<sup>[2]</sup> Institute of Chemical Engineering Sciences, Foundation for Research and Technology – Hellas (FORTH/ICE-HT), Patras, Greece

## Abstract

PMCAMx-UF, a three-dimensional chemical transport model focusing on the simulation of the ultrafine particle size distribution and composition has been extended with the addition of reactions of chemical aging of semi-volatile anthropogenic organic vapors, the emissions and chemical aging by intermediate volatile organic compounds (IVOCs) and the production of extremely low volatility organic compounds (ELVOCs) by monoterpenes. The model is applied in Europe to quantify the effect of these processes on particle number concentrations. The model predictions are evaluated against both ground measurements collected during the PEGASOS 2012 summer campaign across many stations in Europe and airborne observations by a Zeppelin measuring above Po-Valley, Italy. PMCAMx-UF reproduces the ground level daily average concentrations of particles [with diameter](#) larger than 100 nm ( $N_{100}$ ) with normalized mean error (NME) of 45% and normalized mean bias (NMB) close to 10%. For the same simulation, PMCAMx-UF tends to overestimate the concentration of particles larger [with diameter](#) than 10 nm ( $N_{10}$ ) with a daily NMB of 23% and a daily NME of 63%. The model was able to reproduce more than 75% of the  $N_{10}$  and  $N_{100}$  airborne observations (Zeppelin) within a factor of 2.

~~According to the results of PMCAMx-UF predictions, showed that~~ The ELVOC production by monoterpenes ~~is predicted to leads~~ to surprisingly small changes of the average number concentrations over Europe. The total number concentration decreased due to the ELVOC formation by 0.2%, the  $N_{10}$  decreased ~~ds~~ by 1.1%, while  $N_{50}$  ([particles with diameter larger than 50 nm](#)) increased by 3% and  $N_{100}$  by 4% due to this new [secondary organic aerosol \(SOA\)](#) source. This small change is due to the nonlinearity of the system with increases predicted in some areas

31 and decreases in others, but also the cancelation of the effects of the various processes like  
32 accelerated growth and accelerated coagulation. Locally, the effects can be significant. For  
33 example, an increase in  $N_{100}$  by 20-50% is predicted over Scandinavia and significant increases  
34 (10-20%) over some parts of central Europe. The ELVOCs contributed on average around  $0.5 \mu\text{g}$   
35  $\text{m}^{-3}$  and accounted for 10-15% of the  $\text{PM}_{2.5}$  OA. The addition of IVOC emissions and their aging  
36 reactions led to surprising reduction of the total number of particles ( $N_{tot}$ ) and  $N_{10}$  by 10-15 and 5-  
37 10%, respectively, and to an increase of the concentration of  $N_{100}$  by 5-10%. These were due to  
38 the accelerated coagulation and reduced nucleation rates.

39

## 40 **1. Introduction**

41 Two major processes are responsible for the introduction of new particles in the  
42 atmosphere: direct emission from numerous sources and nucleation from low-volatility vapors.  
43 New particles formed by nucleation can either grow by condensation of vapors (e.g. sulfuric acid,  
44 ammonia, nitric acid, and organics) to larger sizes becoming cloud condensation nuclei (CCN) and  
45 thereby may ~~increase~~ the cloud droplet number concentration (CDNC) or affected by  
46 coagulation with pre-existing larger particles and be lost (Adams and Seinfeld, 2002). Globally,  
47 according to large-scale model simulations, atmospheric new particle formation (NPF) and  
48 subsequent particle growth represent the most significant source of atmospheric aerosol particles,  
49 at least in terms of their total number concentration (Kulmala et al., 2004; Makkonen et al., 2009;  
50 Merikanto et al., 2009; Pierce and Adams, 2009; Wang and Penner, 2009; Yu and Luo, 2009). An  
51 increase of the number concentration of particles that ~~can~~ may act as CCN results in higher CDNC  
52 and brighter clouds with longer lifetimes.

53 Globally, organic particulate matter makes up more than 50% of the sub-micrometer mass  
54 concentration of ambient aerosols in locations throughout the world (Kanakidou et al., 2005;  
55 Seinfeld and Pandis, 2006; Zhang et al., 2007). Nearly 70% of this material is thought to be  
56 secondary organic aerosol (SOA) formed from the oxidation of volatile organic compounds  
57 (VOCs) (Hallquist et al., 2009; Schulze et al., 2017). Many of the relevant precursor VOCs are  
58 biogenic in origin, such as monoterpenes ( $\text{C}_{10}\text{H}_{16}$ ) and isoprene ( $\text{C}_5\text{H}_8$ ).

59 Several recent field studies have shown that SOA in polluted areas cannot be explained by  
60 the simulation- of only the first generation of reactions of “traditional” SOA precursors: biogenic  
61 compounds (monoterpenes, sesquiterpenes, and isoprene) and anthropogenic compounds

62 (aromatics, olefins and large alkanes) (de Gouw et al., 2005; Volkamer et al., 2006; Kleinman et  
63 al., 2008; Docherty et al., 2008; Matsui et al., 2009; Dzepina et al., 2009). At the same time, it has  
64 become clear that organic vapors are responsible for most of the new particle growth in  
65 environments with low sulfur dioxide levels (Olenius et al., 2018; Yli-Juuti et al., 2020).

66 Traditional treatment of SOA formation considers only VOCs as the precursors and only  
67 semivolatile products (Odum et al., 1996). Robinson et al. (2007) suggested that intermediate  
68 volatile organic compounds (IVOCs) either emitted directly or resulting from the evaporation of  
69 particles may be an important and previously neglected pool of precursors for SOA formation. In  
70 addition, later generations of reactions of the products of VOCs, IVOCs and SVOCs can lead to  
71 products of even lower volatility and formation of SOA (Donahue et al., 2006). These chemical  
72 reactions can lead to continued SOA production after complete precursor consumption as products  
73 undergo further oxidation (Kroll et al., 2006; Ng et al., 2006).

74 Secondary extremely low volatile organic compounds (ELVOCs) have been detected both  
75 in the ambient atmosphere and laboratory studies (Donahue et al., 2011). These compounds  
76 promote new particle growth and CCN production in the atmosphere (Jokinen et al., 2015; Kirkby  
77 et al., 2016). ELVOCs can be produced rapidly in the gas phase during monoterpene oxidation  
78 (Ehn et al., 2014), and can enhance atmospheric new particle formation and growth (Jokinen et al.,  
79 2015). Due to their exceptionally low volatility, ELVOCs condense essentially irreversibly onto  
80 growing particles at a rate controlled by the Fuchs-adjusted particle surface area (Shrivastava et  
81 al., 2017). [The addition of the ELVOCs in PMCAMx-UFour model increased the effective  
82 biogenic SOA yields, becoming an additional source of SOA especially significant at low OA  
83 levels. At the same time, the addition of this extra material results in a change in the volatility  
84 distribution of the predicted SOA.](#)

