Abstract. Characterization of the spatial distributions of air pollutants on an intracity scale is important for understanding local~~ized~~ sources, secondary formation, and human exposure. In this study, we conducted in situ mobile measurements for the chemical composition of fine particles, volatile organic compounds (VOCs), oxygenated VOCs (OVOCs), and common gas pollutants in winter in the megacity of Beijing. The spatial variations of these gaseous and particulate pollutants under different pollution conditions are investigated. During the less-polluted periods, a large spatial variability exists in the inorganic composition of fine particles, suggesting a wide range of particle neutralization in the megacity of Beijing. Significant spatial variations are also observed in the composition of organic aerosol (OA), which ~~is mainly~~ are driven by ~~local emissions of~~ primary OA emissions from vehicle and cooking exhaust as well as oxygenated OA. The spatial variations of VOCs and OVOCs vary by species. In general, hydrocarbon compounds show a large spatial variability that is ~~driven by~~ attributed to traffic ~~emission~~ plumes, while secondary OVOCs are more spatially homogeneous in concentration because of the predominant contribution of urban background to the on-road air. Other gas pollutants show relatively low spatial variabilities~~, although~~ and some high~~hot~~ concentration spots ~~of concentration frequently appear which~~ that ~~are plausibly caused by~~ indicate high-emitting plumes from local sources as well as fast on-road ozone titration. During the haze periods, the spatial variabilities of air pollutants are largely reduced because of the predominant contribution of regional transport to the on-road concentrations of these pollutants. The concentrations of ~~H~~hydrocarbons and less-oxygenated OVOCs show good positive spatial-temporal correlations ~~in concentration~~. The concentrations of ~~M~~more-oxygenated OVOCs show good positive correlations among themselves ~~and~~ but moderate negative correlations with the concentrations of hydrocarbons, less-oxygenated OVOCs, and particulate components. The ~~results highlight the potential role of~~ similar chemical compositions of particles and their gaseous precursors on the megacity scale suggest a spatially chemical homogeneity that may lead to efficient ~~homogeneity on the~~ SOA production under haze conditions ~~in the megacity under haze conditions~~. On the other hand, the spatial heterogeneity of air pollution under less-polluted conditions calls a future need of using fine-resolution models to evaluate human exposure and pollution control strategies.

1 Introduction

Air quality degradation has become a serious problem in developing countries (Huang et al., 2014; Khuzestani et al., 2017). Cities in northern China suffer from severe haze events, especially in winter (Huang et al., 2014). High concentrations of volatile organic compounds (VOCs) and nitrogen oxides ($NO_x = NO + NO_2$) contribute to high atmospheric oxidation capacity to produce ozone (O_3) and secondary aerosol (Lu et al., 2019b; Wang et al., 2017). The mass concentrations of particles having aerodynamic diameter less than 2.5 μm ($PM_{2.5}$) may reach up to several hundreds of μg m^{-3}, and the O_3 concentrations may exceed 100 ppbv in megacities. Both of high exposures of $PM_{2.5}$ and O_3 are of great concern to human health (Liu et al., 2016; Bell et al., 2006).

Tremendous efforts have been made to characterize air pollutants in populated urban areas in China (Li et al., 2017; Wang et al., 2017; Quan and Jia, 2020). In most studies, stationary measurements were conducted to obtain temporal variations of pollutants for the analysis of sources and formation mechanisms. Sulfate, nitrate, ammonium, and organic aerosol (OA) are the major chemical components of $PM_{2.5}$ in cities in China (Li et al., 2017). Their mass concentrations show decreases nationwide since 2013 as a result of the emission reduction of gaseous precursors such as sulfur dioxide (SO_2), NO_x, and VOCs under clean air actions as well as the changes of meteorological conditions (Zhang et al., 2019). In Beijing, the contribution of secondary OA (SOA) has significantly increased since 2018, while the contribution of primary OA (POA) from burning of coal and biomass (biofuel) and cooking emissions have decreased (Lei et al., 2021). Characterization of organic precursors including VOCs and semivolatile and intermediate volatility organic compounds (S/IVOCs) is crucial for understanding the SOA production. Previous studies have shown that besides alkanes, aromatics and oxygenated VOCs (OVOCs) are abundant in cities in China (Mozaffar and Zhang, 2020; Li et al., 2016; Guo et al., 2017). These VOCs may come from a variety of anthropogenic sources (e.g., vehicles, industries, solvent usage, coal and biomass burning, and household use of volatile chemical products etc.) and have great potential to form O_3 and SOA.

On an intracity scale, local emissions, advection, and boundary layer evolution may affect the spatial distributions of air pollutants. Tower measurements have shown greater vertical gradients of particulate matter (PM) concentration and composition during clean periods than haze periods in Beijing, which is attributed to the influence of both physical (e.g., regional transport, mixing layer height, and inversions etc.) and chemical processes (e.g., gas-particle partitioning and aqueous processing) (Zhou et al., 2018). Significant vertical gradients also present in the concentrations of VOCs in cities, which can be affected by transport of air mass, vertical diffusion, and species reactivity (Sun et al., 2018; Mo et al., 2020). Moreover, grid sampling and simultaneous measurements at multiple sites are often used to investigate the spatial variations of air pollutants on sparse spatial scales. Previous studies show that the surface concentrations of VOCs and $PM_{2.5}$ components vary because of different source contributions in metropolitan areas in China (Chen et al., 2020; Song et al., 2021). However, the spatial variability of air pollutants remains unclear, limiting our understanding of the haze development.

2

To better characterize the spatial distributions of air pollutants, mobile laboratory equipped with fast response in situ instruments have been widely used in Europe and United States (Kolb et al., 2004). For example, mobile measurements in Pittsburgh and Zurich indicate different spatial variability of PM composition (Tan et al., 2014; Gu et al., 2018; Ye et al., 2018; Mohr et al., 2011; Elser et al., 2016). While primary carbonaceous sources perhaps lead to the large spatial heterogeneity of PM composition in Pittsburgh, a rather uniform distribution was observed in the metropolitan area of Zurich especially during thermal inversions over the Swiss plateau, highlighting the complexity of urban air pollution. However, the development and application of advanced mobile laboratory are lagged in China. Mobile measurements have been conducted to obtain the spatial distributions of SO_2, NO_x, carbon monoxide (CO), and black carbon (BC) as well as NO_2 and SO_2 column densities for the evaluation of regional transport routes in North China Plain (NCP) and sources of air pollutants ~~and urban air quality~~ (Wang et al., 2009; Wang et al., 2011; Zhu et al., 2016; Wu et al., 2018). Recent deployments of online mass spectrometers in mobile laboratory have successfully captured the spatial distributions of VOCs and $PM_{2.5}$ composition in cities in China, ~~which can be particularly useful for identifying emission sources~~which may be useful for further investigation of urban air pollution (Wang et al., 2021c; Liang et al., 2020; Liao et al., 2021).

In this study, we conducted in situ sampling with gas analyzers and advanced mass spectrometers on a newly developed mobile laboratory platform in winter in the megacity of Beijing. Spatial distributions of the mass concentrations of non-refractory $PM_{2.5}$ (NR-$PM_{2.5}$) components (i.e., OA, nitrate, sulfate, ammonium, and chloride), VOC and OVOC species, and common gas pollutants such as SO_2, CO, NO, NO_2, and O_3 are obtained. The spatial variabilities of these gaseous and particulate pollutants under different pollution conditions are investigated to provide new insights to urban pollution and to improve our understanding of human exposure.

2 Methods

On-road measurements were conducted by the PKU mobile laboratory (Figure S1 in the Supplement) on the 4th Ring Road of Beijing on 7-21 November 2018 and 21 January 2021. The 4th Ring Road is a 65-km-long highway that passes through commercial, industrial, and residential areas. To show the spatial characteristics, the measurement area is categorized into 4 zones: Zone NE, Zone NW, Zone SE, and Zone SW (Figure S2 in the Supplement). Zone SE and Zone SW are close to industrial facilities, while Zone NE and Zone NW are mostly commercial and residential areas. The average traffic volume on the 4th Ring Road is about 4000-8000 vehicles per hour, and over 90% of the fleet consisted of light duty gasoline vehicles (LDGVs) that meet National Stage III to V emission standards.

