

31 be significant. For example, an increase in N_{100} by 20-50% is predicted over Scandinavia and
32 significant increases (10-20%) over some parts of central Europe. The ELVOCs contributed on
33 average around $0.5 \mu\text{g m}^{-3}$ and accounted for 10-15% of the $\text{PM}_{2.5}$ OA. The addition of IVOC
34 emissions and their aging reactions led to surprising reduction of the total number of particles (N_{tot})
35 and N_{10} by 10-15 and 5-10%, respectively, and to an increase of the concentration of N_{100} by 5-
36 10%. These were due to the accelerated coagulation and reduced nucleation rates.

37

38 **1. Introduction**

39 Two major processes are responsible for the introduction of new particles in the
40 atmosphere: direct emission from numerous sources and nucleation from low-volatility vapors.
41 New particles formed by nucleation can either grow by condensation of vapors (e.g. sulfuric acid,
42 ammonia, nitric acid, and organics) to larger sizes becoming cloud condensation nuclei (CCN) and
43 thereby increasing the cloud droplet number concentration (CDNC) or affected by coagulation
44 with pre-existing larger particles and be lost (Adams and Seinfeld, 2002). Globally, according to
45 large-scale model simulations, atmospheric new particle formation (NPF) and subsequent particle
46 growth represent the most significant source of atmospheric aerosol particles, at least in terms of
47 their total number concentration (Kulmala et al., 2004; Makkonen et al., 2009; Merikanto et al.,
48 2009; Pierce and Adams, 2009; Wang and Penner, 2009; Yu and Luo, 2009). An increase of the
49 number concentration of particles that can act as CCN results in higher CDNC and brighter clouds
50 with longer lifetimes.

51 Globally, organic particulate matter makes up more than 50% of the sub-micrometer mass
52 concentration of ambient aerosols in locations throughout the world (Kanakidou et al., 2005;
53 Seinfeld and Pandis, 2006; Zhang et al., 2007). Nearly 70% of this material is thought to be
54 secondary organic aerosol (SOA) formed from the oxidation of volatile organic compounds
55 (VOCs) (Hallquist et al., 2009; Schulze et al., 2017). Many of the relevant precursor VOCs are
56 biogenic in origin, such as monoterpenes ($\text{C}_{10}\text{H}_{16}$) and isoprene (C_5H_8).

57 Several recent field studies have shown that SOA in polluted areas cannot be explained by
58 the simulation of only the first generation of reactions of “traditional” SOA precursors: biogenic
59 compounds (monoterpenes, sesquiterpenes, and isoprene) and anthropogenic compounds
60 (aromatics, olefins and large alkanes) (de Gouw et al., 2005; Volkamer et al., 2006; Kleinman et
61 al., 2008; Docherty et al., 2008; Matsui et al., 2009; Dzepina et al., 2009). At the same time, it has

62 become clear that organic vapors are responsible for most of the new particle growth in
63 environments with low sulfur dioxide levels (Olenius et al., 2018; Yli-Juuti et al., 2020).

64 Traditional treatment of SOA formation considers only VOCs as the precursors and only
65 semivolatile products (Odum et al., 1996). Robinson et al. (2007) suggested that intermediate
66 volatile organic compounds (IVOCs) either emitted directly or resulting from the evaporation of
67 particles may be an important and previously neglected pool of precursors for SOA formation. In
68 addition, later generations of reactions of the products of VOCs, IVOCs and SVOCs can lead to
69 products of even lower volatility and formation of SOA (Donahue et al., 2006). These chemical
70 reactions can lead to continued SOA production after complete precursor consumption as products
71 undergo further oxidation (Kroll et al, 2006; Ng et al., 2006).

72 Secondary extremely low volatile organic compounds (ELVOCs) have been detected both
73 in the ambient atmosphere and laboratory studies (Donahue et al., 2011). These compounds
74 promote new particle growth and CCN production in the atmosphere (Jokinen et al., 2015; Kirkby
75 et al., 2016). ELVOCs can be produced rapidly in the gas phase during monoterpene oxidation
76 (Ehn et al., 2014), and can enhance atmospheric new particle formation and growth (Jokinen et al.,
77 2015). Due to their exceptionally low volatility, ELVOCs condense essentially irreversibly onto
78 growing particles at a rate controlled by the Fuchs-adjusted particle surface area (Shrivastava et
79 al., 2017).