85 Fanourgakis et al. (2019) evaluated 16 global chemistry transport models during a 4-year  
86 period and compared their prediction to the near-surface observed number concentration of aerosol  
87 particles across Europe and Japan. All models tended to underestimate the number concentrations  
88 for particles larger [with diameter](#) than 50 nm ( $N_{50}$ ). The normalized mean bias (NMB) was -51%  
89 and normalized mean error (NME) was 55% for all stations. Sengupta et al. (2021) used the  
90 GLOMAP (Global Model of Aerosol Processes; Spracklen et al., 2005) modal aerosol  
91 microphysics model (Mann et al., 2010) simulating the production of six surrogate SOA species  
92 from the oxidation of anthropogenic VOCs, monoterpenes, and isoprene. [It was assumed They](#)

93 ~~assumed~~ that ELVOCs derive only from biogenic sources and can nucleate to form new particles  
94 (Gordon et al., 2016). ~~In this study different values of the ELVOC yield were used and the~~  
95 ~~model# predictions were compared to observations of OA mass concentration as well as to the  $N_3$~~   
96 ~~(particles with diameter larger than 3 nm) and  $N_{50}$  number concentrations. A number of metrics~~  
97 ~~were used for model evaluation, but the analysis was based on the Taylor model skill score.~~  
98 Concentrations of ~~particles larger than 3 nm ( $N_3$ )~~ and ~~particles larger than 50 nm ( $N_{50}$ )~~ were  
99 consistently underestimated, while the best model performance (~~based on the Taylor model skill~~  
100 ~~score~~) was achieved when the ELVOC yield from precursor VOCs was around 13%. These studies  
101 suggest that the role of organics and especially ELVOCs on particle formation and growth is still  
102 not well understood.

103 In this study we extend the three-dimensional regional chemical transport model (CTM),  
104 PMCAMx-UF (Jung et al., 2010), with detailed aerosol microphysics (Gaydos et al., 2007; Karydis  
105 et al., 2007) that has been used and evaluated for simulations over the US and Europe (Fountoukis  
106 et al., 2012). ~~The number concentrations of particles with diameter larger than 10 nm ( $N_{10}$ ) and~~  
107 ~~100 nm ( $N_{100}$ ) were used for the analysis of the model predictions of as in Fountoukis et al. (2012),~~  
108 ~~whereas Gordon et al. (2016) have used relied on  $N_3$  and  $N_{50}$ . Different studies have used~~  
109 ~~different~~ ~~The cutoffs with  $N_3$  and  $N_{10}$  are being~~ connected to some extent, but usually there are ~~with~~  
110  ~~$N_{10}$  having more reliable measurements available in more sites for  $N_{10}$ . The same applies for the~~  
111  ~~$N_{50}$  and  $N_{100}$  pair, but the  $N_{100}$  is often closer to the CCN sizes at moderate cloud supersaturations.~~  
112 ~~Additionally, the  $N_{10}$  and  $N_{100}$  were chosen as the metrics in this study also for continuity, given~~  
113 ~~that they have been used in previous PMCAMx-UF evaluations.~~

114 Originally ~~PMCAMx-UF the model~~ assumed that growth of new particles was exclusively  
115 due to sulfuric acid and ammonia condensation while the semivolatile secondary organics  
116 condensed only on the accumulation mode thus contributing to the condensation and coagulation  
117 sinks. This initial model version was found to reproduce more than 70% of the hourly number  
118 concentrations of ~~particles larger than 10 nm ( $N_{10}$ )~~ within a factor of 2 (Fountoukis et al., 2012).  
119 However, the concentration of ~~particles larger than 100 nm ( $N_{100}$ ,~~ as proxy for the number of  
120 particles that can act as CCN) was systematically underpredicted. The growth rates were also  
121 underpredicted, with smaller errors in sites where the sulfate to organics mass ratio was high. These  
122 problems were caused mainly by insufficient organic vapor condensation (Fountoukis et al., 2012)  
123 on ultrafine particles. Patoulias et al. (2018) developed an extended version of PMCAMx-UF in

124 which the SOA components were modeled as semi-volatile first-generation products of the  
125 oxidation of VOCs. The model predictions were compared against size distribution measurements  
126 from 16 stations in Europe during a photochemically active period. Including SOA condensation  
127 on ultrafines in PMCAMx-UF improved its ability to reproduce the  $N_{10}$  and  $N_{100}$  concentration at  
128 ground level. The inclusion of SOA decreased the daily normalized mean bias (NMB) of  $N_{10}$  from  
129 85% to 75% and the daily NMB of  $N_{100}$  from 40% to 20%. However, the results suggested that  
130 there is a need for additional improvements.

131 The primary goal of this study is to examine the role of IVOCs and ELVOCs on particle  
132 number concentrations in Europe. ~~The base case~~ PMCAMx-UF is extended ~~once more~~ to simulate  
133 the multiple generations of IVOC gas-phase oxidation and the production of ELVOCs by  
134 monoterpenes. This extended version is used for the base case simulations in this study. The model  
135 predictions are compared with measurements from 26 sites during the intensive field campaign  
136 that took place in Europe, as part of the Pan-European-Gas-AeroSOI-climate-interaction Study  
137 (PEGASOS) project, from June 5 to July 8, 2012. The airborne data obtained by a Zeppelin  
138 measuring above Po-Valley during the same campaign are also used. An analysis of the Zeppelin  
139 measurement can be found ~~by in~~ Lampilahti et al. (2021). Additional simulations are performed  
140 neglecting certain processes (e.g., production of ELVOCs) to quantify their role in the model  
141 predictions.

142  
143  
144

## 145 2. Model description

146 PMCAMx-UF is a three-dimensional chemical transport model (CTM) that simulates the  
147 aerosol number size distribution in addition to the mass/composition size distribution (Jung et al.,  
148 2010; Fountoukis et al., 2012) and is described in detail in Patoulias et al. (2018). PMCAMx-UF  
149 is based on the framework of PMCAMx (Gaydos et al., 2007; Karydis et al., 2007), describing the  
150 processes of horizontal and vertical advection, emissions, horizontal and vertical dispersion, wet  
151 and dry deposition, aqueous and aerosol phase chemistry, as well as aerosol dynamics and  
152 thermodynamics.

153 For the simulation of aerosol microphysics, PMCAMx-UF uses the updated version of  
154 DMANx which simulates the processes of coagulation, condensation/evaporation and nucleation

155 (Patoulias et al., 2015) with the two-moment aerosol sectional (TOMAS) algorithm (Adams and  
156 Seinfeld, 2002; Jung et al., 2006). A key feature of TOMAS is its ability to track two independent  
157 moments of the aerosol size distribution for each size bin: the aerosol number and mass  
158 concentration.

159 The aerosol size distribution is discretized into 41 sections covering the diameter range from  
160 approximately 0.8 nm to 10  $\mu\text{m}$ . The lowest boundary is at  $3.75 \times 10^{-25}$  kg of dry aerosol mass per  
161 particle. Each successive boundary has twice the mass of the previous one. The particle  
162 components modeled include sulfate, ammonium, nitrate, sodium, chloride, crustal material,  
163 water, elemental carbon, primary organic aerosol (POA) and eight surrogate SOA components.

164 In this work, the nucleation rate is calculated using a scaled ternary parameterization based  
165 on the original expressions of Napari et al. (2002) with a scaling factor of  $10^{-6}$  following the  
166 suggestions of Fountoukis et al. (2012). The binary parameterization of Vehkamäki et al. (2002)  
167 is employed if the  $\text{NH}_3$  concentration is below a threshold value of 0.01 ppt.