The measurements started at around 9:00 a.m. and went one cycle after another till 4:00 p.m. Each cycle took approximately 70 min with a mean speed of 60 km h^{-1}. Self-contamination from the vehicle exhaust is negligible for a vehicle speed over 30 km h^{-1} (Liao et al., 2021). A suite of instruments was deployed in the mobile laboratory. Gas pollutants were detected by gas analyzers including NO_2 (Teledyne, T500U), NO-NO_x (Ecotech, EC9841A), SO_2 (Ecotech, EC9850A), CO (Ecotech,

95 EC9830A), and O_3 (Ecotech, EC9810A) with a time resolution of 2 s. The chemical composition of NR-PM$_{2.5}$ was measured by an Aerodyne time-of-flight aerosol chemical speciation monitor (TOF-ACSM) with PM$_{2.5}$ lens and a capture vaporizer with a time resolution of 40 s and a mass resolution of about 400 (Zheng et al., 2020). The uncertainty for the mass concentrations of NR-PM$_{2.5}$ and its components is about 30% (Canagaratna et al., 2007). VOCs and OVOCs were detected by an Ionicon proton transfer reaction-quadrupole ion guide time-of-flight mass spectrometer (PTR-QiTOF). The overall quantification

100 uncertainties are <20% for calibrated species and 19% and 33% for uncalibrated species with known and unknown reaction rate constants (K_{ptr}), respectively (Huang et al., 2019). Table S1 in the Supplement lists the K_{ptr} values, the mean concentrations, and the tentative categorization of VOCs and OVOCs measured herein. Detailed information about the campaign, sampling system, instrument operation and, calibration, and data analysis has been described elsewhereare provided in Sect. A of the Supplement (Liao et al., 2021). The positive matrix factorization (PMF) analysis was performed on the OA mass spectra by

105 using the Igor PMF evaluation tool (PET, version 3.00B). Five OA factors were resolved including hydrocarbon-like OA (HOA), cooking-related OA (COA), and three oxygenated OA (OOAs) (Section A). The common OA factors related to biomass burning (BBOA) or coal burning (CCOA) were not resolved in this data set and were perhaps mixed with other OOA factors (Liao et al., 2021). Their contributions to OA were however expected to be small because of the stringent emission control in NCP in recent years (Zheng et al., 2020; Duan et al., 2020). VOCs and OVOCs were detected by an Ionicon proton

110 transfer reaction-quadrupole ion guide time-of-flight mass spectrometer (PTR-QiTOF). The overall quantification uncertainties are <20% for calibrated species and 19% and 33% for uncalibrated species with known and unknown reaction rate constants (K_{ptr}), respectively. Table S1 in the Supplement lists the K_{ptr} values, the mean concentrations, and the tentative categorization of VOCs and OVOCs measured herein. Detailed information about the campaign, sampling system, instrument operation, calibration and data analysis has been described elsewhere (Liao et al., 2021).

115 Figure S3 in the Supplement shows the time series of mass concentrations of air pollutants measured at the PKU campus roof site during the campaign. This site is located between the 4th and the 5th north Ring Roads, representing a typical urban environment in Beijing (Cheng et al., 2021). In this study, we classified clean (< 35 μg m^{-3}), haze (> 75 μg m^{-3}), and non-haze (< 75 μg m^{-3}) days based on the daily mean PM$_{2.5}$ mass concentrations for the measurements. Moreover, we computed a batch of 12-hour backward trajectories for the height of 3 m around the 4th Ring Road from the HYSPLIT model to investigate the

120 influence of urban background and regional transport on our measurements during the haze day (Stein et al., 2015). We set the start time of the trajectory analysis at 9:00 a.m. and repeated the trajectory calculations every 1 hour until 4:00 p.m. (Figure S4 in the Supplement). In addition, a moving average window of 10 (i.e., 20 s) was applied to the entire data set for VOC and OVOC species. Concentration baselines for each 2-s point in the 20-s smoothed data were calculated as the 5th percentile concentration within a rolling window of 60 (i.e., 120 s), for which the urban background conditions were identified (Apte et

125 al., 2017). We then computed the peak fraction (PF) parameter as 1 minus the ratio of the mean baseline value to the observed mean concentrations. The time series of the concentrations of common VOC and OVOC species shows significant plumes above the baseline for the on-road measurements (Figure S5 in the Supplement). PF values are used as a semi-quantitative

indicator to show the contributions of the above-baseline concentrations to the observed concentrations of VOCs and OVOCs, which may represent the intensity of transient emission from local sources (e.g., vehicle exhaust).

3 Results and Discussion

3.1 Spatial distribution of NR-PM$_{2.5}$ and its components

A sSignificant spatial variabilitiesy of the mass concentrations of NR-PM$_{2.5}$ and its chemical components is are observed during the campaign. As described briefly by Liao et al. (2021), the mean (± one standard deviation) mass concentration of NR-PM$_{2.5}$ for non-haze days is 30.7 ± 24.7 μg m^{-3}, in which OA is the most abundant component that contributes to about 52% of the NR-PM$_{2.5}$ mass. The mean mass concentration of NR-PM$_{2.5}$ for the haze day is 155.0 ± 27.0 μg m^{-3}, and nitrate becomes the most abundant component that contributes to about 48%. Interestingly, the intracity spatial variations of the concentration and composition of NR-PM$_{2.5}$ are quite different under different pollution conditions.

Figure 1 shows the spatial distributions of the mass concentrations of organic and inorganic components in NR-PM$_{2.5}$ for the example noon cycles on typical clean and haze days. The coefficients of variation (CV) are listed in Table 1. Large spatial variabilities of the mass concentration and the composition of NR-PM$_{2.5}$ present in the clean-day measurements (Figure 1a). The mass concentration of NR-PM$_{2.5}$ ranges from 1.0 to 17 μg m^{-3} with a relatively high CV value of 0.75. OA is the dominant component that explains the most variability of the NR-PM$_{2.5}$ mass (CV = 0.75). The spatial variations of the OA mass are largely attributed to both of POA and OOA. As shown in Fig. 1c, the mass fractions of POA factors such as HOA and COA show a large spatial heterogeneity with hot spots (mass fraction > 60%) in various segments of the 4th Ring Road. These hot spots are plausibly contributed by exhaust plumes from on-road vehicles and nearby restaurants that have not yet well mixed with urban background air. Similarly, the measurements in Pittsburgh show a significant spatial heterogeneity of primary carbonaceous components such as HOA, COA, and BC and less spatial variabilities of OOAs (Gu et al., 2018). The Pittsburgh study show less spatial variabilities of OOAs, whereas the CV value for the OOA concentration are high in Beijing during the clean day. This is perhaps because the precursors and formation pathways of OOAs are more complicated in Beijing than in Pittsburgh (Li et al., 2021; Yang et al., 2019).

Inorganic components show much higher CV values in mass fraction than OA (Table 1), indicating a relatively greater spatial variability of inorganic composition compared with organic composition. As shown in Fig. 1b, ammonium is the predominant inorganic component in Zones NW and SW, while nitrate contributes most in Zone SE. The CV values for ammonium are the highest in both mass concentration and mass fraction. The molar ratio of $n_{NH_4^+}$: ($2{\times}n_{SO_4^{2-}} + n_{NO_3^-}$) range from ~ 0 to 1.0, suggesting a wide range of particle neutralization on the intracity megacity scale under clean-day conditions in winter in Beijing, which is perhaps driven by the difference in chemical processes and local emissions of precursors. In NCP, the aerosol mass can be sensitive to ammonia or nitric acid availability (Nenes et al., 2020). Traffic and agriculture (e.g., livestock) emissions are the main sources of ammonia in Beijing during the clean periods in winter (Sun et al., 2017; Pan et al., 2018).

Traffic emissions depend on on-road vehicle type and volume and may vary greatly in the city. On the other hand, the concentrations of nitric acid depend on the concentrations of NO$_x$ and hydroxyl radical (OH) that are affected by local emissions and atmospheric oxidation and may also vary significantly in the city. Besides, a ~~U~~uniform distribution of solar radiation on the surface is not expected in the megacity because of the shades of buildings as well as cloud covers. Therefore, the spatial heterogeneity of inorganic composition reflects spatially different thermodynamic regimes in the megacity environment, which may challenge the development of further pollution control strategies as clean air action~~s~~ continue~~s~~. For comparison, the inorganic components have less spatial variabilit~~ies~~y in Pittsburgh than in Beijing (Gu et al., 2018), which may be explained by the greater emissions of ammonia and NO$_x$ as well as OH concentrations in urban areas in China.