80 Fanourgakis et al. (2019) evaluated 16 global chemistry transport models during a 4-year
81 period and compared their prediction to the near-surface observed number concentration of aerosol
82 particles across Europe and Japan. All models tended to underestimate the number concentrations
83 for particles larger than 50 nm (N_{50}). The normalized mean bias (NMB) was -51% and normalized
84 mean error (NME) was 55% for all stations. Sengupta et al. (2021) used the GLOMAP (Global
85 Model of Aerosol Processes; Spracklen et al., 2005) modal aerosol microphysics model (Mann et
86 al., 2010) simulating the production of six surrogate SOA species from the oxidation of
87 anthropogenic VOCs, monoterpenes, and isoprene. They assumed that ELVOCs derive only from
88 biogenic sources and can nucleate to form new particles (Gordon et al., 2016). Concentrations of
89 particles larger than 3 nm (N_3) and particles larger than 50 nm (N_{50}) were consistently
90 underestimated, while the best model performance was achieved when the ELVOC yield from
91 precursor VOCs was around 13% . These studies suggest that the role of organics and especially
92 ELVOCs on particle formation and growth is still not well understood.

93 In this study we extend the three-dimensional regional chemical transport model (CTM),
94 PMCAMx-UF (Jung et al., 2010), with detailed aerosol microphysics (Gaydos et al., 2007; Karydis
95 et al., 2007) that has been used and evaluated for simulations over the US and Europe (Fountoukis
96 et al., 2012). Originally the model assumed that growth of new particles was exclusively due to
97 sulfuric acid and ammonia condensation while the semivolatile secondary organics condensed only
98 on the accumulation mode thus contributing to the condensation and coagulation sinks. This initial
99 model version was found to reproduce more than 70% of the hourly number concentrations of
100 particles larger than 10 nm (N_{10}) within a factor of 2 (Fountoukis et al., 2012). However, the
101 concentration of particles larger than 100 nm (N_{100} , a proxy for the number of particles that can act
102 as CCN) was systematically underpredicted. The growth rates were also underpredicted, with
103 smaller errors in sites where the sulfate to organics mass ratio was high. These problems were
104 caused mainly by insufficient organic vapor condensation (Fountoukis et al., 2012) on ultrafine
105 particles. Patoulias et al. (2018) developed an extended version of PMCAMx-UF in which the
106 SOA components were modeled as semi-volatile first-generation products of the oxidation of
107 VOCs. The model predictions were compared against size distribution measurements from 16
108 stations in Europe during a photochemically active period. Including SOA condensation on
109 ultrafines in PMCAMx-UF improved its ability to reproduce the N_{10} and N_{100} concentration at
110 ground level. The inclusion of SOA decreased the daily normalized mean bias (NMB) of N_{10} from
111 85% to 75% and the daily NMB of N_{100} from 40% to 20%. However, the results suggested that
112 there is a need for additional improvements.

113 The primary goal of this study is to examine the role of IVOCs and ELVOCs on particle
114 number concentrations in Europe. PMCAMx-UF is extended once more to simulate the multiple
115 generations of IVOC gas-phase oxidation and the production of ELVOCs by monoterpenes. The
116 model predictions are compared with measurements from 26 sites during the intensive field
117 campaign that took place in Europe, as part of the Pan-European-Gas-AeroSOI-climate-interaction
118 Study (PEGASOS) project, from June 5 to July 8, 2012. The airborne data obtained by a Zeppelin
119 measuring above Po-Valley during the same campaign are also used. An analysis of the Zeppelin
120 measurement can be found by Lampilahti et al. (2021).

121

122

123

124 2. Model description

125 PMCAMx-UF is a three-dimensional chemical transport model (CTM) that simulates the
126 aerosol number size distribution in addition to the mass/composition size distribution (Jung et al.,
127 2010; Fountoukis et al., 2012) and is described in detail in Patoulias et al. (2018). PMCAMx-UF
128 is based on the framework of PMCAMx (Gaydos et al., 2007; Karydis et al., 2007), describing the
129 processes of horizontal and vertical advection, emissions, horizontal and vertical dispersion, wet
130 and dry deposition, aqueous and aerosol phase chemistry, as well as aerosol dynamics and
131 thermodynamics.

132 For the simulation of aerosol microphysics, PMCAMx-UF uses the updated version of
133 DMANx which simulates the processes of coagulation, condensation/evaporation and nucleation
134 (Patoulias et al., 2015) with the two-moment aerosol sectional (TOMAS) algorithm (Adams and
135 Seinfeld, 2002; Jung et al., 2006). A key feature of TOMAS is its ability to track two independent
136 moments of the aerosol size distribution for each size bin: the aerosol number and mass
137 concentration.