168 Coagulation of particles in the atmosphere is an important sink of aerosol number but is  
169 also a mechanism by which freshly nucleated particles grow to larger sizes. Following Adams and  
170 Seinfeld (2002), TOMAS assumes that the aerosol particles coagulate via Brownian diffusion and  
171 that the effects of coagulation from gravitational settling and turbulence on coagulation a-are  
172 negligible. The calculation of the coagulation coefficients is based on the wet diameters of the  
173 particles. These wet diameters are calculated following the approach of Gaydos et al. (2005). For  
174 small particles (<100 nm), we use the expression of Dahneke et al. (1983) to correct for non-  
175 continuum effects. The coagulation algorithm uses an adaptive time step. The time step is limited  
176 so that the aerosol number or mass concentration in any size category does not increase by more  
177 than an order of magnitude or decrease by more than 25% in each step.

178 The extended SAPRC (Statewide Air Pollution Research Center) chemical mechanism  
179 (Carter, 2000; Environ, 2003), which includes 219 reactions of 64 gases and 18 free radicals, is  
180 used for the gas phase chemistry mechanism in PMCAMx-UF. The SAPRC version used for this  
181 work includes five lumped alkanes (ALK1-5), two lumped olefins (OLE1-2), two lumped  
182 aromatics (ARO1-2), isoprene (ISOP), a lumped monoterpene (TERP) and a lumped sesquiterpene  
183 species (SESQ).

184 Condensation of gas-phase species to existing aerosol particles is an important source of  
185 aerosol mass and a means by which small particles grow to CCN sizes. Sulfuric acid is assumed

186 to be in pseudo-steady state in ~~DMAN~~PMCAMx-UF. This pseudo steady-state approximation  
187 (PSSA) for sulfuric acid proposed by Pierce and Adams (2009) increases the computational speed  
188 with a small loss in accuracy. Jung et al. (2010) evaluated the performance of PSSA for sulfuric  
189 acid in DMAN against a 4th order Runge-Kutta algorithm and showed that PSSA was accurate  
190 and computationally efficient. Condensation of ammonia ~~wasis~~ simulated following the approach  
191 described by Jung et al. (2006). Ammonia condensation on the ultrafine particles ends when sulfate  
192 is fully neutralized to ammonium sulfate.

193 ~~N~~Semi-volatile nitric acid and hydrochloric acids in DMAN partition to particles (as nitrate  
194 and chloride, respectively) in the accumulation mode range in PMCAMx-UF assuming that the  
195 system is always in equilibrium. The amounts of nitric acid and hydrochloric acid ~~The PMCAMx-~~  
196 ~~UF uses the bulk equilibrium approach (the most computationally efficient approach) to simulate~~  
197 ~~of inorganic aerosol growth. At each time step the amount of nitric acid and hydrochloric acid~~  
198 ~~transferred at each time step between the gas and aerosol phases is~~are determined by applying the  
199 aerosol thermodynamic ~~equilibrium~~-model ISORROPIA (Nenes et al., 1998). This amount is then  
200 distributed over the aerosol size sections by using weighting factors ~~for each size section~~ based on  
201 their effective surface area (Pandis et al., 1993).

202 ~~The PMCAMx-UF model~~ assumes that organics and inorganics are in different phases, ~~but~~  
203 ~~in the same particles. Therefore, the condensation of one affects the size distribution of the particles~~  
204 ~~and therefore the condensation rate of the other. The inorganic aerosol thermodynamics including~~  
205 ~~the sulfate/bisulfate split and the water uptake by all inorganic aerosol components are simulated~~  
206 ~~by ISORROPIA. The water content of the organic aerosol is neglected in this version of~~  
207 ~~PMCAMx-UF and the aerosol water is dominated by the inorganic aerosol components. Additional~~  
208 ~~information can be found in previous publications describing the evolution of PMCAMx-UF (Jung~~  
209 ~~et al. 2010; Fountoukis et al. 2012; Patoulias et al. 2018).~~

## 211 2.1 Secondary organic aerosol formation

212 Gas-phase oxidation of ~~volatile organic compounds (VOCs)~~ produces semi-volatile and  
213 low-volatility products that can then condense to the particle phase. The volatility-basis set (VBS)  
214 framework used in PMCAMx-UF (Donahue et al., 2006) describes the volatility distribution of  
215 the OA compounds. SOA is formed from anthropogenic (aSOA) and biogenic (bSOA) precursors.  
216 Each of these types is simulated with 5 volatility bins with saturation concentrations of  $10^{-5}$ , 1, 10,

217 100 and 1000  $\mu\text{g m}^{-3}$ . The  $10^{-5}$   $\mu\text{g m}^{-3}$  bin was added in this work to describe the ELVOCs. We  
218 assumed an average molecular weight of 200  $\text{g mol}^{-1}$  for SOA, and an effective enthalpy of  
219 vaporization of 30  $\text{kJ mol}^{-1}$  (Pathak et al., 2007; Stanier et al., 2007). The SOA yields used in this  
220 version of PMCAMx-UF for the semi-volatile components are the  $\text{NO}_x$ -dependent stoichiometric  
221 yields of Murphy et al. (2009).

222 Chemical reactions that change the volatility of the organics in the gas phase will change  
223 the OA mass by influencing their partitioning. In PMCAMx-UF all secondary species are treated  
224 as chemically reactive. Further gas-phase oxidation of OA vapors (chemical aging) is modeled  
225 using a second-order reaction with hydroxyl radicals and a rate constant of  $1 \times 10^{-11} \text{cm}^3 \text{molecule}^{-1}$   
226  $\text{s}^{-1}$  (Atkinson and Arey, 2003). Each reaction is assumed to reduce the volatility of the vapor  
227 material by one order of magnitude (i.e., shifting material from a  $C^*$  of 100 to 10  $\mu\text{g m}^{-3}$ ), with a  
228 small increase in mass (7.5%) to account for the added oxygen (Lane et al., 2008; Shrivastava et  
229 al., 2008). IVOCs were not included in the original emission inventory and therefore have been  
230 added to the emissions. The IVOCs emission rate is scaled/estimated based on the non-volatile  
231 POA emissions included in the inventory and . Their total emission rate is assumed to be 1.5 times  
232 the non-volatile POA emissions. Intermediate volatility organic compounds (IVOCs), are  
233 distributed in the  $10^3$ ,  $10^4$ ,  $10^5$ , and  $10^6$   $\mu\text{g m}^{-3}$  saturation concentration bins and their. ~~The~~  
234 ~~emission rates of the IVOCs~~ are assumed to be equal to 0.3, 0.4, 0.5 and 0.8 times the original non-  
235 volatile POA emission rate, for the  $10^3$ - $10^6$  bins respectively (Robinson et. 2007).

236 ELVOCs were assumed to be produced by the oxidation of monoterpenes with a molar  
237 yield of 5%. For comparison, ELVOCs yields for the  $\alpha$ -pinene ozonolysis in Jokinen et al. (2015)  
238 were  $3.4 \pm 1.7\%$ , by Ehn et al. (2014) of  $7 \pm 4\%$  and  $4.5 \pm 3.8\%$  in Rissanen et al. (2014). An  
239 average molecular weight of 200  $\text{g mol}^{-1}$  for ELVOCs was assumed in this work.

