Abstract. Characterization of the spatial distributions of air pollutants on an intracity scale is important for understanding local sources, secondary formation, and human exposure. In this study, we conducted in situ mobile measurements for the chemical composition of fine particles, volatile organic compounds (VOCs), oxygenated VOCs (OVOCs), and common gas pollutants in winter in the megacity of Beijing. The spatial variations of these gaseous and particulate pollutants under different pollution conditions are investigated. During the less-polluted periods, a large spatial variability exists in the inorganic composition of fine particles, suggesting a wide range of particle neutralization in the megacity of Beijing. Significant spatial variations are also observed in the composition of organic aerosol (OA), which are driven by primary OA emissions from vehicle and cooking exhaust as well as oxygenated OA. The spatial variations of VOCs and OVOCs vary by species. In general, hydrocarbon compounds show a large spatial variability that is attributed to traffic plumes, while secondary OVOCs are more spatially homogeneous in concentration because of the predominant contribution of urban background to the on-road air. Other gas pollutants show relatively low spatial variabilities and some high concentration spots that indicate high-emitting plumes from local sources as well as fast on-road ozone titration. During the haze periods, the spatial variabilities of air pollutants are largely reduced because of the predominant contribution of regional transport to the on-road concentrations of these pollutants. The concentrations of hydrocarbons and less-oxygenated OVOCs show good positive spatial-temporal correlations. The concentrations of more-oxygenated OVOCs show good positive correlations among themselves but moderate negative correlations with the concentrations of hydrocarbons, less-oxygenated OVOCs, and particulate components. The similar chemical compositions of particles and their gaseous precursors on the megacity scale suggest a spatially chemical homogeneity that may lead to efficient SOA production under haze conditions. On the other hand, the spatial heterogeneity of air pollution under less-polluted conditions calls a future need of using fine-resolution models to evaluate human exposure and pollution control strategies.

1 Introduction

35 Air quality degradation has become a serious problem in developing countries (Huang et al., 2014; Khuzestani et al., 2017). Cities in northern China suffer from severe haze events, especially in winter (Huang et al., 2014). High concentrations of volatile organic compounds (VOCs) and nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) contribute to high atmospheric oxidation capacity to produce ozone (O_3) and secondary aerosol (Lu et al., 2019b; Wang et al., 2017). The mass concentrations of particles having aerodynamic diameter less than $2.5 \mu\text{m}$ ($\text{PM}_{2.5}$) may reach up to several hundreds of $\mu\text{g m}^{-3}$, and the O_3 concentrations may exceed 100 ppbv in megacities. Both of high exposures of $\text{PM}_{2.5}$ and O_3 are of great concern to human health (Liu et al., 2016; Bell et al., 2006).

40 Tremendous efforts have been made to characterize air pollutants in populated urban areas in China (Li et al., 2017; Wang et al., 2017; Quan and Jia, 2020). In most studies, stationary measurements were conducted to obtain temporal variations of pollutants for the analysis of sources and formation mechanisms. Sulfate, nitrate, ammonium, and organic aerosol (OA) are the major chemical components of $\text{PM}_{2.5}$ in cities in China (Li et al., 2017). Their mass concentrations show decreases nationwide since 2013 as a result of the emission reduction of gaseous precursors such as sulfur dioxide (SO_2), NO_x , and VOCs under clean air actions as well as the changes of meteorological conditions (Zhang et al., 2019). In Beijing, the contribution of secondary OA (SOA) has significantly increased since 2018, while the contribution of primary OA (POA) from burning of 45 coal and biomass (biofuel) and cooking emissions have decreased (Lei et al., 2021). Characterization of organic precursors including VOCs and semivolatile and intermediate volatility organic compounds (S/IVOCs) is crucial for understanding the SOA production. Previous studies have shown that besides alkanes, aromatics and oxygenated VOCs (OVOCs) are abundant in cities in China (Mozaffar and Zhang, 2020; Li et al., 2016; Guo et al., 2017). These VOCs may come from a variety of 50 anthropogenic sources (e.g., vehicles, industries, solvent usage, coal and biomass burning, and household use of volatile chemical products etc.) and have great potential to form O_3 and SOA.

On an intracity scale, local emissions, advection, and boundary layer evolution may affect the spatial distributions of air pollutants. Tower measurements have shown greater vertical gradients of particulate matter (PM) concentration and composition during clean periods than haze periods in Beijing, which is attributed to the influence of both physical (e.g., 55 regional transport, mixing layer height, and inversions etc.) and chemical processes (e.g., gas-particle partitioning and aqueous processing) (Zhou et al., 2018). Significant vertical gradients also present in the concentrations of VOCs in cities, which can be affected by transport of air mass, vertical diffusion, and species reactivity (Sun et al., 2018; Mo et al., 2020). Moreover, grid sampling and simultaneous measurements at multiple sites are often used to investigate the spatial variations of air pollutants on sparse spatial scales. Previous studies show that the surface concentrations of VOCs and $\text{PM}_{2.5}$ components vary 60 because of different source contributions in metropolitan areas in China (Chen et al., 2020; Song et al., 2021). However, the spatial variability of air pollutants remains unclear, limiting our understanding of the haze development.

To better characterize the spatial distributions of air pollutants, mobile laboratory equipped with fast response in situ instruments have been widely used in Europe and United States (Kolb et al., 2004). For example, mobile measurements in Pittsburgh and Zurich indicate different spatial variability of PM composition (Tan et al., 2014; Gu et al., 2018; Ye et al., 2018; 65 Mohr et al., 2011; Elser et al., 2016). While primary carbonaceous sources perhaps lead to the large spatial heterogeneity of PM composition in Pittsburgh, a rather uniform distribution was observed in the metropolitan area of Zurich especially during thermal inversions over the Swiss plateau, highlighting the complexity of urban air pollution. However, the development and application of advanced mobile laboratory are lagged in China. Mobile measurements have been conducted to obtain the spatial distributions of SO₂, NO_x, carbon monoxide (CO), and black carbon (BC) as well as NO₂ and SO₂ column densities for the 70 evaluation of regional transport routes in North China Plain (NCP) and sources of air pollutants (Wang et al., 2009; Wang et al., 2011; Zhu et al., 2016; Wu et al., 2018). Recent deployments of online mass spectrometers in mobile laboratory have successfully captured the spatial distributions of VOCs and PM_{2.5} composition in cities in China, which may be useful for further investigation of urban air pollution (Wang et al., 2021c; Liang et al., 2020; Liao et al., 2021).