138 The aerosol size distribution is discretized into 41 sections covering the diameter range from
139 approximately 0.8 nm to 10 μm . The lowest boundary is at 3.75×10^{-25} kg of dry aerosol mass per
140 particle. Each successive boundary has twice the mass of the previous one. The particle
141 components modeled include sulfate, ammonium, nitrate, sodium, chloride, crustal material,
142 water, elemental carbon, primary organic aerosol (POA) and eight surrogate SOA components.

143 In this work, the nucleation rate is calculated using a scaled ternary parameterization based
144 on the original expressions of Napari et al. (2002) with a scaling factor of 10^{-6} following the
145 suggestions of Fountoukis et al. (2012). The binary parameterization of Vehkamäki et al. (2002)
146 is employed if the NH_3 concentration is below a threshold value of 0.01 ppt.

147 Coagulation of particles in the atmosphere is an important sink of aerosol number but is
148 also a mechanism by which freshly nucleated particles grow to larger sizes. Following Adams and
149 Seinfeld (2002), TOMAS assumes that the aerosol particles coagulate via Brownian diffusion and
150 the effects of gravitational settling and turbulence are negligible. The calculation of the coagulation
151 coefficients is based on the wet diameters of the particles. These wet diameters are calculated
152 following the approach of Gaydos et al. (2005). For small particles (<100 nm), we use the
153 expression of Dahneke et al. (1983) to correct for non-continuum effects. The coagulation
154 algorithm uses an adaptive time step. The time step is limited so that the aerosol number or mass

155 concentration in any size category does not increase by more than an order of magnitude or
156 decrease by more than 25% in each step.

157 The extended SAPRC (Statewide Air Pollution Research Center) chemical mechanism
158 (Carter, 2000; Environ, 2003), which includes 219 reactions of 64 gases and 18 free radicals, is
159 used for the gas phase chemistry mechanism in PMCAMx-UF. The SAPRC version used for this
160 work includes five lumped alkanes (ALK1-5), two lumped olefins (OLE1-2), two lumped
161 aromatics (ARO1-2), isoprene (ISOP), a lumped monoterpene (TERP) and a lumped sesquiterpene
162 species (SESQ).

163

164 **2.1 Secondary organic aerosol formation**

165 Gas-phase oxidation of volatile organic compounds (VOCs) produces semi-volatile and
166 low-volatility products that can then condense to the particle phase. The volatility-basis set (VBS)
167 framework used in PMCAMx-UF (Donahue et al., 2006) describes the volatility distribution of
168 the OA compounds. SOA is formed from anthropogenic (aSOA) and biogenic (bSOA) precursors.
169 Each of these types is simulated with 5 volatility bins with saturation concentrations of 10^{-5} , 1, 10,
170 100 and $1000 \mu\text{g m}^{-3}$. The $10^{-5} \mu\text{g m}^{-3}$ bin was added in this work to describe the ELVOCs. We
171 assumed an average molecular weight of 200 g mol^{-1} for SOA, and an effective enthalpy of
172 vaporization of 30 kJ mol^{-1} (Pathak et al., 2007; Stanier et al., 2007). The SOA yields used in this
173 version of PMCAMx-UF for the semi-volatile components are the NO_x -dependent stoichiometric
174 yields of Murphy et al. (2009).

175 Chemical reactions that change the volatility of the organics in the gas phase will change
176 the OA mass by influencing their partitioning. In PMCAMx-UF all secondary species are treated
177 as chemically reactive. Further gas-phase oxidation of OA vapors (chemical aging) is modeled
178 using a second-order reaction with hydroxyl radicals and a rate constant of $1 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$
179 (Atkinson and Arey, 2003). Each reaction is assumed to reduce the volatility of the vapor material
180 by one order of magnitude (i.e., shifting material from a C^* of 100 to $10 \mu\text{g m}^{-3}$), with a small
181 increase in mass (7.5%) to account for the added oxygen (Lane et al., 2008; Shrivastava et al.,
182 2008). Intermediate volatility organic compounds (IVOCs), are distributed in the 10^3 , 10^4 , 10^5 , and
183 $10^6 \mu\text{g m}^{-3}$ saturation concentration bins. The emission rates of the IVOCs are assumed to be equal
184 to 0.3, 0.4, 0.5 and 0.8 times the original non-volatile POA emission rate, for the 10^3 - 10^6 bins
185 respectively (Robinson et. 2007).