240 The partitioning of OA between the gas and particulate phases is simulated dynamically in  
241 PMCAMx-UF without assuming equilibrium (Patoulias et al., 2015). The driving force for  
242 condensation of a vapor to an aerosol particle is the difference between its ambient vapor partial  
243 pressure and the equilibrium vapor pressure over the particles, with the latter including the Kelvin  
244 effect which is due to the curvature of the particles. The Kelvin effect is larger for the smaller  
245 particles and acts as a barrier for the condensation of organic vapors on these particles. In this  
246 simulation a surface tension of  $\sigma=0.025 \text{N m}^{-1}$  is assumed for all SOA components (Pierce et al.,  
247 2011; Patoulias et al. 2015).

248 Three different chemical ~~aging~~ schemes are used in this work (Table S1). The first scheme  
249 (case 1 or base case) includes (i) the aging of SOA components from anthropogenic sources, using  
250 a rate constant  $k$  (298 K) =  $10 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> (anthropogenic SOA aging), (ii) the aging  
251 of IVOCs using a rate constant  $k$  (298 K) =  $40 \times 10^{-12}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, (iii) ~~production~~ of  
252 ELVOCs with saturation concentration of  $10^{-5}$  μg m<sup>-3</sup> from the oxidation of monoterpenes with a  
253 yield of 5%. The aSOA aging rate constant is based on OH oxidation of the products of aromatic  
254 VOCs oxidation (Atkinson 2000; 2003). No biogenic SOA aging was simulated in this case, an  
255 assumption based on laboratory studies (Presto et al., 2006; Ng et al., 2006) and the results of Lane  
256 et al. (2008). In the second simulation (case 2), the ELVOC yield was set to zero thus neglecting  
257 their formation. The rest of the parameters were the same as in the base case. Finally, in the third  
258 simulation the emissions of IVOCs and the chemical aging reactions of all VOCs were neglected  
259 while the production of the ELVOCs was simulated similarly to the base case.

260

## 261 2.2 Model application and measurements

262 The PMCAMx-UF modeling domain in this application covers a  $5400 \times 5832$  km<sup>2</sup> region  
263 in Europe, with a  $36 \times 36$  km grid resolution and 14 vertical layers extending up to approximately  
264 7.2 km. The modeling period covers 34 days, from June 5 to July 8, 2012 corresponding to the  
265 PEGASOS 2012 intensive period. PMCAMx-UF was set to perform simulations on a rotated polar  
266 stereographic map projection. The first two days of each simulation were excluded from the  
267 analysis to minimize the effect of the initial conditions on the results. For the boundary conditions,  
268 constant and relatively low values have been used (Table S12) so that the predicted particle number  
269 concentrations over central Europe are determined for all practical purposes by the emissions and  
270 corresponding processes simulated by the model. [The boundary conditions are identical to those  
271 used in Patoulias et al. \(2018\).](#) The effect of these boundary conditions on the predicted number  
272 concentrations are discussed in Patoulias et al. (2018).

273 Meteorological inputs to PMCAMx-UF include horizontal wind components, vertical  
274 diffusivity, temperature, pressure, water vapor, clouds and rainfall. The Weather Research and  
275 Forecasting (WRF) model (Skamarock et al., 2005) was used to generate the above inputs. WRF  
276 was driven by geographical and dynamic meteorological data generated by the Global Forecast  
277 System ~~(GFSv15) of NOAA/NCEP~~ [the \(National Oceanic and Atmospheric Administration/  
278 National Centers for Environmental Prediction\)](#). Each layer of PMCAMx-UF was aligned with the

279 layers used in WRF. The WRF simulation was periodically re-initialized every 3 days with  
280 observed conditions to ensure accuracy in the corresponding fields used as inputs in PMCAMx-  
281 UF. The measurements were pre-processed by the WPS (WRF Preprocessing System) package,  
282 which provides each atmospheric and static field with fidelity appropriate to the chosen grid  
283 resolution of the model. The performance of WRF for Europe against observed meteorological  
284 variables has been the topic of several recent studies (Jimenez-Guerrero et al., 2008; de Meij et al.,  
285 2009; Im et al., 2010; Argueso et al., 2011; Garcia-Diez et al., 2012) demonstrating good  
286 performance.

287         The particle emissions were based on the pan-European anthropogenic particle number  
288 emission inventory (Denier van der Gon et al., 2009; Kulmala et al., 2011) and the carbonaceous  
289 aerosol inventory (Kulmala et al., 2011) developed during the EUCAARI (European Integrated  
290 project on Aerosol, Cloud, Climate, and Air Quality Interactions) project. The resulting  
291 number/mass inventories includes both number emissions and consistent size-resolved  
292 composition for particles over the size range of approximately 10 nm to 10  $\mu$ m. Hourly gridded  
293 anthropogenic and biogenic emissions included both gases and primary particulate matter. The  
294 natural emissions include both particulate matter and gases and combine three different data sets:  
295 emissions from ecosystems based on the Model of Emissions of Gases and Aerosols from Nature  
296 (MEGAN; Guenther et al., 2006), marine emissions based on the model of O'Dowd et al. (2008)  
297 as sea surface covers a considerable area of the domain, and wildfire emissions (Sofiev et al.,  
298 2008a, b). MEGAN uses as inputs the plant functional type, the leaf area index, various chemical  
299 species emission factors and weather data provided by the WRF. Wind speed fields from WRF  
300 and chlorophyll-a concentrations were used as inputs of the marine aerosol model. VOCs were  
301 speciated based on the approach proposed by Visschedijk et al. (2007). Anthropogenic gas  
302 emissions included land emissions from the GEMS (global and regional Earth-system monitoring  
303 using satellite and in-situ data) dataset (Visschedijk et al., 2007). The international shipping,  
304 industrial, domestic, agricultural and traffic aerosol emission sources were included in the  
305 anthropogenic inventory (Denier van der Gon et al., 2009; Kulmala et al., 2011).

306         The model results were compared against measurements in 26 ground sites, which are  
307 available in the European Supersites for Atmospheric Aerosol Research (EUSAAR), and EBAS  
308 databases (<https://ebas.nilu.no>) and the Aerosols, Clouds and Trace gases Research Infrastructure  
309 (ACTRIS) (<https://actris.nilu.no>). Particle size distribution measurements at all sites were made

310 using either a Differential Mobility Particle Sizer (DMPS) or a Scanning Mobility Particle Sizer  
311 (SMPS). Information about all stations can be found in Table S23.