In this study, we conducted in situ sampling with gas analyzers and advanced mass spectrometers on a newly developed mobile 75 laboratory platform in winter in the megacity of Beijing. Spatial distributions of the mass concentrations of non-refractory PM_{2.5} (NR-PM_{2.5}) components (i.e., OA, nitrate, sulfate, ammonium, and chloride), VOC and OVOC species, and common gas pollutants such as SO₂, CO, NO, NO₂, and O₃ are obtained. The spatial variabilities of these gaseous and particulate pollutants under different pollution conditions are investigated to provide new insights to urban pollution and to improve our understanding of human exposure.

80 **2 Methods**

On-road measurements were conducted by the PKU mobile laboratory (Figure S1 in the Supplement) on the 4th Ring Road of Beijing on 7-21 November 2018 and 21 January 2021. The 4th Ring Road is a 65-km-long highway that passes through commercial, industrial, and residential areas. To show the spatial characteristics, the measurement area is categorized into 4 zones: Zone NE, Zone NW, Zone SE, and Zone SW (Figure S2 in the Supplement). Zone SE and Zone SW are close to 85 industrial facilities, while Zone NE and Zone NW are mostly commercial and residential areas. The average traffic volume on the 4th Ring Road is about 4000-8000 vehicles per hour, and over 90% of the fleet consisted of light duty gasoline vehicles (LDGVs) that meet National Stage III to V emission standards.

The measurements started at around 9:00 a.m. and went one cycle after another till 4:00 p.m. Each cycle took approximately 70 min with a mean speed of 60 km h⁻¹. Self-contamination from the vehicle exhaust is negligible for a vehicle speed over 30 90 km h⁻¹ (Liao et al., 2021). A suite of instruments was deployed in the mobile laboratory. Gas pollutants were detected by gas analyzers including NO₂ (Teledyne, T500U), NO-NO_x (Ecotech, EC9841A), SO₂ (Ecotech, EC9850A), CO (Ecotech, EC9830A), and O₃ (Ecotech, EC9810A) with a time resolution of 2 s. The chemical composition of NR-PM_{2.5} was measured

by an Aerodyne time-of-flight aerosol chemical speciation monitor (TOF-ACSM) with PM_{2.5} lens and a capture vaporizer with a time resolution of 40 s and a mass resolution of about 400 (Zheng et al., 2020). The uncertainty for the mass concentrations of NR-PM_{2.5} and its components is about 30% (Canagaratna et al., 2007). VOCs and OVOCs were detected by an Ionicon proton transfer reaction-quadrupole ion guide time-of-flight mass spectrometer (PTR-QiTOF). The overall quantification uncertainties are <20% for calibrated species and 19% and 33% for uncalibrated species with known and unknown reaction rate constants (K_{ptr}), respectively (Huang et al., 2019). Table S1 in the Supplement lists the K_{ptr} values, the mean concentrations, and the tentative categorization of VOCs and OVOCs measured herein. Detailed information about the campaign, sampling system, instrument operation and calibration, and data analysis are provided in Sect. A of the Supplement. The positive matrix factorization (PMF) analysis was performed on the OA mass spectra by using the Igor PMF evaluation tool (PET, version 3.00B). Five OA factors were resolved including hydrocarbon-like OA (HOA), cooking-related OA (COA), and three oxygenated OA (OOAs) (Section A). The common OA factors related to biomass burning (BBOA) or coal burning (CCOA) were not resolved in this data set and were perhaps mixed with other OA factors (Liao et al., 2021). Their contributions to OA were however expected to be small because of the stringent emission control in NCP in recent years (Zheng et al., 2020; Duan et al., 2020).

Figure S3 in the Supplement shows the time series of mass concentrations of air pollutants measured at the PKU campus roof site during the campaign. This site is located between the 4th and the 5th north Ring Roads, representing a typical urban environment in Beijing (Cheng et al., 2021). In this study, we classified clean ($< 35 \mu\text{g m}^{-3}$), haze ($> 75 \mu\text{g m}^{-3}$), and non-haze ($< 75 \mu\text{g m}^{-3}$) days based on the daily mean PM_{2.5} mass concentrations for the measurements. Moreover, we computed a batch of 12-hour backward trajectories for the height of 3 m around the 4th Ring Road from the HYSPLIT model to investigate the influence of urban background and regional transport on our measurements during the haze day (Stein et al., 2015). We set the start time of the trajectory analysis at 9:00 a.m. and repeated the trajectory calculations every 1 hour until 4:00 p.m. (Figure S4 in the Supplement). In addition, a moving average window of 10 (i.e., 20 s) was applied to the entire data set for VOC and OVOC species. Concentration baselines for each 2-s point in the 20-s smoothed data were calculated as the 5th percentile concentration within a rolling window of 60 (i.e., 120 s), for which the urban background conditions were identified (Apte et al., 2017). We then computed the peak fraction (PF) parameter as 1 minus the ratio of the mean baseline value to the observed mean concentrations. The time series of the concentrations of common VOC and OVOC species shows significant plumes above the baseline for the on-road measurements (Figure S5 in the Supplement). PF values are used as a semi-quantitative indicator to show the contributions of the above-baseline concentrations to the observed concentrations of VOCs and OVOCs, which may represent the intensity of transient emission from local sources (e.g., vehicle exhaust).