186 ELVOCs were assumed to be produced by the oxidation of monoterpenes with a molar
187 yield of 5%. For comparison, ELVOC yields for the α -pinene ozonolysis in Jokinen et al. (2015)
188 were $3.4 \pm 1.7\%$, by Ehn et al. (2014) of $7 \pm 4\%$ and $4.5 \pm 3.8\%$ in Rissanen et al. (2014). An
189 average molecular weight of 200 g mol^{-1} for ELVOCs was assumed in this work.

190 The partitioning of OA between the gas and particulate phases is simulated dynamically in
191 PMCAMx-UF without assuming equilibrium (Patoulias et al., 2015). The driving force for
192 condensation of a vapor to an aerosol particle is the difference between its ambient vapor partial
193 pressure and the equilibrium vapor pressure over the particles, with the latter including the Kelvin
194 effect which is due to the curvature of the particles. The Kelvin effect is larger for the smaller
195 particles and acts as a barrier for the condensation of organic vapors on these particles. In this
196 simulation a surface tension of $\sigma=0.025 \text{ Nm}^{-1}$ is assumed for all SOA components (Pierce et al.,
197 2011; Patoulias et al. 2015).

198 Three different chemical aging schemes are used in this work (Table S1). The first scheme
199 (case 1 or base case) includes (i) the aging of SOA components from anthropogenic sources, using
200 a rate constant $k(298 \text{ K}) = 10 \times 10^{-12} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ (anthropogenic SOA aging), (ii) the aging of
201 IVOCs using a rate constant $k(298 \text{ K}) = 40 \times 10^{-12} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$, (iii) production of ELVOCs
202 with saturation concentration of $10^{-5} \mu\text{g m}^{-3}$ from the oxidation of monoterpenes with a yield of
203 5%. The aSOA aging rate constant is based on OH oxidation of the products of aromatic VOCs
204 oxidation (Atkinson 2000; 2003). No biogenic SOA aging was simulated in this case, an
205 assumption based on laboratory studies (Presto et al., 2006; Ng et al., 2006) and the results of Lane
206 et al. (2008). In the second simulation (case 2), the ELVOC yield was set to zero thus neglecting
207 their formation. The rest of the parameters were the same as in the base case. Finally, in the third
208 simulation the emissions of IVOCs and the chemical aging reactions of all VOCs were neglected
209 while the production of the ELVOCs was simulated similarly to the base case.

210

211 2.2 Model application and measurements

212 The PMCAMx-UF modeling domain in this application covers a $5400 \times 5832 \text{ km}^2$ region
213 in Europe, with a $36 \times 36 \text{ km}$ grid resolution and 14 vertical layers extending up to approximately
214 7.2 km. The modeling period covers 34 days, from June 5 to July 8, 2012 corresponding to the
215 PEGASOS 2012 intensive period. PMCAMx-UF was set to perform simulations on a rotated polar
216 stereographic map projection. The first two days of each simulation were excluded from the

217 analysis to minimize the effect of the initial conditions on the results. For the boundary conditions,
218 constant and relatively low values have been used (Table S2) so that the predicted particle number
219 concentrations over central Europe are determined for all practical purposes by the emissions and
220 corresponding processes simulated by the model. The effect of these boundary conditions on the
221 predicted number concentrations are discussed in Patoulias et al. (2018).

222 Meteorological inputs to PMCAMx-UF include horizontal wind components, vertical
223 diffusivity, temperature, pressure, water vapor, clouds and rainfall. The Weather Research and
224 Forecasting (WRF) model (Skamarock et al., 2005) was used to generate the above inputs. WRF
225 was driven by geographical and dynamic meteorological data generated by the Global Forecast
226 System. Each layer of PMCAMx-UF was aligned with the layers used in WRF. The WRF
227 simulation was periodically re-initialized every 3 days with observed conditions to ensure accuracy
228 in the corresponding fields used as inputs in PMCAMx-UF. The measurements were pre-processed
229 by the WPS (WRF Preprocessing System) package, which provides each atmospheric and static
230 field with fidelity appropriate to the chosen grid resolution of the model. The performance of WRF
231 for Europe against observed meteorological variables has been the topic of several recent studies
232 (Jimenez-Guerrero et al., 2008; de Meij et al., 2009; Im et al., 2010; Argueso et al., 2011; Garcia-
233 Diez et al., 2012) demonstrating good performance.