312 An intensive field campaign took place in Europe, as part of the Pan-European-Gas-  
313 AeroSOI-climate-interaction Study (PEGASOS) project, from June 5 to July 8, 2012.  
314 Measurements of aerosol mass concentration PM<sub>1</sub> (particulate matter particles of diameter less  
315 than 1 micrometer) from the PEGASOS project are also available for the same period for Patras  
316 (Greece), Finokalia (Greece), San Pietro Capofiume (Italy) and Bologna (Italy) (Table S3a4) and  
317 filter PM<sub>2.5</sub> (particulate matter particles of diameter less than 2.5 micrometer) measurements from  
318 6 additional stations in Europe (Table S3b5). The organic aerosol mass concentration was  
319 estimated from the organic carbon measurements assuming an ~~For the calculation of organic mass~~  
320 ~~from filter, we used from measurements an average~~ organic mass to ~~organic~~ carbon ratio ~~value~~  
321 equal to 1.8 (Kostenidou et al., 2015).

322 The measurement of organic carbon and therefore the estimated OA using filters is  
323 characterized by two main artifacts: a positive one involving adsorption of organic vapors on the  
324 quartz filters used for the sampling and a negative one related to the evaporation of some of the  
325 semi-volatile material (Turpin et al., 2000; Mikuška et al., 2011). There is a rich literature on the  
326 magnitude of these artifacts and on ways to minimize them or correct for them (involving denuders  
327 for removal of organic vapors and after-filters). In this work, we use the reported measurements  
328 for the model evaluation keeping in mind their uncertainty.

329 The airborne measurements acquired by the PEGASOS Zeppelin were acquired during the  
330 simulation period over the Po Valley. The Po Valley region is situated between the Alps in the  
331 north and the Apennines Mountains in the south–southwest. The mountains surround the valley on  
332 three sides and high levels of pollutants are often observed in the region due to the industrial,  
333 agricultural, and other anthropogenic emissions. In addition, emissions from ship traffic on the  
334 Adriatic Sea (Hamed et al., 2007) and long-range transport from central-eastern Europe also  
335 contribute pollutants to the region (Sogacheva et al., 2007). A SMPS was used to measure the  
336 number size distribution of particles in the size range of 10 to 430 nm. Details of the relevant  
337 PEGASOS Zeppelin measurements can be found in Lampilahti et al. (2021).

338  
339  
340

### 341 3. Results

#### 342 3.1 Base case

343 The average predicted ground level average number concentrations for the total number of  
344 particles ( $N_{tot}$ ) and for particles with diameters above 10 nm ( $N_{10}$ ), 50 nm ( $N_{50}$ ) and 100 nm ( $N_{100}$ ),  
345 during June 5 to July 8, 2012 are shown in Figure 1. The  $N_{50}$  and  $N_{100}$  concentrations are often  
346 used as proxies for- CCN number concentrations (Fountoukis et al., 2012). On a domain average  
347 basis, the model predicted for the ground level  $4780 \text{ cm}^{-3}$  for  $N_{tot}$ ,  $3630 \text{ cm}^{-3}$  for  $N_{10}$ ,  $1990 \text{ cm}^{-3}$   
348 for  $N_{50}$ , and  $820 \text{ cm}^{-3}$  for  $N_{100}$  during the simulated period. The highest  $N_{tot}$  average concentrations  
349 (more than  $15000 \text{ cm}^{-3}$ ) were predicted over Bulgaria, southern Romania, Turkey, Poland,  
350 Holland, Portugal, Northern Spain, Eastern UK and Russia. On the other hand, the highest  $N_{50}$  and  
351  $N_{100}$  are predicted over the Mediterranean, mainly in areas near Southern Spain, Southern Italy,  
352 and the Balkans. The  $N_{tot}$  and  $N_{10}$  are high in areas of frequent nucleation events and areas with  
353 high particle number emissions, whereas the  $N_{50}$  and  $N_{100}$  levels are affected significantly by  
354 secondary particulate matter production. The high photochemical activity over the Eastern  
355 Mediterranean leads to the corresponding high levels of  $N_{50}$  and  $N_{100}$  during this period.

356

#### 357 3.2 Evaluation of PMCAMx-UF predictions

##### 358 3.2.1 Comparison of PMCAMx-UF predictions to ground aerosol number observations

359 The prediction skill metrics of PMCAMx-UF, for the daily average ground measurements  
360 from the 26 stations, are summarized in Tables [24](#) and [32](#) for both the base case and the case in  
361 which the ELVOCs are neglected.

362 For the base case simulation, the model has a tendency to overestimate the  $N_{10}$  levels. The  
363 normalized mean bias (NMB) for the daily average concentrations is 23% and the normalized  
364 mean error (NME) 63%. The  $N_{10}$  was overpredicted in 18 sites, underpredicted in 7 and there was  
365 [practically zero bias \(less than 0.1%\) in the last station](#)~~no bias in one~~. The NMB in 8 sites (Prague-  
366 Suchdol, Ispra, Melpitz, Patras, ~~—~~K-Puszt, Hohen-peissenberg, Hyytiala and San Pietro  
367 Capofiume) was less than  $\pm 15\%$ , and for another 8 stations ~~between~~  $\pm 15\%$  and  $\pm 40\%$  (Annaberg-  
368 Buchholz, Cabauw, Dresden Nord and Winckelmannstrasse, Finokalia, Giordan Lighthouse,  
369 Kosetice, Montseny and Varrio). The highest discrepancies with the measurements of  $N_{10}$  were  
370 found in Aspvreten, Birkness II, Usti n.L.-mesto, Vavihill, Vielsalm, Zugspitze-Schneefernerhaus,  
371 Waldhof, Costa Navarino, and Thesssaloniki with NMB higher than  $\pm 40\%$ .

372 The model performed better for  $N_{100}$ . There was little bias in the corresponding predictions  
373 on average (the NMB was -10%) and the NME was 45%. The NMB for 10 sites (Cabauw, Giordan  
374 Lighthouse, Hyytiala, Kosetice, Melpitz, Patras, Prague-Suchdol, Vielsalm, Waldhof and  
375 Zugspitze) was less than  $\pm 15\%$  and for another 12 (Annaberg-Buchholz, Birkenes II, Dresden  
376 Nord and Winckelmannstrasse, Finokalia, Hohenpeissenberg, Ispra, K-Pusztza, Montseny, Costa  
377 Navarino, San Pietro Capofiume, Usti n.L-mesto. and Vavihill) between  $\pm 15\%$  and  $\pm 40\%$  (Table  
378 [32](#)). The absolute NMB for  $N_{100}$  exceeded 40% only in Aspvreten, Varrio and Thessaloniki.

### 379 **3.3.2 Evaluation of aerosol composition predictions**

380 The PMCAMx-UF predictions can be evaluated during that period using available  $PM_{10}$   
381 measurements from Aerosol Mass Spectrometers at four stations (Bologna and San Pietro  
382 Capofiume, in Italy and Finokalia and Patras, in Greece) that were part of the PEGASOS  
383 campaign.

384 In Italy and Greece, the model reproduces the observations of the  $PM_{10}$  concentrations of  
385 the major inorganic aerosol components (sulfate, ammonium, nitrate) reasonably well (Table [43](#)).  
386 The model tends to underpredict the organic aerosol concentrations in Patras and Bologna, while  
387 it overpredicts the OA in Finokalia and San Pietro Capofiume (Table [54](#)). The OA NMB is -2%  
388 and the NME is 38%, with the Finokalia site presenting the higher NMB value (50%) and San  
389 Pietro Capofiume, Bologna the lower ( $\pm 20\%$ ) (Table [54](#)).