3 Results and Discussion

3.1 Spatial distribution of NR-PM_{2.5} and its components

125 Significant spatial variabilities of the mass concentrations of NR-PM_{2.5} and its chemical components are observed during the campaign. As described briefly by Liao et al. (2021), the mean (\pm one standard deviation) mass concentration of NR-PM_{2.5} for non-haze days is $30.7 \pm 24.7 \mu\text{g m}^{-3}$, in which OA is the most abundant component that contributes to about 52% of the NR-PM_{2.5} mass. The mean mass concentration of NR-PM_{2.5} for the haze day is $155.0 \pm 27.0 \mu\text{g m}^{-3}$, and nitrate becomes the most abundant component that contributes to about 48%. Interestingly, the intracity spatial variations of the concentration and composition of NR-PM_{2.5} are quite different under different pollution conditions.

130 Figure 1 shows the spatial distributions of the mass concentrations of organic and inorganic components in NR-PM_{2.5} for the example noon cycles on typical clean and haze days. The coefficients of variation (CV) are listed in Table 1. Large spatial variabilities of the mass concentration and the composition of NR-PM_{2.5} present in the clean-day measurements (Figure 1a). The mass concentration of NR-PM_{2.5} ranges from 1.0 to $17 \mu\text{g m}^{-3}$ with a relatively high CV value of 0.75. OA is the dominant component that explains the most variability of the NR-PM_{2.5} mass (CV = 0.75). The spatial variations of the OA mass are attributed to both of POA and OOA. As shown in Fig. 1c, the mass fractions of POA factors such as HOA and COA show a large spatial heterogeneity with hot spots (mass fraction > 60%) in various segments of the 4th Ring Road. These hot spots are plausibly contributed by exhaust plumes from on-road vehicles and nearby restaurants that have not yet well mixed with urban background air. Similarly, the measurements in Pittsburgh show a significant spatial heterogeneity of primary carbonaceous components such as HOA, COA, and BC (Gu et al., 2018). The Pittsburgh study show less spatial variabilities of OOAs, whereas the CV value for the OOA concentration are high in Beijing during the clean day. This is perhaps because the precursors and formation pathways of OOAs are more complicated in Beijing than in Pittsburgh (Li et al., 2021; Yang et al., 2019).

145 Inorganic components show much higher CV values in mass fraction than OA (Table 1), indicating a relatively greater spatial variability of inorganic composition. As shown in Fig. 1b, ammonium is the predominant inorganic component in Zones NW and SW, while nitrate contributes most in Zone SE. The CV values for ammonium are the highest in both mass concentration and mass fraction. The molar ratio of $n_{\text{NH}_4^+} : (2 \times n_{\text{SO}_4^{2-}} + n_{\text{NO}_3^-})$ range from ~ 0 to 1.0, suggesting a wide range of particle neutralization on the megacity scale under clean-day conditions in winter in Beijing, which is perhaps driven by the difference in chemical processes and local emissions of precursors. In NCP, the aerosol mass can be sensitive to ammonia or nitric acid availability (Nenes et al., 2020). Traffic and agriculture (e.g., livestock) emissions are the main sources of ammonia in Beijing during the clean periods in winter (Sun et al., 2017; Pan et al., 2018). Traffic emissions depend on on-road vehicle type and volume and may vary greatly in the city. On the other hand, the concentrations of nitric acid depend on the concentrations of NO_x and hydroxyl radical (OH) that are affected by local emissions and atmospheric oxidation and may also vary significantly in the city. Besides, a uniform distribution of solar radiation on the surface is not expected in the megacity because of the shades of buildings as well as cloud covers. Therefore, the spatial heterogeneity of inorganic composition reflects spatially

155 different thermodynamic regimes in the megacity environment, which may challenge the development of further pollution control strategies as clean air actions continue. For comparison, the inorganic components have less spatial variabilities in Pittsburgh than in Beijing (Gu et al., 2018), which may be explained by the greater emissions of ammonia and NO_x as well as OH concentrations in urban areas in China.

By contrast, the mass concentration of NR-PM_{2.5} has a low CV value of 0.12, and it is consistently higher in Zones NE and NW (163.2 ± 12.3 μg m⁻³) than in Zones SE and SW (138.8 ± 16.9 μg m⁻³) during the haze day (Figure 1d). The mass fractions of inorganic (i.e., ammonium, sulfate, nitrate, chloride) and organic components (i.e., HOA, COA, and OOA) are similar across the city (CV < 0.35), although a few hot spots of COA exist (Figure 1f). The sampling inlets of the PKU mobile lab are located at 3.4 m above the ground, which may sample air from both of urban background and instantaneous plumes. The 40-s PM_{2.5} measurements by TOF-ACSM may roughly represent a maximum area of 0.16 km² upwind when the mobile laboratory was run on the 4th Ring Road by cycles. The similar chemical composition along the road suggests relatively homogeneous spatial distributions of the mass concentration and composition of NR-PM_{2.5} across the city under haze conditions. This is supported by the fact that the particle composition observed at the PKU roof site was similar to our mobile measurements (Figure S3). Although stagnant conditions facilitate the accumulation of local emissions (e.g., vehicle emissions on the road), over 60% of the PM_{2.5} mass in Beijing can be contributed by regional transport during the winter haze episodes (Sun et al., 2014; Wu et al., 2021). The predominant contribution of regional transport suggests similar sources of PM_{2.5} in Beijing. Similar particle composition suggests a spatial chemical homogeneity at least on the megacity scale in terms of gas-to-particle equilibrium or partitioning as well as the heterogeneous or particle-phase production. The north-south difference in mass concentration is perhaps driven by the differences in atmospheric dilution on the intracity scale (Sun et al., 2016; Chen et al., 2020). The uniform spatial distributions of PM composition under haze conditions are similar to the observations in the metropolitan area of Zurich when thermal inversions occur over the Swiss plateau and secondary pollution is built up regionally (Mohr et al., 2011), highlighting stagnant metrological conditions as one of the key drivers of the city-scale chemical homogeneity.

