability is driven by stratospheric loss on annual (NH) and QBO (SH) cycles, and it is clearly tied to the STE flux. Given the connection between O<sub>3</sub> and cN<sub>2</sub>O STE, this relational metric can be used to constrain the O<sub>3</sub> STE for a model ensemble.

## 5. Lowermost stratosphere

If we accept that matching the observed annual and QBO cycles in surface N<sub>2</sub>O constrains the modeled STE cN<sub>2</sub>O flux, then how can we use that to also constrain the modeled STE O<sub>3</sub> flux? All evidence, theoretical, observational, and modeled, shows that the STE flux is simultaneous for all species (e.g., Figure 1) and in proportion to their relative abundances (i.e., tracer:tracer slopes) in the lowermost stratosphere, defined roughly as the region 100-200 hPa in each hemisphere outside the tropics (Plumb and Ko, 1992).

### 5.1. The O<sub>3</sub>:N<sub>2</sub>O slopes and STE fluxes

We can test the Plumb and Ko hypothesis in our model framework by comparing the relative STE fluxes for O<sub>3</sub>, cN<sub>2</sub>O and cF11 with the modeled tracer-tracer slopes in the lowermost stratosphere. These slopes can then be tested using SCISAT-1 ACE-FTS (Scientific Satellite-1 Atmospheric Chemistry Experiment-Fourier Transform Spectrometer) measurements of O<sub>3</sub> and N<sub>2</sub>O in the lowermost stratosphere to establish the ratio of the two STE fluxes. [The ACE-FTS O<sub>3</sub>:N<sub>2</sub>O slopes were used for model transport and chemistry evaluation \(Hegglin and Shepherd, 2007\) and found to be very sensitive to satellite sampling, except in the lowermost stratosphere.](#)

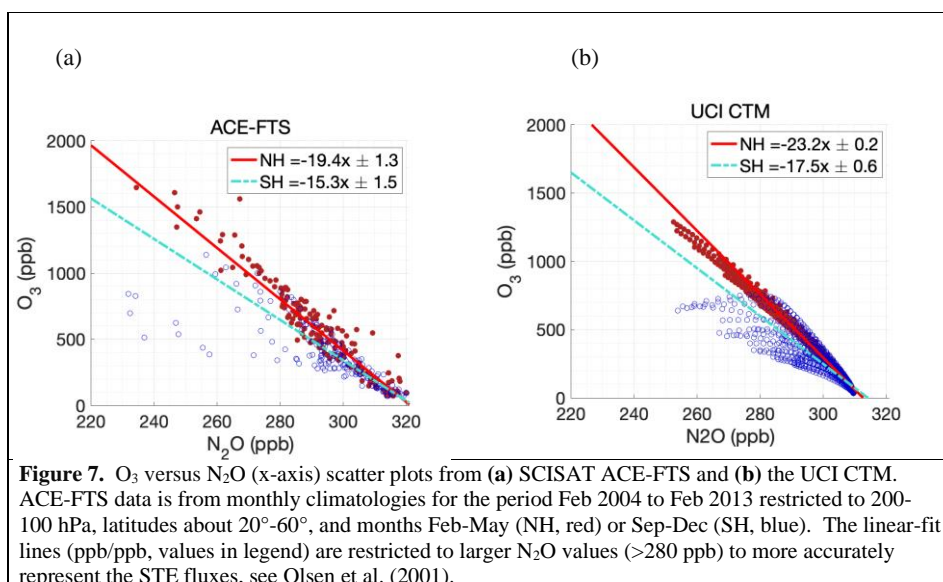

Formatted: Subscript

Formatted: Subscript

Figure 7ab shows the N<sub>2</sub>O-O<sub>3</sub> slope in each hemisphere taken from the ACE climatology dataset and the UCI CTM. The current ACE dataset (version 3.5) has been curated from measurements made by ACE-FTS from February 2004 to February 2013 (Koo et al., 2017). The SCISAT orbit results in irregular season-latitude coverage, and thus we average the lowermost stratosphere data over a wide range of latitudes centered on the peak STE flux (20°-60° in both hemispheres). For both ACE data and the CTM we keep to the lowermost stratosphere (200-100 hPa) and average over the 4-month peak of STE flux, Feb-May in the NH and Sep-Dec in the SH (see Figure 1). Extending into the upper tropical troposphere at 20° helps define the tropospheric end-point of the slope (low O<sub>3</sub>, high N<sub>2</sub>O). [Our method described here for deriving the slopes from the ACE-FTS data is slightly different from that of Hegglin and Shepherd \(2007; e.g., we do not anchor the tropospheric point\), and we have the advantage of a longer record.](#)