390 For the rest of Europe,  $PM_{2.5}$  filter measurements have been used, available in the European  
391 Supersites for Atmospheric Aerosol Research (EUSAAR) and EBAS databases  
392 (<http://ebas.nilu.no/>) for stations that had available data for more than 15 days during the simulated  
393 period (6 additional stations in Europe: Payerne, Melpitz, Montseny, Ispra, Diabla Gora, and  
394 Iskrba; Table [65](#)). For the calculation of OA mass concentration, we assumed OA:OC=1.8  
395 (Kostenidou et al., 2015). For these sites, the model has a tendency towards overestimating the  
396  $PM_{2.5}$  OA concentration for 4 out of 6 stations, presenting an average NMB of 20% and NME of  
397 62% (Table [65](#)).

### 398 **3.3.3 Comparison of PMCAMx-UF predictions to Zeppelin measurements**

399 One of the challenges of the PMCAMx-UF evaluation using airborne measurements is that  
400 the model predictions are available every 15 min while the corresponding measurements by the  
401 Zeppelin were taken every 3 min in different heights. For comparison purposes, the model output

402 was interpolated to the times of the Zeppelin measurement periods. PMCAMx-UF reproduced  
403 more than 75% of the 2000 3-min  $N_{10}$  and  $N_{100}$  measurements by the Zeppelin with a factor of 2  
404 (Figure S1). The vertical profiles shown in Fig.2, are averages of different flights that collected  
405 data in different days and different altitudes each time. The number of samples at different altitudes  
406 changed for each flight creating additional variability in the measured profiles.

407 To facilitate the comparison between measurements and predictions the corresponding  
408 average profiles (matched in space and time) were calculated using 80 m altitude bins for all the  
409 PEGASOS flights. PMCAMx-UF reproduced on average the  $N_{10}$  measurements over Po Valley at  
410 the lower 160 m and above 400 m, but underestimated the higher  $N_{10}$  levels measured in the  
411 residual layer at heights between 160-400 m at several of the flights that started several hours  
412 before sunrise (Fig. 2a). The average measured  $N_{10}$  at all heights was  $6,000 \text{ cm}^{-3}$ , while the  
413 predicted concentration was equal to  $4,700 \text{ cm}^{-3}$ .

414 PMCAMx-UF reproduced well the  $N_{100}$  concentration at all heights (Fig 2b). The model  
415 also reproduced 80% of the 3-min  $N_{100}$  Zeppelin measurements within a factor of 2. The measured  
416 average  $N_{100}$  at all heights was  $1,500 \text{ cm}^{-3}$  and the average predicted by PMCAMx-UF was  $1,800$   
417  $\text{cm}^{-3}$ . The ability of the revised model to reproduce reasonably well the high-time resolution (3-  
418 minute) Zeppelin measurements at multiple altitudes and locations is encouraging.

419 The predictions of PMCAMx-UF for the aerosol mass concentration were compared to the  
420 Zeppelin PM<sub>1</sub> composition measurements obtained by an AMS (each 3 minutes, 9 flights; ~1300  
421 points-data points). The average vertical profiles of organics, sulfate, ammonium, and nitrate are  
422 shown in Fig. S2. Overall, the model performance aloft was quite similar with that at the ground  
423 level. For example, for the 9 Zeppelin flights the OA normalized mean bias was -4% and the  
424 normalized mean error equal to 40% (Table S4). The measured and the predicted OA mean values  
425 are close to each other (4.6 and  $4.4 \mu\text{g m}^{-3}$ , respectively).

426

### 427 **3.2 Effect of ELVOC production on particle number and OA concentrations**

428 An additional simulation was performed neglecting the production of ELVOCs from  
429 terpenes (case 2). The addition of ELVOCs, increased the PM<sub>2.5</sub> OA mass by approximately as  
430 much as  $0.5 \mu\text{g m}^{-3}$  in Central/Eastern Europe and Russia, accounting for approximately 10-15%  
431 of the OA (Fig. 3). In these areas a combination of high terpene emissions and high photochemical  
432 reaction rates existed during the simulated period. The highest relative predicted increase of OA

433 was 15-25% in northern Europe. In central Europe the ELVOC formation increased average OA  
434 by approximately 10%.

435 The average fractional increase of  $N_x$ , due to the production of ELVOCs is calculated as:

$$436 \quad f_{N_x} = \frac{N_x(\text{with ELVOCs}) - N_x(\text{without ELVOCs})}{N_x(\text{without ELVOCs})} \quad (1)$$

437 where,  $x$ , is 10, 50, 100 nm or zero (total number). Rather surprisingly, the average fractional  
438 change for all number concentrations ( $N_{\text{tot}}$ ,  $N_{10}$ ,  $N_{50}$  and  $N_{100}$ ,) is small ranging between 1% and -  
439 4% (Fig. 4) ( $N_{\text{tot}}$ : -8 cm<sup>-3</sup> or -0.14%,  $N_{10}$ : 40 cm<sup>-3</sup> or -1.14%,  $N_{50}$ : 60 cm<sup>-3</sup> or 3 %,  $N_{100}$ : 35 cm<sup>-3</sup> or  
440 4%). One reason for the small average change is that both increases and decreases are predicted  
441 for different areas in Europe. These mixed results are due to the fact that the ELVOC condensation  
442 accelerates the growth of new and preexisting particles to larger sizes, but at the same time  
443 accelerates their losses due to the increase of the coagulation sink and decreases the nucleation  
444 rate due to the increase of the condensation sink.

445 The formation of ELVOCs resulted in a predicted decrease of  $N_{\text{tot}}$  by 20% (300-600 cm<sup>-3</sup>)  
446 in parts of the Nordic countries and by 5% in central Europe (Fig. 4). The decreases are predicted  
447 for most Europe with the exception of a few areas in which increases are predicted (northern  
448 Iberian Peninsula, parts of France, areas in the Balkans with high sulfur dioxide levels, etc.) (Fig.  
449 5). The predicted  $N_{10}$  increased by 5-15% (150-400 cm<sup>-3</sup>) over Finland, northwestern Russia,  
450 France, Ireland and northern Portugal. At the same time there were small decreases of a few percent  
451 over several areas in Europe especially in the south and in the east as well over the Baltic Sea.  $N_{50}$   
452 increased over almost of Europe by 50 to 300 cm<sup>-3</sup>. This  $N_{50}$  increase corresponds to 20-40% over  
453 Scandinavia and northwestern Russia, and 10% for central Europe. Finally, the ELVOCs caused  
454 an increase in  $N_{100}$  of 20-50% over Scandinavia and 10-20% increases over central Europe. The  
455 absolute corresponding  $N_{100}$  changes in these areas are 100-200 cm<sup>-3</sup>.