By contrast, ~~relatively homogeneous spatial distributions of the mass concentration and composition of NR-PM$_{2.5}$ present under haze conditions (Figure 1d). T~~the mass concentration of NR-PM$_{2.5}$ has a low CV value of 0.12, and it is consistently higher in Zones NE and NW (163.2 ± 12.3 μg m^{-3}) than in Zones SE and SW (138.8 ± 16.9 μg m^{-3}) during the haze day (Figure 1d). The mass fractions of inorganic (i.e., ammonium, sulfate, nitrate, chloride) and organic components (i.e., HOA, COA, and OOA~~s~~) are similar across the city (CV < 0.35), although a few hot spots of COA exist (Figure 1f). The sampling inlets of the PKU mobile lab are located at 3.4 m above the ground, which may sample air from both of urban background and instantaneous plumes. The 40-s PM$_{2.5}$ measurements by TOF-ACSM may roughly represent a maximum area of 0.16 km^2 upwind when the mobile laboratory was run on the 4th Ring Road by cycles. The similar chemical composition along the road suggests relatively homogeneous spatial distributions of the mass concentration and composition of NR-PM$_{2.5}$ across the city under haze conditions. This is supported by the fact that the particle composition observed at the PKU roof site was similar to our mobile measurements (Figure S3). ~~is consistent with the understanding of haze evolution in NCP during which regional transport becomes a main contributor to the PM pollution in Beijing.~~ Although stagnant conditions facilitate the accumulation of local emissions (e.g., vehicle emissions on the road), ~~O~~over 60% of the ~~PM$_1$ and~~ PM$_{2.5}$ mass in Beijing can be contributed by regional transport during the winter haze episodes (Sun et al., 2014; Wu et al., 2021). The predominant contribution of regional transport suggests similar sources of PM$_{2.5}$ in Beijing. ~~The s~~Similar particle composition ~~may~~ suggest~~s~~ a spatial chemical homogeneity at least on the megacity scale in terms of gas-to-particle equilibrium or partitioning as well as the heterogeneous or particle-phase production. ~~, and t~~The north-south difference in mass concentration is perhaps driven by the differences in atmospheric dilution on the intracity scale (Sun et al., 2016; Chen et al., 2020). ~~Moreover, the~~The ~~haze day~~ uniform spatial distribution~~s~~ of PM composition under haze conditions ~~is~~ are similar to the observations in the metropolitan area of Zurich when thermal inversions occur over the Swiss plateau and secondary pollution is built up regionally (Mohr et al., 2011), highlighting stagnant metrological conditions as one of the key drivers of the ~~intra~~city-scale chemical homogeneity.

Figure 2 shows the CV values of the mass fractions of ammonium, sulfate, nitrate, and OA in PM$_{2.5}$ for all cycles measured during the mobile campaign. ~~In addition, t~~The large spatial variabilities of the mass concentration and composition of NR-PM$_{2.5}$ present in all measurement cycles during the clean day~~s~~, ~~and~~ while the mass concentration and composition~~s~~ of NR-PM$_{2.5}$ ~~on the 4th Ring Road~~ are ~~similar in each cycle~~rather uniform in all cycles during the haze day~~s~~ on the 4th Ring Road,

not limited to the noon cycle presented in Figure 1. The mass concentration and composition of NR-PM$_{2.5}$ show significantly day-to-day and diurnal variations as indicated by the stationary measurements at the PKU roof site (Figure S3). Such temporal variations are driven by source variations and meteorological conditions, which have been studied extensively in the past (Duan et al., 2020; Lei et al., 2021; and the reference therein).

3.2 Spatial distribution of gaseous pollutants

Figure 3$\overline{2}$ shows the spatial distributions of the mixing ratios of gaseous pollutants for the example noon cycles. The concentrations of SO$_2$ are low (< 10 ppbv) throughout the campaign (Figure 2a3a). During the clean day, the SO$_2$ concentrations are low in the north and relatively high in the west of the 4th Ring Road, which is different from the distributions of the NR-PM$_{2.5}$ mass concentrations. The SO$_2$ concentrations has a CV of 0.13. The low spatial variability of SO$_2$ may be explained by the predominant contribution of regional transport as a result of the relocation of steel industry and power plants out of Beijing and the ban of high emission vehicles from the road (Ge et al., 2018). Previous mobile measurements in Beijing captured specific transport events of SO$_2$ from the south and found that the SO$_2$ concentration decreased from Zone SE to Zone NW (Wang et al., 2011; Zhu et al., 2016), which is consistent with our clean-day observations. During the haze day, the SO$_2$ concentrations are lower than the concentrations observed during the clean day, which may be explained by the large conversion of gaseous SO$_2$ to sulfate by photochemical and aqueous processes under winter-haze conditions (Wang et al., 2021b). The haze-day distribution of SO$_2$ concentration is different from the clean-day distribution and has a greater CV value of 0.27. The 12-hour backward trajectories around the 4th Ring Road show that the air masses were mostly from the east in the morning, started shifting towards south at ~12:00 p.m., and then were mainly originated from the south around 4:00 p.m. (Figure S4 in the Supplement). The spatial distribution of SO$_2$ is therefore affected by the transport routes. Southwesterly, southeasterly, and easterly flux pathways have been recognized as typical regional transport routes to Beijing (Chang et al., 2019).

CO and NO are common gaseous pollutants emitted from combustion sources. The mean on-road concentrations of CO are 1.53 ± 0.66 ppm for non-haze days. For comparison, the concentrations of CO measured concurrently at the PKU roof site are 0.50 ± 0.26 ppm for non-haze days. The on-road concentrations are about three times greater than the urban background concentrations, explained by the direct contribution of vehicle emissions exhaust plumes (Gentner et al., 2017). For NO, the concentrations measured at the PKU roof site are very low because of the O$_3$ titration. The on-road concentrations are 1-2 orders of magnitude greater, which is mainly contributedalso explained by the fleet integrated emissions. The clean-day spatial distribution of CO concentrations (CV = 0.26) is quite homogeneous except a few hot spots in Zone SW (Figure 23b). The clean-day spatial distribution of NO concentrations (CV = 0.22) is different from that of CO (Figure 32c), showing higher concentrations in Zone SE where the traffic volume is usually greater than in other Zones. One explanation for such differences between CO and NO may be much greater contributions of background concentrations and non-vehicular sources to CO. In addition, relatively slower response of instrument detection of CO and NO may smooth out some of the concentration variations. As shown in Fig. S6 in the Supplement, the on-road time series of NO$_2$ concentrations shows more short-duration

225 peaks than the time series of CO and NO concentrations. During the haze day, greater CO and NO concentrations present. The spatial distributions of CO, NO, SO$_2$, and NR-PM$_{2.5}$ concentrations all show relatively low concentrations in Zone SW. The greater haze-day concentrations and the similar ~~ity of~~ spatial distributions of these pollutants are consistent with the large contribution of regional transport to urban air pollution and the stagnant meteorologic~~y~~al condition during the haze episode.

The clean-day spatial distribution of NO$_2$ concentrations is ~~in general~~ similar to that of NO, although more concentration hot
230 spots exist (Figure ~~2~~3d). The on-road NO$_2$ are contributed by direct tailpipe NO$_2$ emissions, secondary NO$_2$ through on-road NO$_x$ titration, and background NO$_2$. The tailpipe NO$_2$ emissions are small for LDGVs (National Stage III and above) (Wu et al., 2017). The urban background concentrations of NO$_2$ measured at the PKU roof site on 18 November 2018 (clean day) are low at noon (5.2 ± 0.6 ppbv). The high on-road NO$_2$ concentrations (16.8-94 ppbv) are ~~therefore mainly~~plausibly contributed by the fast on-road NO$_x$ titration, which is similar to the findings in North Carolina, U.S. (Yang et al., 2018). As shown in Fig.
235 S7a in the Supplement, the clean-day on-road concentrations of O$_3$ range from 3.2 to 15.4 ppbv, which are 3-4 times lower than the concentrations measured at the PKU roof site (40.0-44.5 ppbv). The spatial distribution of O$_3$ concentration is opposite to that of NO, which is consistent with the titration effect. The more-frequent appearance of hot spots in the clean-day NO$_2$ distribution is likely because of the faster detection of NO$_2$ by the cavity attenuated phase shift technique than the chemi-luminescence detection of NO. During the haze day, the spatial distribution of O$_3$ concentration is ~~in general~~ opposite to that
240 of NO but shows much lower concentrations (i.e., a few ppbv) than during the clean day, which can be explained by the stronger titration effect with higher NO concentrations. However, the concentrations of NO, NO$_2$, and O$_3$ are all high in Zone NW. The backward trajectories suggest transport of air masses from the east and the south to Beijing. The high concentrations of air pollutants in Zone NW therefore may~~can~~ not be explained by regional transport and are perhaps related to local meteorological conditions affected by specific land surface conditions.