Based on the long-term mean STE fluxes in the model, we would expect an O<sub>3</sub>:N<sub>2</sub>O slope of about -24 (ppb/ppb) in the NH and -17 in the SH. The slopes fitted to our modeled grid-cell values of O<sub>3</sub> and N<sub>2</sub>O in the lowermost stratosphere are remarkably similar: -23.2 (NH) and -17.5 (SH). The ACE data are more scattered but show similar, smaller slopes of -19.4 (NH) and -15.3 (SH). Thus, the NH-SH asymmetry in O<sub>3</sub> versus N<sub>2</sub>O STE fluxes is clearly reflected in the tracer-tracer slopes, both modeled and observed. Hegglin and Shepherd (2007) had already identified these NH:SH differences when comparing their model to the ACE-FTS observations (their Fig. 13cd), but implications for STE fluxes were not brought forward.

In the modeled SH (Figure 7b), one can see strings of points that are samples along neighboring cells and reflect a linear mixing line between two different end points, one of which has experienced extensive O<sub>3</sub> depletion (i.e., the Antarctic O<sub>3</sub> hole). We know that there is some chemical loss of O<sub>3</sub> in the NH lowermost polar stratosphere during very cold winters (Manney et al., 2011; Isaksen et al., 2012), but it is not extensive enough to systematically affect the O<sub>3</sub>:N<sub>2</sub>O slope over the mid-latitude lowermost stratosphere in either the ACE observations or the CTM simulations.

## 5.2. IAV of the Antarctic ozone hole and the SH STE O<sub>3</sub> flux

The Antarctic ozone hole appears to be the source of the NH-SH asymmetry in the STE fluxes of O<sub>3</sub> versus N<sub>2</sub>O. It is known that the massive chemical depletion of O<sub>3</sub> inside the Antarctic vortex between about 13 and 23 km altitude creates an air mass with lower O<sub>3</sub>:N<sub>2</sub>O ratios than usually found in the mid-latitude lowermost stratosphere. When the vortex breaks up, nominally in late November, much of this O<sub>3</sub>-depleted air can mix along isentropes into the mid-latitude lowermost stratosphere, changing the O<sub>3</sub>:N<sub>2</sub>O ratios and reducing the SH STE O<sub>3</sub> flux.

We have additional information on the SH O<sub>3</sub> STE flux from the year-to-year variations in the size of the ozone hole. The best measure of the scale of Antarctic ozone depletion is the October mean ozone column (DU) averaged from the pole to 63°S equivalent latitude (see Fig. 4-5 of WMO, 2018). When we compare the CTM with the observations (Figure 8), we find remarkable verisimilitude in the model: the root-mean-squared difference is 9 DU out of a standard deviation of 29 DU and the correlation coefficient is 0.96. Thus, we have confidence that we are simulating the correct IAV of the ozone hole. Next, we plot the modeled O<sub>3</sub> STE flux (summed over the 12 months following the peak ozone hole, November-October) with the modeled October ozone column and find a fairly linear relationship. If we estimate the STE O<sub>3</sub> flux

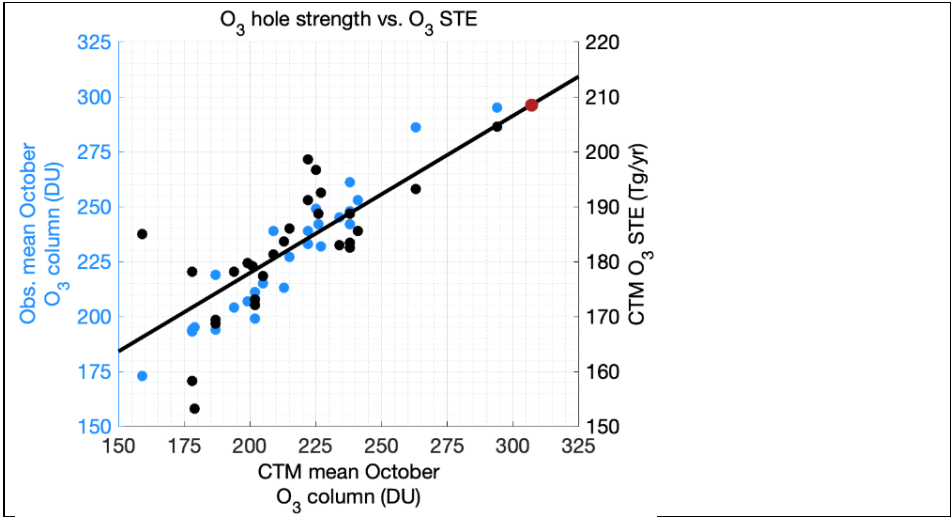

501 before the O<sub>3</sub> hole, when the mean October O<sub>3</sub> column was about 307 DU, then our O<sub>3</sub> flux  
502 increases to 209 Tg/yr (see Figure 8, red marker), eliminating the hemispheric asymmetry in O<sub>3</sub>  
503 STE flux.