456 The corresponding changes of the number concentrations for particles with diameters  
457 between 1 and 10 nm ( $N_{1-10}$ ), 10 and 50 nm ( $N_{10-50}$ ) and (iii) 50 and 100 nm ( $N_{50-100}$ ) are  
458 summarized in Fig. S32. These figures illustrate the complex effect of the ELVOCs on different  
459 parts of the aerosol number distribution. Decreases in the concentrations of the 1-10 nm particles  
460 (decreasing nucleation rate due to increased condensation sink, increasing coagulation with larger  
461 particles), increases in the concentrations of the particles with diameter larger than 100 nm (due to  
462 accelerated growth of the sub-100 nm particles to larger sizes) and both increases and decreases in  
463 the 10-50 nm size range depending on the magnitude of the different competing processes in each

464 area. The effect of the ELVOCs in this PMCAMx simulation is clearly a lot more complex than a  
465 uniform increase of particle number concentrations.

466 Figure S4 shows the spatial variability of the fractional change in the number  
467 concentration of  $N_{1-10}$  (reflecting nucleation rates); up to 60%), sulfuric acid concentration (30%),  
468 condensational sink (CS) and coagulation sink due to the ELVOCs is depicted in Figure S4. This  
469 figure supports quantitatively that in areas such as the Scandinavian Peninsula the production of  
470 ELVOCs is predicted to lead to a 20-30% average increase of the coagulation and condensational  
471 sinks and a corresponding decrease of nucleation rates and sulfuric acid levels and  $N_{1-10}$  decrease.  
472 ; and coagulation/condensational sinks increase when ELVOCs are added to the model. Similar  
473 changes are predicted for several other areas (e.g., Central Europe) but are less. These changes are  
474 especially pronounced in the Scandinavian Peninsula.

475 The results in the Hyytiälä station in Finland were examined in more detail because the  
476 predicted number concentrations in Finland are quite sensitive, according to PMCAMx-UF, to the  
477 addition of the ELVOCs. The predicted  $N_3$ ,  $N_{10}$ ,  $N_{50}$  and  $N_{100}$  concentrations for the base case are  
478 in reasonable agreement with the field measurements in this area (Figure S53), with a tendency of  
479 the model to overpredict the  $N_3$  levels during a few nucleation events. For all concentrations the  
480 simulation with the ELVOCs (base case) reproduces the measurements better than the simulation  
481 in which they are neglected. The condensation sink (CS) for Hyytiälä increases by a few percent  
482 due to the additional mass of the ELVOCs (Figure S53). The average measured and predicted  
483 number size distributions in Hyytiälä site (Finland) are shown in Figure S64. The addition of the  
484 ELVOCs leads to increased levels in the part of the size distribution above 50 nm. A decrease of  
485 the concentration of particles with diameter below 7 nm is predicted due to the addition of the  
486 ELVOCs because of both increased coagulation losses but also lower nucleation rates. The  
487 difference in the predictions of the two simulations (with and without ELVOCs) in this Hyytiälä  
488 site is are modest. The discrepancy between model predictions and measurements is due to both  
489 the weaknesses of the measurements (particles smaller than 3 nm were not measured) and a  
490 tendency of the model to overpredict nucleation event intensity in this area.

491 The ELVOC addition played a minor role on the overall performance of PMCAMx-UF. The  
492 NMB for  $N_{10}$  decreased (in absolute terms) by 1%, it increased by 5% for  $N_{100}$  due to the addition  
493 of the ELVOCs in the simulation (Table 2-31-2). The addition of the ELVOCs affects mainly the  
494 PMCAMx-UF predictions in northern Europe and especially Finland, where the predictions of

495  $N_{100}$  significantly improve. In Hyytiala site the NMB decreases from -34% to -14% and in Varrio  
496 drops from -72% to -49% (Table 3). The corresponding normalized mean errors changed by 1-2%.  
497 These small changes in the performance metrics are consistent with the small overall changes  
498 caused by the ELVOC addition.

499 The small change in the OA mass concentration due to the addition of the ELVOCs has a  
500 modest impact on the performance of PMCAMx-UF for OA (Table S56 and S67). For example,  
501 the  $PM_1$  OA bias improves from -6% to 2% while the  $PM_{2.5}$  OA bias increases from 15% to 20%.  
502 The changes in normalized error are 1% or less.

503

### 504 3.3 Effect of IVOCs on particle number concentrations

505 The emissions of IVOCs ( $C^* \geq 10^{-3} \mu\text{g m}^{-3}$ ) were set to zero in a sensitivity test (Case 3) to  
506 quantify their effect on the predicted particle number concentration and size distribution. The  
507 SOA formed by the IVOCs (SOA-iv) exceeds  $1 \mu\text{g m}^{-3}$  in southern Europe, over the Mediterranean  
508 Sea, but also in large areas over central and eastern Europe (Fig. 6). The high SOA-iv levels over  
509 the Mediterranean are due to the oxidation of IVOCs emitted from large wildfires that occurred  
510 during the simulation period. The corresponding SOA-iv is 10-25% of the total OA over  
511 continental Europe and even higher (about 60%) over parts of the marine atmosphere.

512 The average fractional increase of  $N_x$ , due to emission and aging of IVOCs is calculated  
513 as:

$$514 f_{N_x} = \frac{N_x(\text{with IVOCs}) - N_x(\text{without IVOCs})}{N_x(\text{without IVOCs})} \quad (2)$$

515 where,  $x$ , is 10, 50, 100 nm or zero (total number).

516 According to PMCAMx-UF the addition of the emissions of IVOCs and their aging  
517 reactions lead to a reduction of  $N_{\text{tot}}$  by 5-10% and  $N_{10}$  by 5% (Fig. 7) for continental Europe. On  
518 the other hand, this addition of IVOCs leads to an increase of  $N_{50}$  by 5% and  $N_{100}$  by 5-10% mainly  
519 in central Europe and the Mediterranean Sea (Fig. 7). The corresponding changes of the number  
520 concentrations for the various size ranges  $N_{1-10}$ ,  $N_{10-50}$  and  $N_{50-100}$  are summarized in Fig. 8. The  
521 predicted  $N_{1-10}$  decreases approximately 15-20% for most of Europe except for the Scandinavian  
522 peninsula due to the IVOCs.  $N_{10-50}$  decreases 10-15% mainly in southern Europe and  $N_{50-100}$   
523 changes less than  $\pm 5\%$  or  $\pm 100 \text{ cm}^{-3}$  in the simulated domain.

524 The atmospheric oxidation of the emitted IVOCs produces semi-volatile organic  
525 compounds, which condense preferentially on particles in the accumulation mode and not so much

526 on the smallest particles due to the Kelvin effect. This results in an increase of both the  
527 condensation and coagulation sinks, which then lead to a decrease of the nucleation rate but also  
528 on the coagulation rate of the smaller with the larger particles.

529 The effect of the addition of the IVOCs on the performance of PMCAM<sub>x</sub>-UF is modest and  
530 mixed. The NMB for  $N_{10}$  increased by 4% (from 23% to 27%) and decreased by 5% for  $N_{100}$  (from  
531 10% to 5%) (Table S75). The corresponding NME for both  $N_{10}$  and  $N_{100}$  changed slightly  
532 (approximately 1%). The modest overall changes on the number distribution of the ultrafine  
533 particles caused by the addition of IVOCs and the corresponding aging reactions are consistent  
534 with the small changes in the PMCAM<sub>x</sub>-UF performance metrics.