245 The spatial distributions of VOCs vary by species. LDGVs emit aromatic hydrocarbons (e.g., benzene, toluene, ethylbenzene, and xylenes), some oxygenated species (e.g., acetaldehyde), and so on (Gentner et al., 2017). As expected, the on-road concentrations of such primary VOC species are much greater than the concentrations measured at the urban and suburban sites in Beijing (Table S1 in the Supplement). Figure ~~3~~2e-f shows the spatial distributions of benzene and toluene concentrations. During the clean day, both of the distributions show large spatial variabilities with high CV values (Table 1).
250 Concentration h~~H~~ot spots ~~of concentration exist~~present and are plausibly contributed by transient plumes of vehicle exhaust or nearby local sources (e.g., in industrial areas of Zone SW). Interestingly, the distributions of the hot spots for benzene and toluene are not the same, highlighting the difference in emissions from individual vehicles (Mo et al., 2016).

The toluene-to-benzene concentration ratio (T/B) is widely used to differentiate the VOC sources (Song et al., 2021; and references therein). According to literature, traffic emissions have T/B ratios from 1 to 3 depending on vehicle type and fuel
255 composition. Industry emissions have a wide range of T/B ratios (1.4 to 5.8). Solvent emissions may have high T/B ratio of ~ 8.8. Biomass burning emissions typically have a low ratio of ~ 0.3. During the clean day, most of the concentration hot spots for benzene and toluene corresponds to T/B ratios of 1.1-2.6, which is consistent with vehicle emissions (Fig. S7b in the

Supplement). Some of the high T/B ratios (e.g., 2-3 in the south) are perhaps related to industry plumes. The T/B ratios for on-road background (not high-emitting plumes) are low (0.6-1.3), which may be explained by faster photochemical consumption

260   of toluene than benzene. By contrast, the spatial variability for OVOCs (CV ~ 0.6) is much lower than that for hydrocarbons (Table 1), owing to their secondary nature because of the lack of local~~ized~~ sources in Beijing (Wang et al., 2021a).

During the haze day, a remarkable enhancement of VOC concentrations is observed with mean enhancement ratios of 3.3-16.3 (e.g., 8.7 for benzene, 6.5 for toluene, 6.5 for C_8-aromatics, 5.2 for methyl ethyl ketone, and 4.8 for propene) (Figure S8 in the Supplement). The spatial distributions of benzene and toluene show consistent high concentrations in Zones NW, SW, and SE

265   (Figure ~~2e~~3e-f) but low T/B ratios in those segments that indicate aged air masses (de Gouw et al., 2005), considering the limited~~because~~ biomass burning ~~sources are limited~~ contributions during the campaign (Fig. S7b) ~~(de Gouw et al., 2005)~~. The spatial distributions of benzene and toluene are different from the distributions of other air pollutants under haze conditions, suggesting that the influence of regional transport may vary by species. Moreover, the haze-day spatial distributions of OVOC concentrations are quite homogeneous with relatively small CV values (i.e., 0.14 for Σ (Aldehyde & Ketones) and Σ (Acids &

270   Anhydrides) in Table 1). The distribution of individual OVOCs is similar among species except for the OVOCs having 3-4 oxygen atoms in their formulae, which will be discussed further in Sect. 3.3. The calculated PF values in Figure 4 suggest 30-40% contributions of high-emitting plumes to the on-road concentrations of aromatic species during the clean day compared with 9-13% during the haze day. For OVOCs (e.g., formic acid), the contribution of high-emitting plumes to the on-road concentrations are comparable for the clean and haze days (i.e., 6-13%), owing to their secondary nature ~~(Figure 3)~~.

275   ~~Photochemical oxidation can play an important role in concentrations of reactive organic species.~~Figure 5 shows t~~T~~he spatial-temporal variations of the concentrations of the detected VOCs and OVOCs measured during the non-haze and haze periods of the mobile campaign ~~are shown in Figure 4~~. The concentrations of $\sum$ hydrocarbons (i.e., aromatics and alkenes) are the highest in the morning (~~8~~9:00 a.m. to 1~~1~~0:00 a.m.) for both non-haze and haze periods, which may be explained by shallow boundary layer, rush-hour traffic emissions, and slow chemical removal (de Gouw et al., 2009). The on-road measurements of

280   hydrocarbons are largely affected by instantaneous vehicle plumes. The greater concentrations of hydrocarbon in the afternoon (2:00 p.m. to 4:00 p.m.) than in the earlier period (11:00 a.m. to 2:00 p.m.) suggest that the mobile measurements captured less vehicle plumes, which is consistent with the less traffic volume on the road. ~~Their concentrations decrease first as the boundary layer develops, and then increase in the afternoon as the pollution accumulates in the boundary layer under non-haze conditions.~~ Under non-haze conditions, the spatial variabilities of hydrocarbons vary significantly during the day. Their CV

285   values are high in the morning and low in the afternoon. It is likely that ~~the~~ photochemistry and ~~the~~ better mixing conditions in the afternoon smooth out some of the spatial variabilities caused by on-road vehicle emissions (Mellouki et al., 2015; Karl et al., 2018). By contrast, their concentrations keep decreasing during the day under haze conditions, and the greater ~~day time~~ concentrations of $\sum$ hydrocarbons than during the clean days are plausibly driven by the greater contribution of regional transport to on-road air and stagnant meteorological conditions that favour the accumulation of on-road vehicle plumes. ~~Under~~

290   ~~non-haze conditions, the spatial variabilities of hydrocarbons vary significantly during the day. Their CV values are high in~~

9

the morning and low in the afternoon. It is likely that the photochemistry and the better mixing conditions in the afternoon smooth out some of the spatial variabilities caused by on-road vehicle emissions. Under haze conditions, the spatial variability of hydrocarbons is slightly greater in the afternoon, which is probably because of the change of regional transport direction in the afternoon. As shown in Fig. S4, The the backward trajectories suggest that the air masses gradually shifted from eastern to southern during the haze day (Figure S4). For the two categories of OVOCs, the non-haze temporal variations are similar to that of hydrocarbons. Their CV values indicate much smaller spatial variabilities of OVOCs in the morning rush hour (98:00 a.m. to 110:00 a.m.) than that of hydrocarbons. This is consistent with previous source apportionment results of source apportionment that secondary production is the main contributor of most OVOCs in Beijing (Wang et al., 2021a). As the photochemical production proceeds during the day, the spatial variabilities of OVOCs increase and then decrease, similar to that of hydrocarbons. On the other hand, the haze-day temporal and spatial variations of OVOCs are all similar to that of hydrocarbons (CV < 0.36), corresponding to the influence predominant contribution of regional transport to the on-road concentrations of these pollutants.

3.3 Chemical homogeneityheterogeneity under haze conditions

Figure 65 shows the correlation heatmaps of the concentrations of VOCs and OVOCs measured during the clean day and haze day for all measurement cycles on the 4th Ring Road of Beijing. Day-to-day variations are not included because of the possible change of sources. Only primary hydrocarbons show good correlations with each other during the clean day (Figure 5a6a). This is consistent with the predominant contribution of traffic emissions to the on-road concentrations. Secondary species like OVOCs and PM$_{2.5}$ are more regional and do not correlate with these primary hydrocarbons (Figure S9a in the Supplement). They do not correlate with each other either, indicating a spatial chemical heterogeneity in OVOC and PM$_{2.5}$ formation. By contrast, the haze-day heatmaps show significantly different patterns (Figure 5b 6b and Figure S10b in the Supplement). Primary hydrocarbons not only correlate well with each other (Pearson's $r > 0.7$, $\alpha = 0.01$). They but also show good positive correlations with many less-oxygenated OVOCs (e.g., aldehydes and ketones with 1-2 oxygen atoms in their formulae (Table S1). These OVOCs may be contributed by both primary and secondary sources, and they can be formed and accumulated during the regional transport process. The NR-PM$_{2.5}$ components also correlate with these VOCs and OVOCs (Figure S9b). Such good spatial-temporal correlations are consistent with the predominant contribution of regional transport to high concentrations of hydrocarbons, less-oxygenated OVOCs, and PM$_{2.5}$ in Beijing during the haze event.