Figure 2 shows the CV values of the mass fractions of ammonium, sulfate, nitrate, and OA in PM_{2.5} for all cycles measured during the mobile campaign. Large spatial variabilities of the mass concentration and composition of NR-PM_{2.5} present in all measurement cycles during the clean days, while the mass concentration and composition of NR-PM_{2.5} are rather uniform in all cycles during the haze days on the 4th Ring Road, not limited to the noon cycle presented in Figure 1. The mass concentration and composition of NR-PM_{2.5} show significantly day-to-day and diurnal variations as indicated by the stationary measurements at the PKU roof site (Figure S3). Such temporal variations are driven by source variations and meteorological conditions, which have been studied extensively in the past (Duan et al., 2020; Lei et al., 2021; and the reference therein).

3.2 Spatial distribution of gaseous pollutants

185 Figure 3 shows the spatial distributions of the mixing ratios of gaseous pollutants for the example noon cycles. The concentrations of SO₂ are low (< 10 ppbv) throughout the campaign (Figure 3a). During the clean day, the SO₂ concentrations

are low in the north and relatively high in the west of the 4th Ring Road, which is different from the distributions of the NR-PM_{2.5} mass concentrations. The SO₂ concentrations has a CV of 0.13. The low spatial variability of SO₂ may be explained by the predominant contribution of regional transport as a result of the relocation of steel industry and power plants out of Beijing and the ban of high emission vehicles from the road (Ge et al., 2018). Previous mobile measurements in Beijing captured specific transport events of SO₂ from the south and found that the SO₂ concentration decreased from Zone SE to Zone NW (Wang et al., 2011; Zhu et al., 2016), which is consistent with our clean-day observations. During the haze day, the SO₂ concentrations are lower than the concentrations observed during the clean day, which may be explained by the large conversion of gaseous SO₂ to sulfate by photochemical and aqueous processes under winter-haze conditions (Wang et al., 2021b). The haze-day distribution of SO₂ concentration is different from the clean-day distribution and has a greater CV value of 0.27. The 12-hour backward trajectories around the 4th Ring Road show that the air masses were mostly from the east in the morning, started shifting towards south at ~12:00 p.m., and then were mainly originated from the south around 4:00 p.m. (Figure S4 in the Supplement). The spatial distribution of SO₂ is therefore affected by the transport routes. Southwesterly, southeasterly, and easterly flux pathways have been recognized as typical regional transport routes to Beijing (Chang et al., 2019).

CO and NO are common gaseous pollutants emitted from combustion sources. The mean on-road concentrations of CO are 1.53 ± 0.66 ppm for non-haze days. For comparison, the concentrations of CO measured concurrently at the PKU roof site are 0.50 ± 0.26 ppm for non-haze days. The on-road concentrations are about three times greater than the urban background concentrations, explained by the contribution of vehicle exhaust plumes (Gentner et al., 2017). For NO, the concentrations measured at the PKU roof site are very low because of the O₃ titration. The on-road concentrations are 1-2 orders of magnitude greater, which is also explained by the fleet emissions. The clean-day spatial distribution of CO concentrations (CV = 0.26) is quite homogeneous except a few hot spots in Zone SW (Figure 3b). The clean-day spatial distribution of NO concentrations (CV = 0.22) is different from that of CO (Figure 3c), showing higher concentrations in Zone SE where the traffic volume is usually greater than in other Zones. One explanation for such differences between CO and NO may be much greater contributions of background concentrations and non-vehicular sources to CO. In addition, relatively slower response of instrument detection of CO and NO may smooth out some of the concentration variations. As shown in Fig. S6 in the Supplement, the on-road time series of NO₂ concentrations shows more short-duration peaks than the time series of CO and NO concentrations. During the haze day, greater CO and NO concentrations present. The spatial distributions of CO, NO, SO₂, and NR-PM_{2.5} concentrations all show relatively low concentrations in Zone SW. The greater haze-day concentrations and the similar spatial distributions of these pollutants are consistent with the large contribution of regional transport to urban air pollution and the stagnant meteorological condition during the haze episode.

The clean-day spatial distribution of NO₂ concentrations is similar to that of NO, although more concentration hot spots exist (Figure 3d). The on-road NO₂ are contributed by direct tailpipe NO₂ emissions, secondary NO₂ through on-road NO_x titration, and background NO₂. The tailpipe NO₂ emissions are small for LDGVs (National Stage III and above) (Wu et al., 2017). The

220 urban background concentrations of NO₂ measured at the PKU roof site on 18 November 2018 (clean day) are low at noon
(5.2 ± 0.6 ppbv). The high on-road NO₂ concentrations (16.8-94 ppbv) are plausibly contributed by the fast on-road NO_x
titration, which is similar to the findings in North Carolina, U.S. (Yang et al., 2018). As shown in Fig. S7a in the Supplement,
the clean-day on-road concentrations of O₃ range from 3.2 to 15.4 ppbv, which are 3-4 times lower than the concentrations
measured at the PKU roof site (40.0-44.5 ppbv). The spatial distribution of O₃ concentration is opposite to that of NO, which
225 is consistent with the titration effect. The more-frequent appearance of hot spots in the clean-day NO₂ distribution is likely
because of the faster detection of NO₂ by the cavity attenuated phase shift technique than the chemiluminescence detection of
NO. During the haze day, the spatial distribution of O₃ concentration is opposite to that of NO but shows much lower
concentrations (i.e., a few ppbv) than during the clean day, which can be explained by the stronger titration effect with higher
NO concentrations. However, the concentrations of NO, NO₂, and O₃ are all high in Zone NW. The backward trajectories
230 suggest transport of air masses from the east and the south to Beijing. The high concentrations of air pollutants in Zone NW
therefore may not be explained by regional transport and are perhaps related to local meteorological conditions affected by
specific land surface conditions.