504  
505 The annual deficit in SH STE O<sub>3</sub> flux brought on by the Antarctic ozone hole ranges from about  
506 5 to 55 Tg/yr and with a central value of 30 Tg/yr or 14% of the total. Using the decadal trends  
507 1965-2000 from Hegglin and Shepherd (2009), this deficit is 8%; and from Meul et al. (2018),  
508 5%. Since both of these models calculate a much larger SH flux (~300 Tg/yr), we estimate their  
509 absolute change in O<sub>3</sub> flux to be 24 and 15 Tg/yr, respectively. Because the ozone hole  
510 effectively removes a fixed, rather than proportional, amount of ozone that presumably is  
511 mapped onto the STE flux the following year, we believe the absolute change is the best  
512 measure. Thus the three models estimate the ozone hole causes a deficit in the SH O<sub>3</sub> STE flux  
513 in the range of 15-30 Tg/yr. The UCI CTM's ability to match the observed IAV of the ozone  
514 hole, and to match that linearly with the deficit in STE flux provides support for the upper end of  
515 the range. Note that the difference in O<sub>3</sub>:N<sub>2</sub>O slopes between NH and SH in Figure 7 is about 5.  
516 If we attribute that solely to the ozone hole and split the flux of N<sub>2</sub>O-depleted air evenly between  
517 hemispheres, then the ozone-hole-driven O<sub>3</sub> STE flux difference is about 55 Tg/yr, about twice  
518 that derived from the variability in our model. This difference in estimated flux indicates that  
519 even without chlorine-driven ozone depletion, the O<sub>3</sub>:N<sub>2</sub>O slopes may be inherently different  
520 simply because of the strong descent inside the wintertime Antarctic vortex. This can be readily  
521 investigated with further model studies.

522  
523 We looked for any relationship between ozone hole IAV and the STE fluxes of cN<sub>2</sub>O or cF11  
524 and found mostly a scatter plot with no clear relationship. Given the analysis above, we expect  
525 that much of the scatter is related to QBO cycles.