Interestingly, more oxygenated OVOCs (e.g., anhydrides and acids with 2-4 oxygen atoms in their formulae) that are mainly contributed by secondary sources show good positive correlations with each other ($r > 0.7$, $\alpha = 0.01$) and but moderately negative correlations with hydrocarbons and less-oxygenated OVOCs as well as the NR-PM$_{2.5}$ components. These species include CH$_2$O$_2$ (tentatively assigned as formic acid), C$_2$H$_4$O$_3$, C$_3$H$_4$O$_3$, C$_4$H$_4$O$_4$, C$_4$H$_4$O$_3$, C$_5$H$_4$O$_3$, and C$_5$H$_4$O$_2$. The spatial-temporal correlations for these more oxygenated OVOCs suggest similar more-oxygenated OVOC composition on the megacity scale during the haze day, which may be explained byindicate a homogeneous photochemical production as well as

gas-to-particle partitioning ~~on the intracity scale~~. High oxidation capacity in winter in NCP has been reported (Lu et al., 2019a; Slater et al., 2020). Secondary OVOCs are formed and accumulated along the transport route. ~~Regional transport leads to relatively uniform spatial distributions of these species during the haze day (Figure 4).~~ With a rather uniform distribution of hydroxyl radical which likely happens under winter haze conditions because of the thick cloud cover and increased particle scattering, the formation of more-oxygenated OVOCs from less-oxygenated OVOCs can be relatively homogeneous in the city. Although these more-oxygenated OVOCs may partition to the particle phase, the gas-to-particle partitioning are not expected to affect much the spatial variability of the more-oxygenated OVOCs because of the similar chemical composition of $PM_{2.5}$ ~~present on the intracity~~ and the narrow loading range on the intracity scale under haze conditions. The secondary production thus ~~and potential gas to particle partitioning~~ explains the negative correlations of the more-oxygenated OVOCs with their precursors (e.g., hydrocarbon and less-oxygenated OVOCs) and $PM_{2.5}$. Moreover, the gas-particle repartitioning caused by temperature difference may affect the distribution of more-oxygenated OVOCs. This effect is however expected to be minor considering the range of OA loadings, the vapor pressures of these more-oxygenated OVOCs, and the possible temperature elevation of 1-3 ℃ ~~for the megacity~~ in the city (Chen et al., 2020; Wang et al., 2020; Yang et al., 2013). Peroxyacetyl nitrate (PAN, $C_2H_4O_3$) is more sensitive to temperature and less stable than the other more-oxygenated OVOCs (Seinfeld and Pandis, 2016), which may explain its lower correlation coefficient in Fig. ~~5~~6b.

4 Conclusions

In this study, we conducted on-road mobile measurements of air pollutants including NR-$PM_{2.5}$ and its components, gaseous pollutants, VOCs, and OVOCs under different pollution levels in winter in Beijing. During the clean periods, large spatial variabilities of the pollutants ~~were~~ are observed, which can be largely attributed to the influence of local~~ized~~ sources and secondary production. In particular, the inorganic composition of NR-$PM_{2.5}$ vary greatly, indicating a wide range of particle neutralization on the intracity scale under less-polluted conditions in winter Beijing. For OA, the spatial variability is ~~mainly~~ driven by local HOA and COA emissions as well as OOA. The spatial variations of regular gas pollutants are relatively smaller than those of the $PM_{2.5}$ components. The spatial distributions of the concentrations of VOCs and OVOCs vary by species. Detected hydrocarbons (i.e. mostly aromatic species) are~~-~~ largely affected by on-road vehicle emissions, and thus show large spatial variabilities during the clean periods. Our results suggest about 30-40% contributions of high-emitting plumes to the on-road concentrations of aromatic species during the clean periods compared with 9-13% during the haze periods. Overall, ~~Tt~~he ~~large~~ great spatial heterogeneity of the particle composition and VOCs may challenge the development of future pollution control strategies as clean air actions continue. The results also indicate different human exposures to particles and gaseous pollutants on the intracity scale, which requires fine-resolution models to evaluate. ~~Moreover, our results suggest about 30-40% contributions of high emitting plumes to the on-road concentrations of aromatic species during the clean periods compared with 9-13% during the haze periods.~~

~~Under haze conditions~~During the haze days, stagnant weather conditions and predominant~~ly~~ contributions from regional transport to urban background concentrations of particulate and gaseous pollutants largely reduce the spatial variabilities of these ~~particulate and gaseous~~ pollutants in the megacity. More-oxygenated OVOCs show good positive correlation among themselves ~~and~~ but moderate negative correlations with hydrocarbons, less-oxygenated OVOCs, and PM$_{2.5}$ components, suggesting a spatially homogeneous photochemical production as well as gas-to-particle partitioning on the ~~intracity~~ megacity scale. ~~This~~ Such a chemical homogeneity may lead to efficient local production of semivolatile oxidation products that ~~may~~ enhance~~s~~ the SOA production ~~under winter haze conditions~~ in the megacity to enhance the haze development.