The spatial distributions of VOCs vary by species. LDGVs emit aromatic hydrocarbons (e.g., benzene, toluene, ethylbenzene,
and xylenes), some oxygenated species (e.g., acetaldehyde), and so on (Gentner et al., 2017). As expected, the on-road
235 concentrations of such primary VOC species are much greater than the concentrations measured at the urban and suburban
sites in Beijing (Table S1 in the Supplement). Figure 3e-f shows the spatial distributions of benzene and toluene concentrations.
During the clean day, both of the distributions show large spatial variabilities with high CV values (Table 1). Concentration
hot spots present and are plausibly contributed by transient plumes of vehicle exhaust or nearby local sources (e.g., in industrial
areas of Zone SW). Interestingly, the distributions of the hot spots for benzene and toluene are not the same, highlighting the
240 difference in emissions from individual vehicles (Mo et al., 2016).

The toluene-to-benzene concentration ratio (T/B) is widely used to differentiate the VOC sources (Song et al., 2021; and
references therein). According to literature, traffic emissions have T/B ratios from 1 to 3 depending on vehicle type and fuel
composition. Industry emissions have a wide range of T/B ratios (1.4 to 5.8). Solvent emissions may have high T/B ratio of ~
8.8. Biomass burning emissions typically have a low ratio of ~ 0.3. During the clean day, most of the concentration hot spots
245 for benzene and toluene corresponds to T/B ratios of 1.1-2.6, which is consistent with vehicle emissions (Fig. S7b in the
Supplement). Some of the high T/B ratios (e.g., 2-3 in the south) are perhaps related to industry plumes. The T/B ratios for on-
road background (not high-emitting plumes) are low (0.6-1.3), which may be explained by faster photochemical consumption
of toluene than benzene. By contrast, the spatial variability for OVOCs (CV ~ 0.6) is much lower than that for hydrocarbons
(Table 1), owing to their secondary nature because of the lack of local sources in Beijing (Wang et al., 2021a).

250 During the haze day, a remarkable enhancement of VOC concentrations is observed with mean enhancement ratios of 3.3-16.3
(e.g., 8.7 for benzene, 6.5 for toluene, 6.5 for C₈-aromatics, 5.2 for methyl ethyl ketone, and 4.8 for propene) (Figure S8 in the
Supplement). The spatial distributions of benzene and toluene show consistent high concentrations in Zones NW, SW, and SE

(Figure 3e-f) but low T/B ratios in those segments that indicate aged air masses (de Gouw et al., 2005), considering the limited biomass burning contributions during the campaign (Fig. S7b). The spatial distributions of benzene and toluene are different from the distributions of other air pollutants under haze conditions, suggesting that the influence of regional transport may vary by species. Moreover, the haze-day spatial distributions of OVOC concentrations are quite homogeneous with relatively small CV values (i.e., 0.14 for Σ (Aldehyde & Ketones) and Σ (Acids & Anhydrides) in Table 1). The distribution of individual OVOCs is similar among species except for the OVOCs having 3-4 oxygen atoms in their formulae, which will be discussed further in Sect. 3.3. The calculated PF values in Figure 4 suggest 30-40% contributions of high-emitting plumes to the on-road concentrations of aromatic species during the clean day compared with 9-13% during the haze day. For OVOCs (e.g., formic acid), the contribution of high-emitting plumes to the on-road concentrations are comparable for the clean and haze days (i.e., 6-13%), owing to their secondary nature.

Figure 5 shows the spatial-temporal variations of the concentrations of the detected VOCs and OVOCs measured during the non-haze and haze periods of the mobile campaign. The concentrations of Σ hydrocarbons (i.e., aromatics and alkenes) are the highest in the morning (9:00 a.m. to 11:00 a.m.) for both non-haze and haze periods, which may be explained by shallow boundary layer, rush-hour traffic emissions, and slow chemical removal (de Gouw et al., 2009). The on-road measurements of hydrocarbons are largely affected by instantaneous vehicle plumes. The greater concentrations of hydrocarbon in the afternoon (2:00 p.m. to 4:00 p.m.) than in the earlier period (11:00 a.m. to 2:00 p.m.) suggest that the mobile measurements captured less vehicle plumes, which is consistent with the less traffic volume on the road. Under non-haze conditions, the spatial variabilities of hydrocarbons vary significantly during the day. Their CV values are high in the morning and low in the afternoon. It is likely that photochemistry and better mixing conditions in the afternoon smooth out some of the spatial variabilities caused by on-road vehicle emissions (Mellouki et al., 2015; Karl et al., 2018). By contrast, their concentrations keep decreasing during the day under haze conditions, and the greater concentrations of Σ hydrocarbons than during the clean days are plausibly driven by the greater contribution of regional transport to on-road air and stagnant meteorological conditions that favour the accumulation of on-road vehicle plumes. Under haze conditions, the spatial variability of hydrocarbons is slightly greater in the afternoon, which is probably because of the change of regional transport direction. As shown in Fig. S4, the backward trajectories suggest that the air masses gradually shifted from eastern to southern during the haze day. For the two categories of OVOCs, the non-haze temporal variations are similar to that of hydrocarbons. Their CV values indicate much smaller spatial variabilities of OVOCs in the morning rush hour (9:00 a.m. to 11:00 a.m.) than that of hydrocarbons. This is consistent with previous results of source apportionment that secondary production is the main contributor of most OVOCs in Beijing (Wang et al., 2021a). As the photochemical production proceeds during the day, the spatial variabilities of OVOCs increase and then decrease, similar to that of hydrocarbons. On the other hand, the haze-day temporal and spatial variations of OVOCs are all similar to that of hydrocarbons ($CV < 0.36$), corresponding to the predominant contribution of regional transport to the on-road concentrations of these pollutants.