535 The addition of the IVOCs and the resulting SOA-iv from their oxidation also had mixed  
536 results in the PMCAM<sub>x</sub>-UF performance for OA in Europe. This added SOA removed the  
537 underprediction of OA against the AMS measurements in Italy and Greece; the NMB changed  
538 from -18% when IVOCs were neglected to 2% when IVOCs were included (Table S8). The NME  
539 ~~inde~~creased a little (from ~~385~~% to 35%) with the IVOC addition. The performance against the OA  
540 measurements in the other European sites became a little worse when IVOCs were included in the  
541 model (Table S9). The small underprediction (NMB=-8%) in OA became a larger overprediction  
542 (NMB=20%) and the NME increased from 50% to 62%. These results are characteristic of the  
543 uncertainties in primary OA emissions but also SOA production from the various VOCs and  
544 IVOCs emitted by anthropogenic and biogenic sources.

545

#### 546 4. Conclusions

547 A new version of PMCAM<sub>x</sub>-UF was developed with the ability to simulate the formation  
548 and dynamic condensation of ELVOCs during the oxidation of the monoterpenes and the  
549 emissions and multi-generational chemistry of IVOCs. The model was applied to the PEGASOS  
550 summer intensive period campaign during the summer of 2012. The available measurements  
551 included both ground stations across Europe and airborne measurements from a Zeppelin over the  
552 Po Valley.

553 The number concentration predictions of PMCAM<sub>x</sub>-UF, are compared against ground  
554 measurements from 26 stations in Europe. The model tends to overestimate daily average  $N_{10}$  with  
555 a normalized bias of 35% and an average error of 64%. PMCAM<sub>x</sub>-UF performed well for  $N_{100}$   
556 with a low bias (-2 %) and an error of 41%. The performance of the model in the lowest 1 km of

557 the atmosphere above Po Valley for both  $N_{10}$  and  $N_{100}$  was even better than its average performance  
558 over Europe. The model's predicted  $PM_1$  and  $PM_{2.5}$  concentrations and composition had NMB of  
559 15% and errors less than 60% depending on the PM component. These results suggest that  
560 PMCAMx-UF does a reasonable job reproducing the aerosol mass and number concentrations over  
561 Europe during the simulated period.

562 The ELVOCs produced by the monoterpene oxidation contributed, according to the  
563 PMCAMx-UF predictions on average around  $0.5 \mu\text{g m}^{-3}$  and accounted for 10-15% of the  $PM_{2.5}$   
564 OA. The highest relative predicted increase of OA was 15-25% in northern Europe, while the  
565 ELVOC formation increased average OA by approximately 10% in central Europe.

566 The ELVOC production by monoterpenes led to surprisingly small changes of the average  
567 number concentrations over Europe. The total number concentration decreased by 0.2%, the  $N_{10}$   
568 decreases by 1.1%, while  $N_{50}$  increased by 3% and  $N_{100}$  by 4% due to this new SOA source. One  
569 of the reasons for these small average increases is the nonlinearity of the system leading to both  
570 increases and decreases in different parts of Europe. Even if ELVOCs accelerate the growth of the  
571 newly formed particles to larger sizes increasing in this way their lifetime, at the same time they  
572 increase the aerosol mass and surface area as they mostly condense on the accumulation mode.  
573 Therefore, they increase the condensation sink, decreasing the sulfuric acid supersaturation and  
574 the corresponding nucleation rate. They also increase the coagulation sink and thus accelerate the  
575 removal of all nanoparticles.

576 Locally the effects of the ELVOC production could be higher. For example, it is estimated  
577 that the ELVOC productions leads to a decrease of the total particle concentration  $N_{tot}$  by 20% in  
578 parts of the Nordic countries and by 5% in central Europe. At the same time, the predicted  $N_{10}$   
579 increased by 5-15% ( $150-400 \text{ cm}^{-3}$ ) over Finland, northwestern Russia, France, Ireland and  
580 northern Portugal due to these secondary organic compounds. The predicted  $N_{50}$  increased almost  
581 everywhere in continental Europe by  $50-300 \text{ cm}^{-3}$ . This is 10% increase of  $N_{50}$  over central Europe  
582 and 20-40% over Scandinavia and northwestern Russia.

583 The addition of IVOC emissions and their aging reactions led to surprising reduction of the  
584 total number of particles ( $N_{tot}$ ) and  $N_{10}$  by 10-15 and 5-10%, respectively, and to an increase of the  
585 concentration of  $N_{100}$  by 5-10%. In this case semi-volatile organic mass is produced, which  
586 condenses preferentially on particles in the accumulation mode, increasing the condensation and  
587 coagulation sinks and leading to a decrease in the concentration of the sub-10 nm particles.

588

589 **Data and code availability.** Field measurement data are available in [ebas.nilu.no](http://ebas.nilu.no) and  
590 <https://actris.nilu.no/>. The Zeppelin-relevant, San Pietro Capofume and Bologna data are available  
591 in <https://doi.org/10.5281/zenodo.4660145> (Lampilahti et al. 2021). The field datasets for Patras,  
592 Thessaloniki and Costa Navarino can be obtained after request to the authors. The PMCAMx-UF  
593 is available from the authors ([spyros@chemeng.upatras.gr](mailto:spyros@chemeng.upatras.gr)).

594

595 **Supplement.**

596

597 **Author contributions.** DP wrote the code, conducted the simulations, analyzed the results, and  
598 wrote the paper. SNP was responsible for the design of the study and the synthesis of the results  
599 and contributed to the writing of the paper.

600

601 **Competing interests.** The authors declare that they have no conflict of interest.

602

603 **Acknowledgments:** The authors would like to thank the PEGASOS team and the members and  
604 personnel of ACTRIS measurement sites. The ACTRIS project has received funding from  
605 the European Union Seventh Framework Programme (ACTRIS, FP7/2007-2013, grant agreement  
606 no. 262254) and the ACTRIS-2 project has received funding from the European Union's Horizon  
607 2020 research and innovation programme under grant agreement No 654109. We would like to  
608 especially thank: Pasi Aalto, Andres Alastuey, Benjamin Bergmans, Wolfram Birmili, Miroslav  
609 Bitter, Raymond Ellul, Markus Fiebig, Harald Flentje, Spiridon Bezantakos, George Biskos,  
610 Evangelos Gerasopoulos, Johannes Groess, Bas Henzing, Nikos Kalivitis, Hans Karlsson,  
611 Evangelia Kostenidou, Giorgos Kouvarakis, Markku Kulmala, Fabian Lenartz, Gunter Loeschau,  
612 Chris Lunder, Nikos Mihalopoulos, Marcel Moerman, David Munao, Colin O'Dowd, Noemi  
613 Perez, Helena Placha, Jean-Philippe Putaud, Alexander Schladitz, Franz Rohrer, Erik Swietlicki,  
614 Ralf Tillmann, Thomas Tuch, Kay Weinhold, Alfred Wiedensohler, Vladimir Zdimal, Hans-  
615 Christen Hansson, Peter Tunved and Radovan Krejci for the results of the field measurements.

616

617 **Financial support:** This work was supported by the project FORCeS funded from the European  
618 Union's Horizon 2020 research and innovation programme under grant agreement No 821205. We  
619 also acknowledge support by the project by the Greek PERAN project MIS 5002358.