575
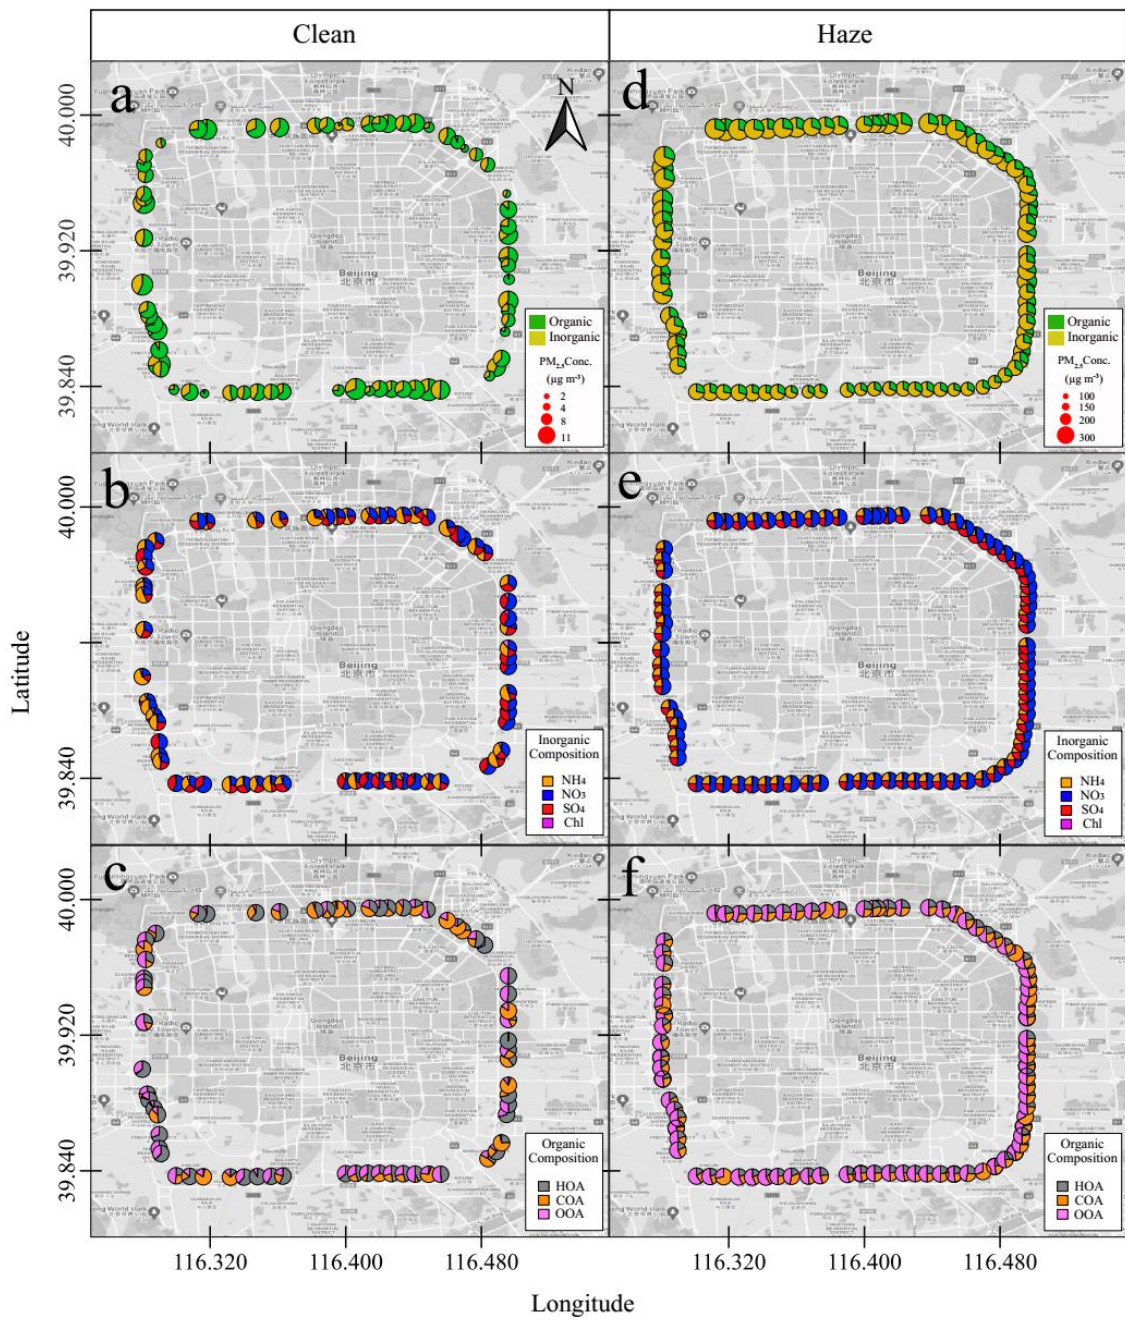

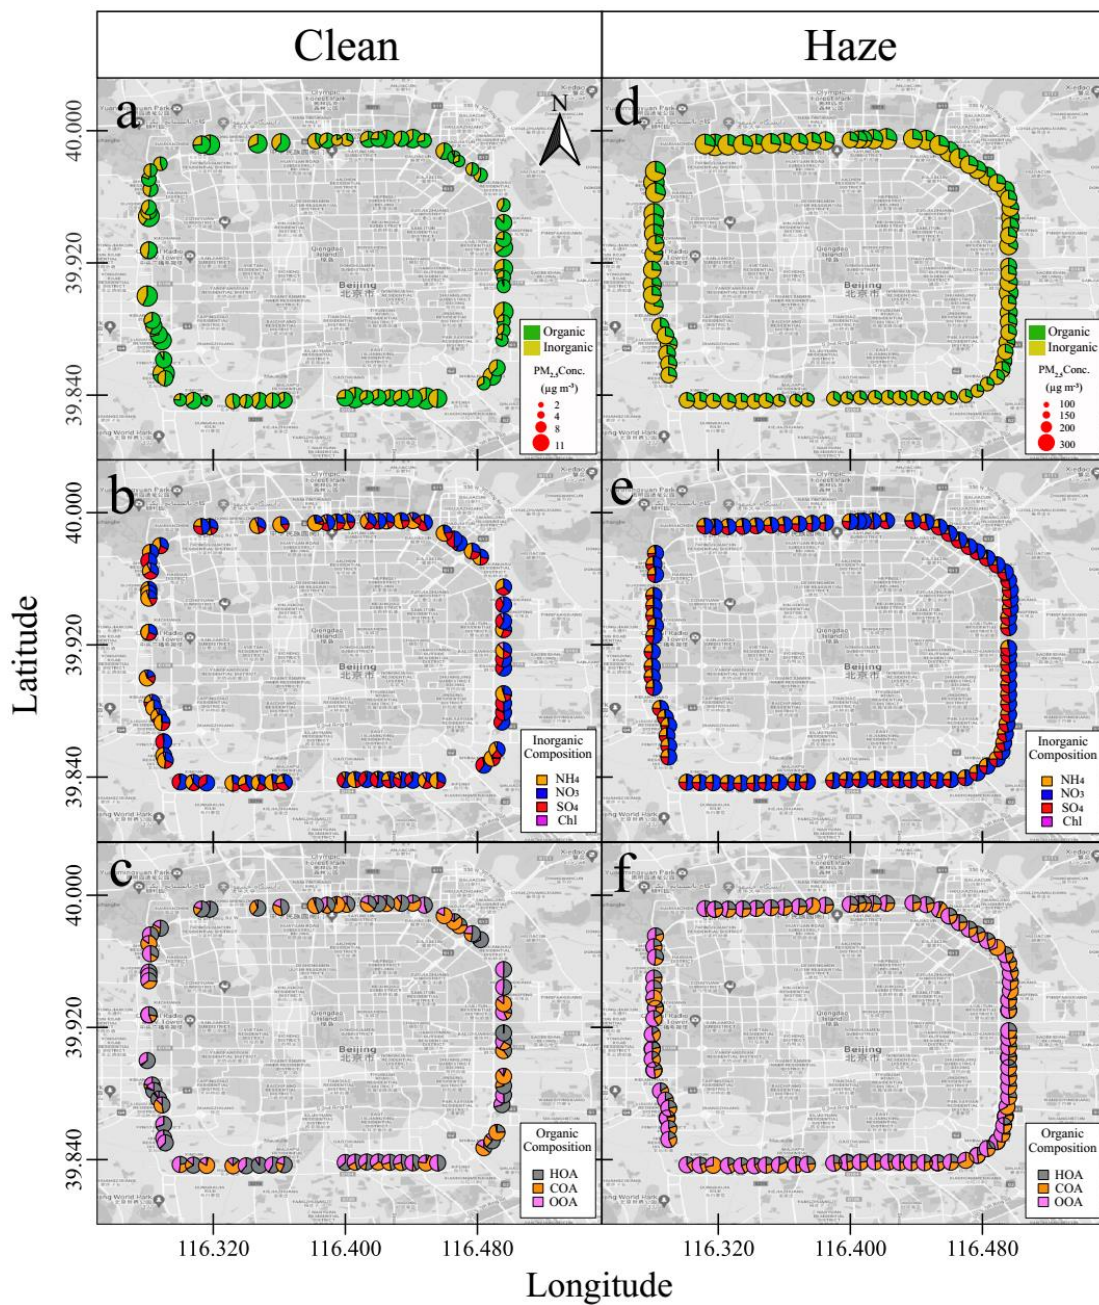

Figure 1. Spatial distribution of (a, d) the mass concentration (μg m^{-3}), (b, e) the inorganic composition, and (c, f) the organic composition of NR-PM$_{2.5}$ measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018. The size of the pies for inorganic and organic composition is the same and does not correspond to the mass