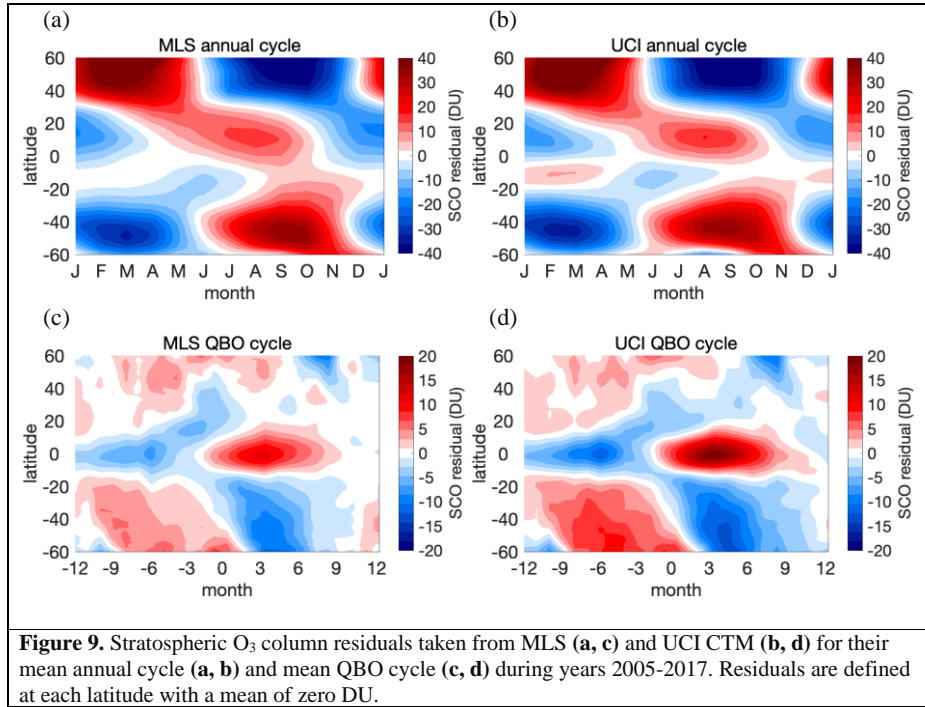

526  
527

**Figure 8.** Interannual variability of the observed Antarctic ozone hole from 1990 to 2017 (blue dots; left y-axis) versus the CTM modeled ozone hole (x-axis); plus the CTM modeled SH STE O<sub>3</sub> flux (black dots; right y-axis) versus the modeled ozone hole (x-axis). The ozone hole is measured by the total ozone column (DU) averaged daily over October poleward of 63°S in equivalent latitude (see Figure 4.5 of WMO 2018). The SH STE O<sub>3</sub> flux (Tg/yr) is centered on May 1 of the following year (i.e., the 12 months following the nominal breakup of the ozone hole). The black line is a simple regression fit of the modeled STE to the modeled ozone hole (black dots), and the red dot is our estimate of pre-ozone-hole SH STE O<sub>3</sub> flux based on the observed 1979-82 O<sub>3</sub> column.

### 5.3 Other model-measurement metrics related to STE

What else might affect O<sub>3</sub> STE? Stratospheric column O<sub>3</sub> (DU) varies on annual and QBO timescales. These changes in O<sub>3</sub> overhead can have a direct influence on O<sub>3</sub> transport to the troposphere, but the link requires further analysis. Tang et al. (2021) showed the UCI CTM is able to capture the observed annual cycle of stratospheric O<sub>3</sub> column as extracted from total column using the Ziemke et al. (2019) method. QBO modulation of stratospheric column O<sub>3</sub> has not been fully investigated since Tung and Yang (1994b). Yet, the fluctuations in mass over the annual cycle are comparable to the corresponding variability in O<sub>3</sub> STE flux (1 DU = 10.9 Tg) and likely connected (Figure 9).

**Figure 9.** Stratospheric O<sub>3</sub> column residuals taken from MLS (a, c) and UCI CTM (b, d) for their mean annual cycle (a, b) and mean QBO cycle (c, d) during years 2005-2017. Residuals are defined at each latitude with a mean of zero DU.

## 6. Conclusions

This work examines how closely O<sub>3</sub> STE is linked to STE fluxes of other trace gases. By including our complementary N<sub>2</sub>O and F11 tracers, we can follow stratospheric loss of these gases along with stratospheric O<sub>3</sub> across the tropopause. The magnitudes of the fluxes are proportional to their abundances in the lower stratosphere as expected (Plumb and Ko, 1992), and their variability is highly correlated with one another, indicating that they are entering the troposphere simultaneously. Even the distinct QBO pattern of STE fluxes is consistent across O<sub>3</sub>, N<sub>2</sub>O and F11. We further constrain the N<sub>2</sub>O transport pathway by linking STE of depleted-N<sub>2</sub>O air with surface fluctuations of N<sub>2</sub>O abundance. The surface response in modeled N<sub>2</sub>O matches well with the observed surface variability in the SH, indicating that surface variability is driven largely by STE flux.

Consistency of STE O<sub>3</sub> flux. As summarized here, there are a number of model diagnostics and observational constraints that provide a reality check on the consistency of the modeled O<sub>3</sub> STE flux. In Table 1, we examine these for our model and also for the CMAM model (Hegglin and Shepherd, 2007, 2009) because it is one of the few with enough published results. For UCI we calculate NH:SH fluxes of O<sub>3</sub> (208:182 Tg-O<sub>3</sub>/yr) and N<sub>2</sub>O (5.1:6.4 Tg-N/yr). Thus the mole fraction slopes in the lowermost stratosphere should be -23.8 (NH) and -16.6 (SH). Our model O<sub>3</sub>:N<sub>2</sub>O slopes are -23.2 (NH) and -17.5 (SH). Given the seasonal variability and scatter in the correlation plots (Figure 7), we count this as consistent. For CMAM, the modeled O<sub>3</sub>:N<sub>2</sub>O slopes, -23±24 (NH) and -18±3 (SH) are similar to ours and also to the ACE-FTS observations as analyzed by Hegglin and Shepherd (2007), -22-22+4 (NH) and -14+35 (SH), or by us, -19 (NH) and -15 (SH). CMAM does not report the implied STE N<sub>2</sub>O fluxes derived from their photochemical loss of N<sub>2</sub>O, but their model seems to match observations of N<sub>2</sub>O in the middle stratosphere, and so we assume that the Aura-MLS-derived N<sub>2</sub>O fluxes are a close estimate (12.9 Tg-N/yr). Note we are using Aura-MLS N<sub>2</sub>O values here to calculate the photochemical loss, which occurs in the middle to upper stratosphere (see R2021 for methodology). Just using the CMAM global numbers for O<sub>3</sub> STE flux, we calculate the O<sub>3</sub>:N<sub>2</sub>O slope in the lowermost stratosphere should average to -30. We conclude that their diagnosis of the STE O<sub>3</sub> flux, 655 Tg/yr, is inconsistent with the circulation that generated the O<sub>3</sub>:N<sub>2</sub>O slopes and is 50% too large. We do not view this as a critical assessment of CMAM since it involves us combining diagnostics from two separate publications and possibly different model simulations, but it is an example of how we might expect future studies of the STE O<sub>3</sub> flux to self-evaluate.