3.3 Chemical homogeneity under haze conditions

Figure 6 shows the correlation heatmaps of the concentrations of VOCs and OVOCs measured during the clean day and haze day for all measurement cycles on the 4th Ring Road of Beijing. Day-to-day variations are not included because of the possible change of sources. Only primary hydrocarbons show good correlations with each other during the clean day (Figure 6a). This is consistent with the predominant contribution of traffic emissions to the on-road concentrations. Secondary species like OVOCs and PM_{2.5} are more regional and do not correlate with these primary hydrocarbons (Figure S9 in the Supplement). They do not correlate with each other either, indicating a spatial chemical heterogeneity in OVOC and PM_{2.5} formation. By contrast, the haze-day heatmaps show significantly different patterns (Figure 6b and Figure S10). Primary hydrocarbons correlate well with each other (Pearson's $r > 0.7$, $\alpha = 0.01$). They also show good positive correlations with many less-oxygenated OVOCs (e.g., aldehydes and ketones with 1-2 oxygen atoms in their formulae (Table S1)). These OVOCs may be contributed by both primary and secondary sources, and they can be formed and accumulated during the regional transport process. The NR-PM_{2.5} components also correlate with these VOCs and OVOCs (Figure S9). Such good spatial-temporal correlations are consistent with the predominant contribution of regional transport to high concentrations of hydrocarbons, less-oxygenated OVOCs, and PM_{2.5} in Beijing during the haze event.

Interestingly, more oxygenated OVOCs (e.g., anhydrides and acids with 2-4 oxygen atoms in their formulae) that are mainly contributed by secondary sources show good positive correlations with each other ($r > 0.7$, $\alpha = 0.01$) but moderately negative correlations with hydrocarbons and less-oxygenated OVOCs as well as the NR-PM_{2.5} components. These species include CH₂O₂ (tentatively assigned as formic acid), C₂H₄O₃, C₃H₄O₃, C₄H₄O₄, C₄H₄O₃, C₅H₄O₃, and C₅H₄O₂. The spatial-temporal correlations for these more oxygenated OVOCs suggest similar more-oxygenated OVOC composition on the megacity scale during the haze day, which may indicate a homogeneous photochemical production as well as gas-to-particle partitioning. High oxidation capacity in winter in NCP has been reported (Lu et al., 2019a; Slater et al., 2020). Secondary OVOCs are formed and accumulated along the transport route. With a rather uniform distribution of hydroxyl radical which likely happens under winter haze conditions because of the thick cloud cover and increased particle scattering, the formation of more-oxygenated OVOCs from less-oxygenated OVOCs can be relatively homogeneous in the city. Although these more-oxygenated OVOCs may partition to the particle phase, the gas-to-particle partitioning are not expected to affect much the spatial variability of the more-oxygenated OVOCs because of the similar chemical composition of PM_{2.5} and the narrow loading range on the intracity scale under haze conditions. The secondary production thus explains the negative correlations of the more-oxygenated OVOCs with their precursors (e.g., hydrocarbon and less-oxygenated OVOCs) and PM_{2.5}. Moreover, the gas-particle repartitioning caused by temperature difference may affect the distribution of more-oxygenated OVOCs. This effect is however expected to be minor considering the range of OA loadings, the vapor pressures of these more-oxygenated OVOCs, and the possible temperature elevation of 1-3 °C in the city (Chen et al., 2020; Wang et al., 2020; Yang et al., 2013). Peroxyacetyl nitrate (PAN, C₂H₄O₃) is more sensitive to temperature and less stable than the other more-oxygenated OVOCs (Seinfeld and Pandis, 2016), which may explain its lower correlation coefficient in Fig. 6b.

4 Conclusions

In this study, we conducted on-road mobile measurements of air pollutants including NR-PM_{2.5} and its components, gaseous pollutants, VOCs, and OVOCs under different pollution levels in winter in Beijing. During the clean periods, large spatial variabilities of the pollutants are observed, which can be largely attributed to the influence of local sources and secondary production. In particular, the inorganic composition of NR-PM_{2.5} vary greatly, indicating a wide range of particle neutralization on the intracity scale under less-polluted conditions in winter Beijing. For OA, the spatial variability is driven by local HOA and COA emissions as well as OOA. The spatial variations of regular gas pollutants are relatively smaller than those of the PM_{2.5} components. The spatial distributions of the concentrations of VOCs and OVOCs vary by species. Detected hydrocarbons (i.e. mostly aromatic species) are largely affected by on-road vehicle emissions, and thus show large spatial variabilities during the clean periods. Our results suggest about 30-40% contributions of high-emitting plumes to the on-road concentrations of aromatic species during the clean periods compared with 9-13% during the haze periods. Overall, the great spatial heterogeneity of the particle composition and VOCs may challenge the development of future pollution control strategies as clean air actions continue. The results also indicate different human exposures to particles and gaseous pollutants on the intracity scale, which requires fine-resolution models to evaluate.

During the haze days, stagnant weather conditions and predominant contributions from regional transport to urban background concentrations of particulate and gaseous pollutants largely reduce the spatial variabilities of these pollutants in the megacity. More-oxygenated OVOCs show good positive correlation among themselves but moderate negative correlations with hydrocarbons, less-oxygenated OVOCs, and PM_{2.5} components, suggesting a spatially homogeneous photochemical production as well as gas-to-particle partitioning on the megacity scale. Such a chemical homogeneity may lead to efficient local production of semivolatile oxidation products that enhances the SOA production in the megacity to enhance the haze development.

555 **Figure 1.** Spatial distribution of (a, d) the mass concentration ($\mu\text{g m}^{-3}$), (b, e) the inorganic composition, and (c, f) the organic composition of NR-PM_{2.5} measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018. The size of the pies for inorganic and organic composition is the same and does not correspond to the mass concentrations of components. The organic composition is obtained from the PMF analysis, in which OOA represents the sum of the three OOA factors.

560

Figure 2. The CV values for the inorganic and organic mass fraction in NR-PM_{2.5} for all cycles during the mobile campaign. The box plots show the 75th, median, and 25th percentiles.