concentrations of components. The organic composition is obtained from the PMF analysis, in which OOA represents the sum of the three OOA factors.
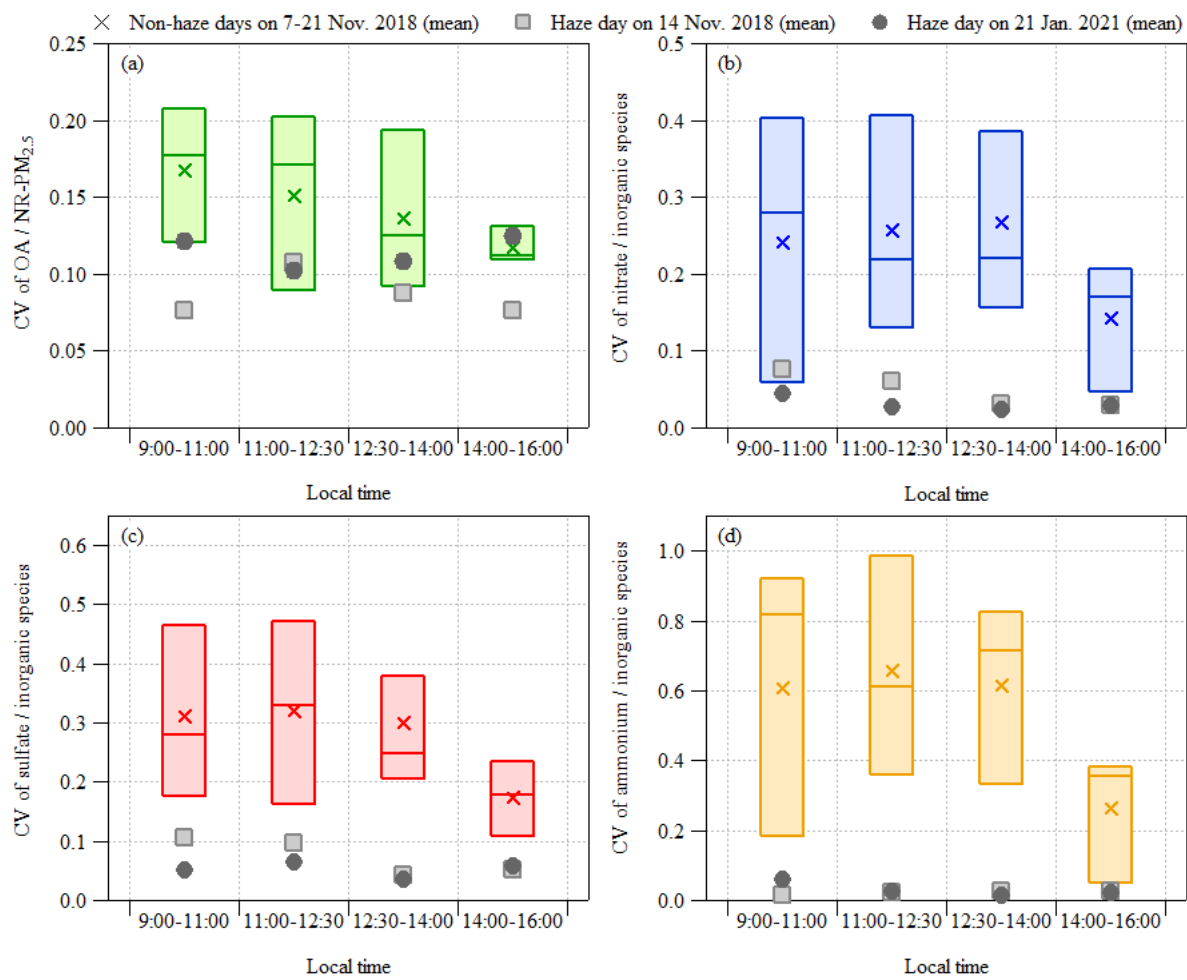

Figure 2. The CV values for the inorganic and organic mass fraction in NR-PM$_{2.5}$ for all cycles during the mobile campaign. The box plots show the 75th, median, and 25th percentiles.
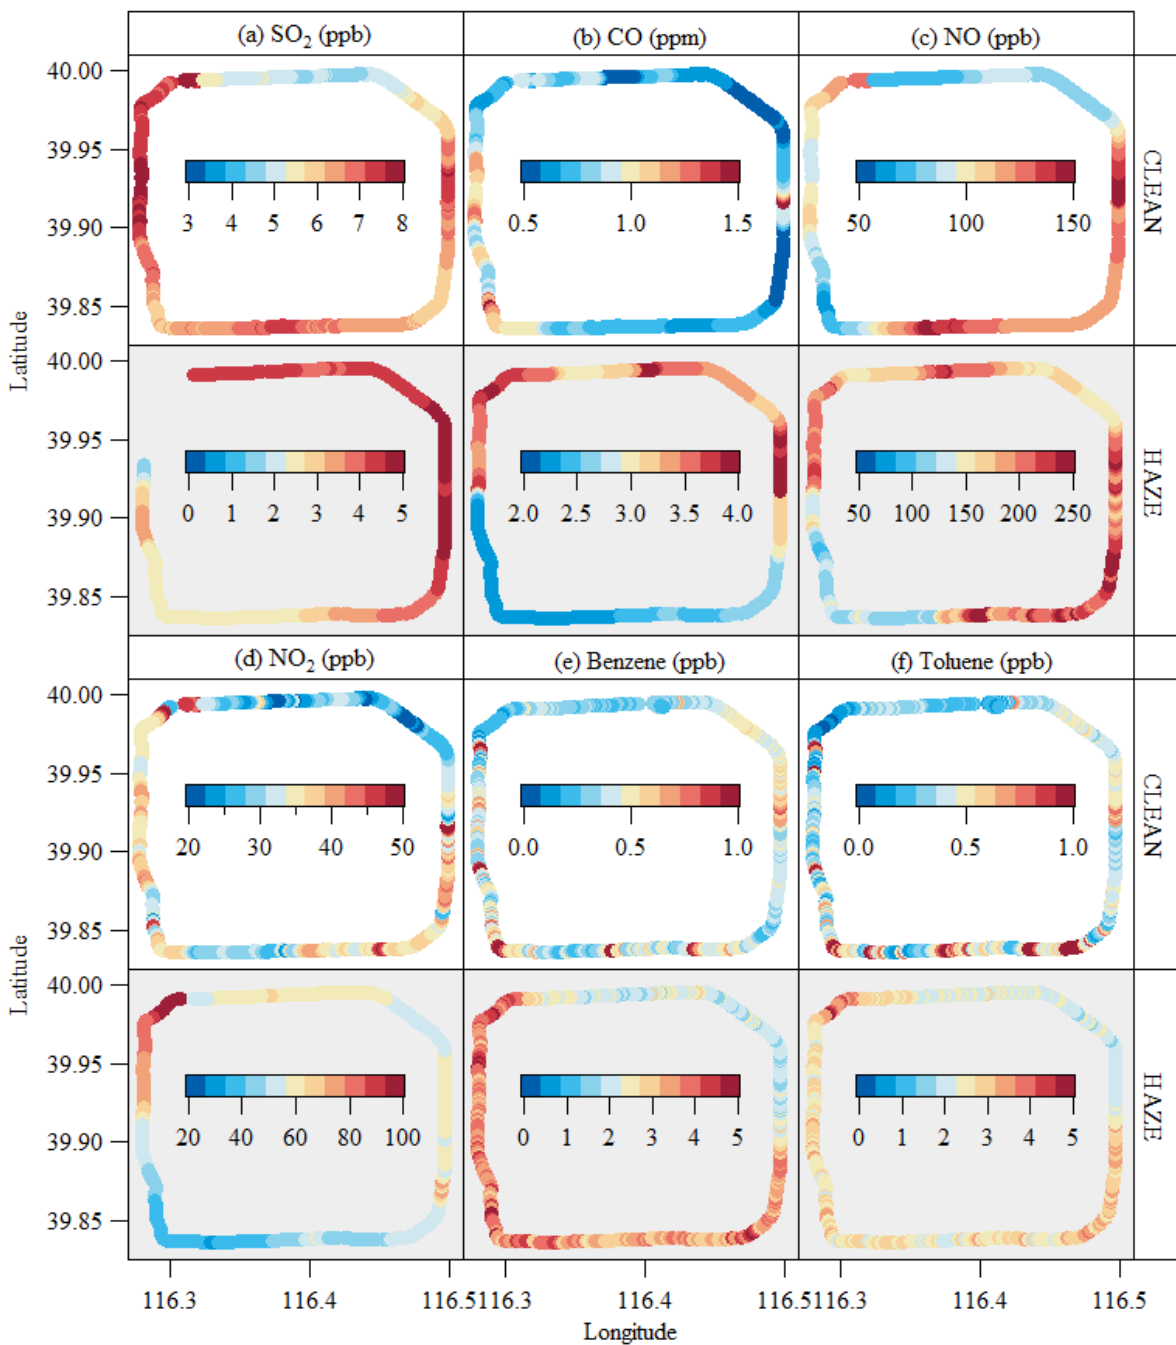