Uncertainty Quantification in STE O<sub>3</sub> flux. Deriving a best estimate and uncertainty from this work involves expert judgment. Changes in meteorological data used by the UCI CTM (IFS Cycles 29r1, 36r1, and 38r1, all at 60-layer 1.1° resolution, see Table 1) give a standard deviation in STE of 13% (only 3 values). If we use observations to derive a value as in Murphy and Fahey (1994), we must expand our dimensions to the uncertainty in the NH:SH split of N<sub>2</sub>O flux to calculate each hemisphere's O<sub>3</sub> flux. The factors are: (1) total STE N<sub>2</sub>O flux is 12.9 Tg-N/yr from the MLS data and we assign a ±10% one-sigma uncertainty; (2) the NH:SH split of the N<sub>2</sub>O flux is 44:56 in our current model, was not diagnosed for previous ones, and so we assume a value of 50:50 that ranges from 40:60 to 60:40; (3) analysis of the ACE-FTS observations (ours and Hegglin and Shepherd, 2007) gives O<sub>3</sub>:N<sub>2</sub>O slopes of about -21 (NH) and

Formatted: Subscript

Formatted: Subscript

Formatted: Subscript

588 -15 (SH) to which we assign a one-sigma uncertainty of  $\pm 3$ . Propagating these as root-mean  
589 square errors, we find a  $\pm 15\%$  uncertainty in the global value,  $400 \pm 60$  Tg/yr. Uncertainty in the  
590 hemispheric values is more difficult to assess, and from a range of model results shown in Table  
591 1, we can only estimate that the NH:SH ratio is between 60:40 and 50:50, a range that bounds  
592 our and CMAM results plus 2%. Note that this estimate is for current conditions with a regularly  
593 occurring Antarctic ozone hole. We believe the low 50:50 ratio is plausible because we have  
594 shown that our large SH STE N<sub>2</sub>O flux is consistent with the surface QBO variability in N<sub>2</sub>O.  
595 For pre-1980, and for when the ozone hole recovers later this century, we anticipate that the SH  
596 O<sub>3</sub>:N<sub>2</sub>O slope will revert to -18 to -21, and the total STE O<sub>3</sub> flux to 430-460 Tg/yr. This  
597 simplistic estimate is based on a fixed atmospheric circulation.

598  
599 A major surprise from our model is that the STE flux of O<sub>3</sub> is predominantly NH biased  
600 currently, only because of the Antarctic ozone hole. Prior to 1980, and after 2060, it would/will  
601 be symmetric between the hemispheres. Our model calculates slightly greater STE fluxes for  
602 trace gases like N<sub>2</sub>O or F11 in the SH, which is counter to prevailing theory that the wave-driven  
603 fluxes force relatively greater STE in the NH. This difference cannot be directly tested with  
604 observations of trace gases, but a range of N<sub>2</sub>O hemispheric observations are well modeled and  
605 support this premise. More extensive work with multi-model ensembles that include both  
606 chemical and dynamical diagnostics in the stratosphere would be needed to overturn the  
607 established theory. Our work reemphasizes the importance of trace-gas correlations in the  
608 lowermost stratosphere as a key observational metric for climate models that may be able to  
609 constrain total STE fluxes. The tracer slopes may go beyond just relative STE fluxes because we  
610 have other measurements from the upper stratosphere to the surface that constrain, for example,  
611 the absolute flux of N<sub>2</sub>O better than we first did using just the modeled lifetime.

612  
613 In Table 2, we gather a set of observation-based model metrics that relate to STE fluxes and will  
614 help the community build more robust models to better derive the STE flux of O<sub>3</sub>.