Figure 3. Spatial distributions of gaseous pollutants including (a) SO₂, (b) CO, (c) NO, (d) NO₂, (e) benzene, and (f) toluene measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.

565

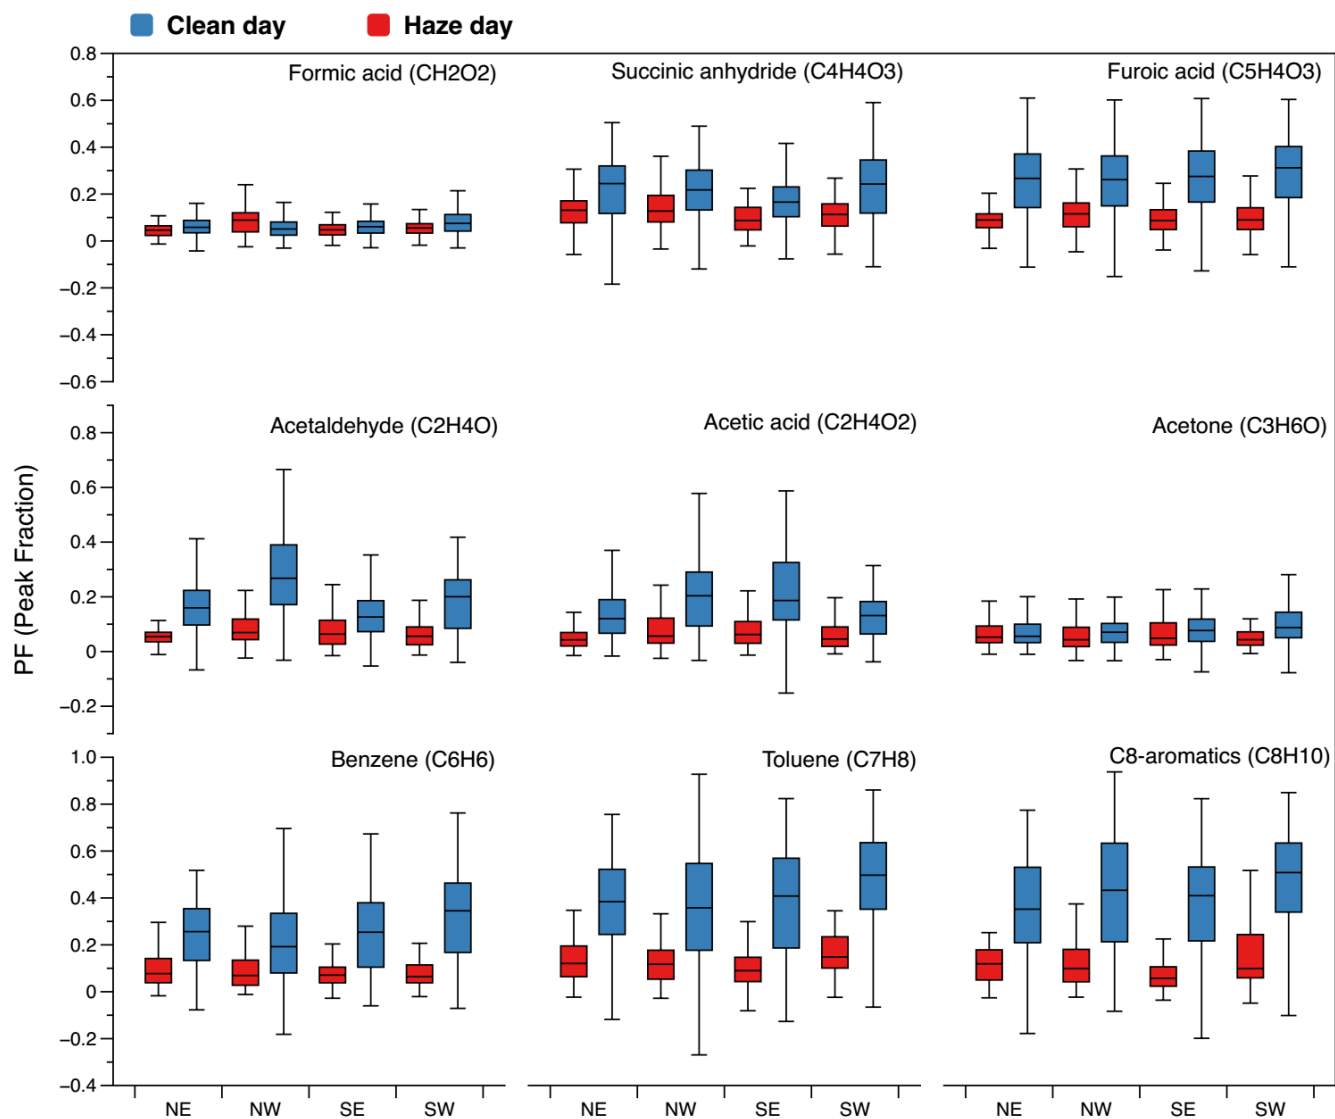

Figure 4. The spatial distributions of peak fraction values for common VOC species measured during the noon cycles from 570 ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.