Figure 23. Spatial distributions of gaseous pollutants including (a) SO$_2$, (b) CO, (c) NO, (d) NO$_2$, (e) benzene, and (f) toluene measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.
590
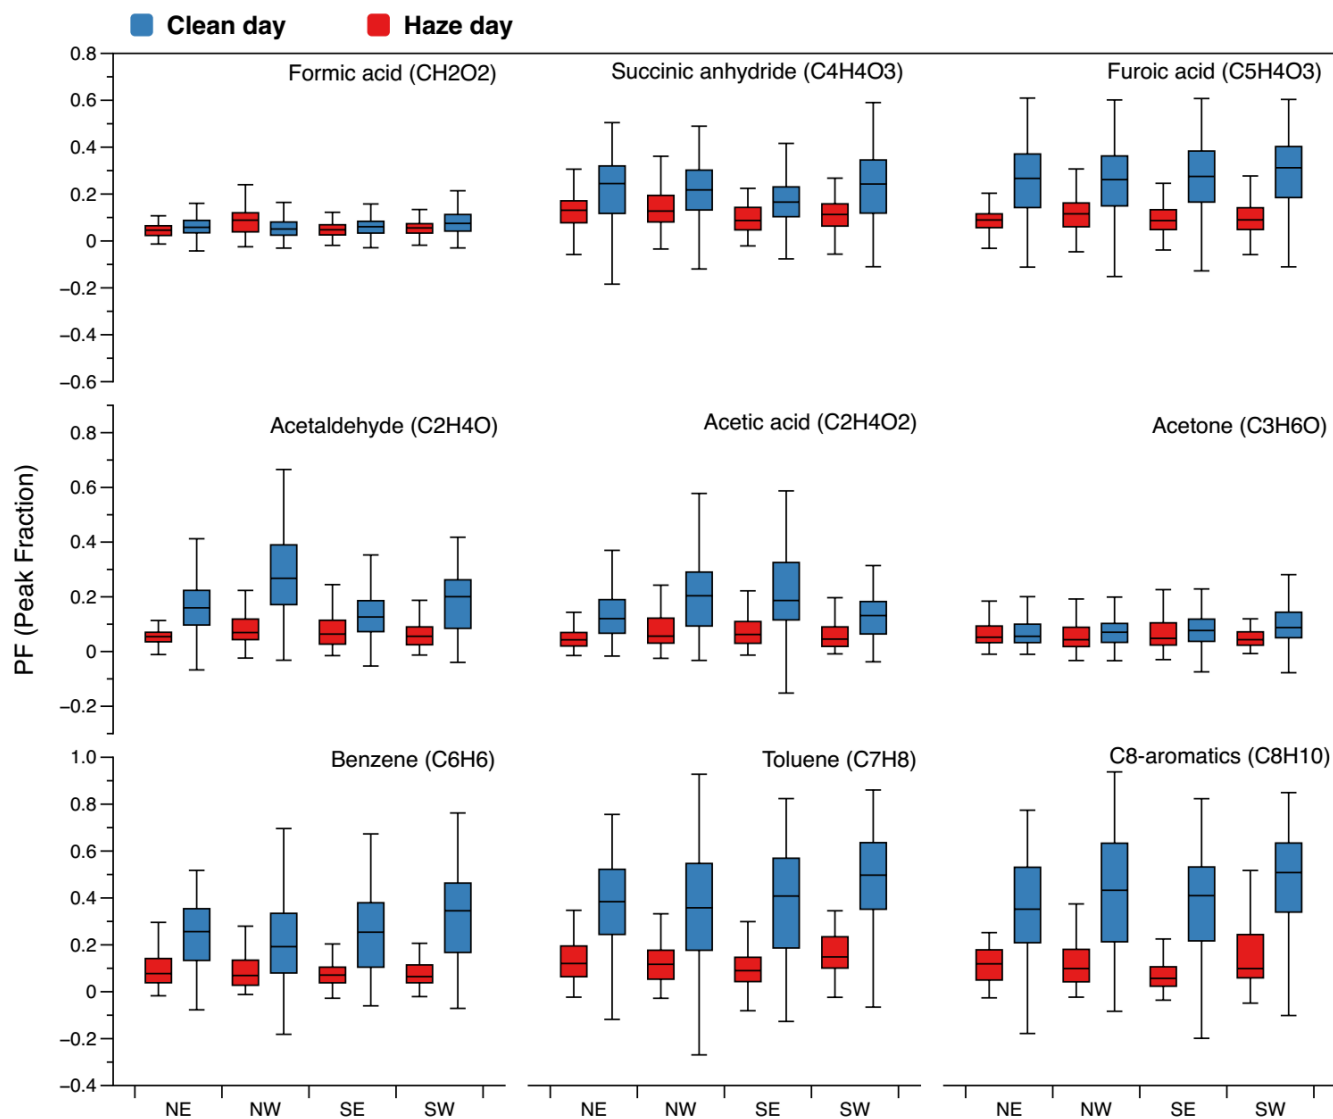

Figure 34. The spatial distributions of peak fraction values for common VOC species measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.
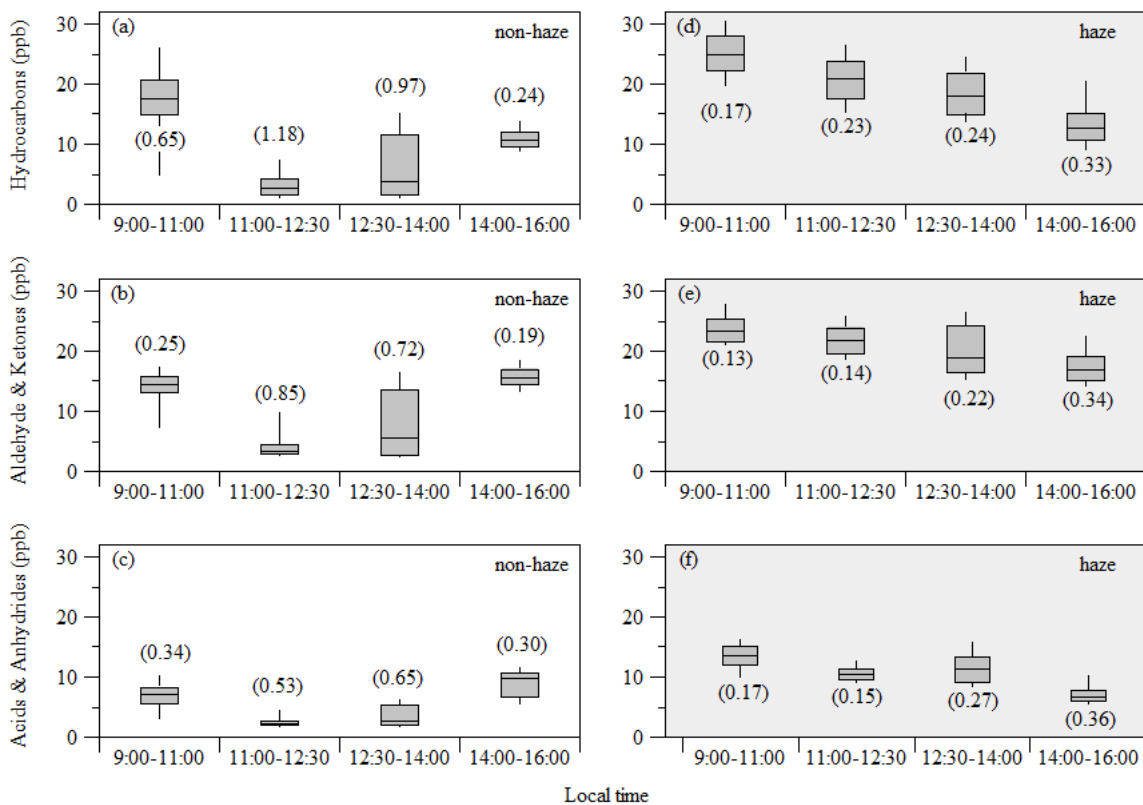

595

Figure 45. Spatial-temporal distributions of the concentrations of $\sum$ hydrocarbons, $\sum$ (aldehydes and ketones), and $\sum$ (acids and anhydrides) measured during the non-haze and haze days. The numbers in parentheses represent the CV values. The box and whisker plots show median, 75th and 25th percentiles, 90th and 10th percentiles.

600

Figure 56. Correlation heatmaps for the concentrations of the main VOCs and OVOCs measured during (a) the clean day on 18 November 2018 and (b) the haze day on 14 November 2018.

Table 1. The CV values for the concentrations or mass fractions of air pollutants measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.

Air pollutants		CV for concentration		CV for mass fraction	
		Clean	Haze	Clean	Haze