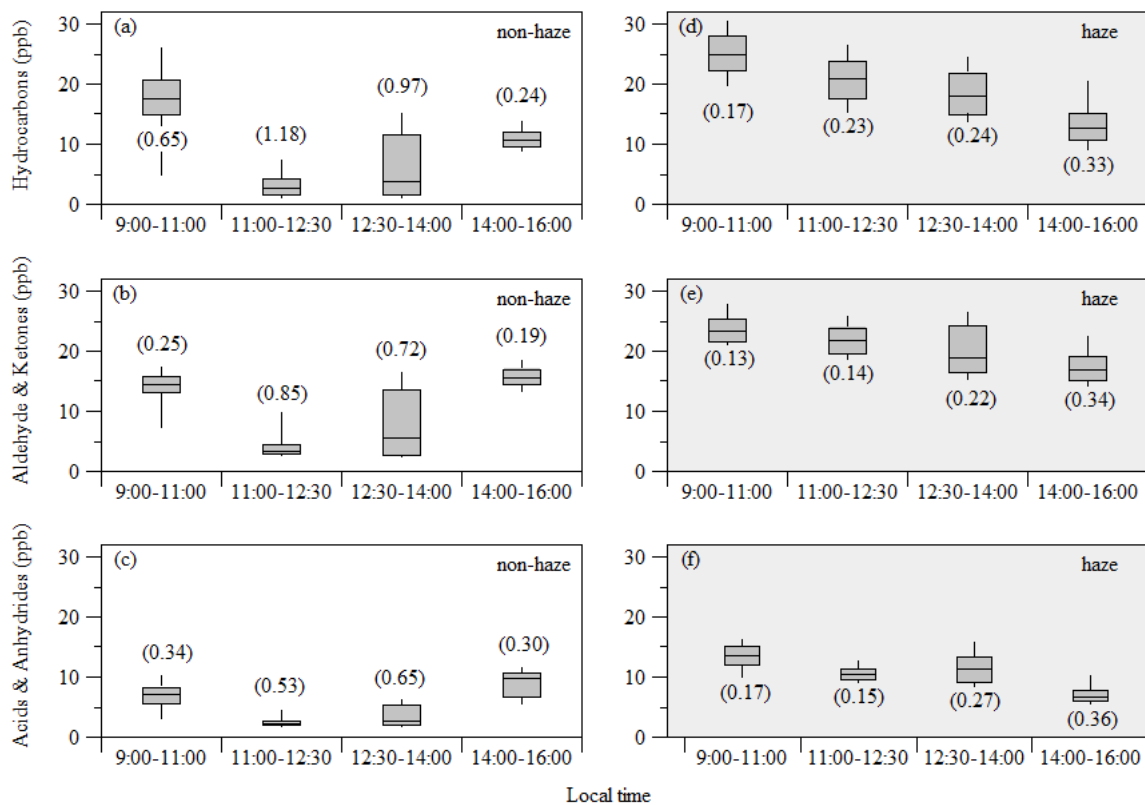

Figure 5. Spatial-temporal distributions of the concentrations of Σ hydrocarbons, Σ (aldehydes and ketones), and Σ (acids and anhydrides) measured during the non-haze and haze days. The numbers in parentheses represent the CV values. The box and whisker plots show median, 75th and 25th percentiles, 90th and 10th percentiles.

575

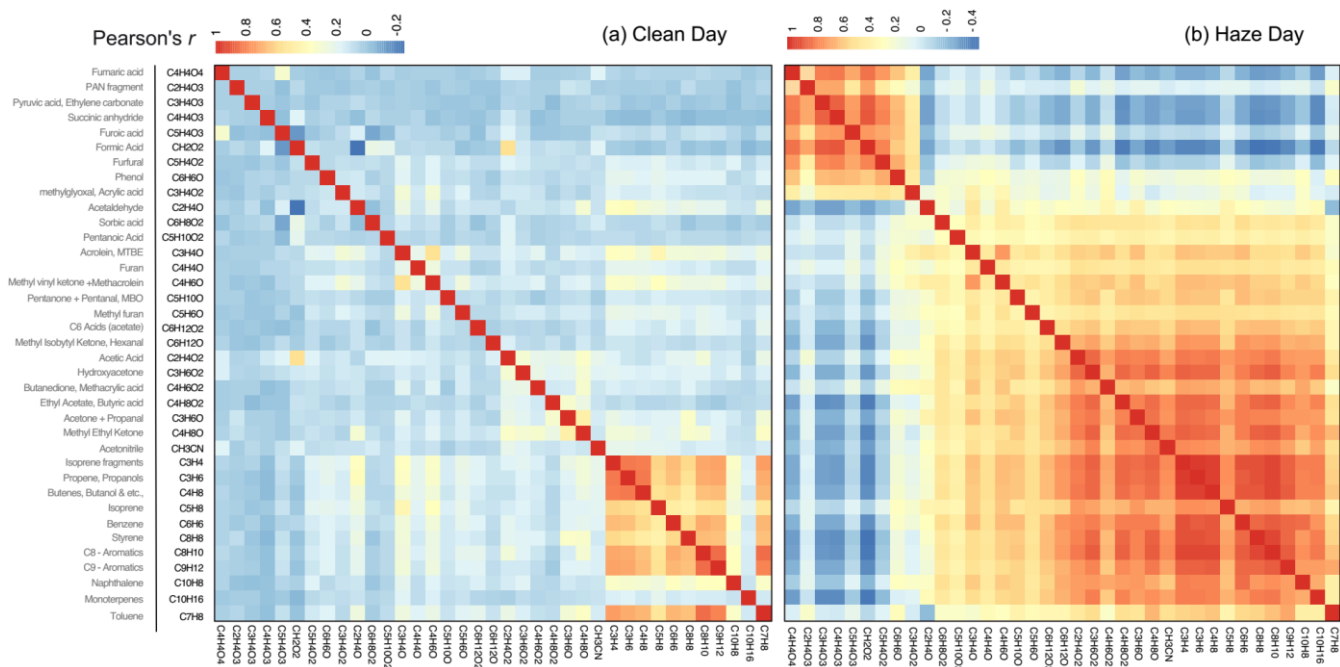

Figure 6. Correlation heatmaps for the concentrations of the main VOCs and OVOCs measured during (a) the clean day on 18 November 2018 and (b) the haze day on 14 November 2018.

Table 1. The CV values for the concentrations or mass fractions of air pollutants measured during the noon cycles from ~11:00 AM to ~12:30 PM for the clean day on 18 November 2018 and the haze day on 14 November 2018.

Air pollutants		CV for concentration		CV for mass fraction	
		Clean	Haze	Clean	Haze
NR-PM _{2.5}	Total NR-PM _{2.5}	0.75	0.12	n/a	n/a