234 The particle emissions were based on the pan-European anthropogenic particle number
235 emission inventory (Denier van der Gon et al., 2009; Kulmala et al., 2011) and the carbonaceous
236 aerosol inventory (Kulmala et al., 2011) developed during the EUCAARI (European Integrated
237 project on Aerosol, Cloud, Climate, and Air Quality Interactions) project. The resulting
238 number/mass inventories includes both number emissions and consistent size-resolved
239 composition for particles over the size range of approximately 10 nm to 10 μm . Hourly gridded
240 anthropogenic and biogenic emissions included both gases and primary particulate matter. The
241 natural emissions include both particulate matter and gases and combine three different data sets:
242 emissions from ecosystems based on the Model of Emissions of Gases and Aerosols from Nature
243 (MEGAN; Guenther et al., 2006), marine emissions based on the model of O'Dowd et al. (2008)
244 as sea surface covers a considerable area of the domain, and wildfire emissions (Sofiev et al.,
245 2008a, b). MEGAN uses as inputs the plant functional type, the leaf area index, various chemical
246 species emission factors and weather data provided by the WRF. Wind speed fields from WRF
247 and chlorophyll-a concentrations were used as inputs of the marine aerosol model. VOCs were

248 speciated based on the approach proposed by Visschedijk et al. (2007). Anthropogenic gas
249 emissions included land emissions from the GEMS (global and regional Earth-system monitoring
250 using satellite and in-situ data) dataset (Visschedijk et al., 2007). The international shipping,
251 industrial, domestic, agricultural and traffic aerosol emission sources were included in the
252 anthropogenic inventory (Denier van der Gon et al., 2009; Kulmala et al., 2011).

253 The model results were compared against measurements in 26 ground sites, which are
254 available in the European Supersites for Atmospheric Aerosol Research (EUSAAR), and EBAS
255 databases (<https://ebas.nilu.no>) and the Aerosols, Clouds and Trace gases Research Infrastructure
256 (ACTRIS) (<https://actris.nilu.no>). Particle size distribution measurements at all sites were made
257 using either a Differential Mobility Particle Sizer (DMPS) or a Scanning Mobility Particle Sizer
258 (SMPS). Information about all stations can be found in Table S3.

259 An intensive field campaign took place in Europe, as part of the Pan-European-Gas-
260 AeroSOI-climate-interaction Study (PEGASOS) project, from June 5 to July 8, 2012.
261 Measurements of aerosol mass concentration PM_1 (particulate matter particles of diameter less
262 than 1 micrometer) from the PEGASOS project are also available for the same period for Patras
263 (Greece), Finokalia (Greece), San Pietro Capofiume (Italy) and Bologna (Italy) (Table S4) and
264 filter $PM_{2.5}$ (particulate matter particles of diameter less than 2.5 micrometer) measurements from
265 6 additional stations in Europe (Table S5). For the calculation of organic mass, we used an average
266 organic mass to organic carbon ratio value equal to 1.8 (Kostenidou et al., 2015).

267 The airborne measurements acquired by the PEGASOS Zeppelin were acquired during the
268 simulation period over the Po Valley. The Po Valley region is situated between the Alps in the
269 north and the Apennines Mountains in the south–southwest. The mountains surround the valley on
270 three sides and high levels of pollutants are often observed in the region due to the industrial,
271 agricultural, and other anthropogenic emissions. In addition, emissions from ship traffic on the
272 Adriatic Sea (Hamed et al., 2007) and long-range transport from central-eastern Europe also
273 contribute pollutants to the region (Sogacheva et al., 2007). A SMPS was used to measure the
274 number size distribution of particles in the size range of 10 to 430 nm. Details of the relevant
275 PEGASOS Zeppelin measurements can be found in Lampilahti et al. (2021).

276

277

278

279 3. Results

280 3.1 Base case

281 The average predicted ground level average number concentrations for the total number of
282 particles (N_{tot}) and for particles with diameters above 10 nm (N_{10}), 50 nm (N_{50}) and 100 nm (N_{100}),
283 during June 5 to July 8, 2012 are shown in Figure 1. The N_{50} and N_{100} concentrations are often
284 used as proxies for CCN number concentrations (Fountoukis et al., 2012). On a domain average
285 basis, the model predicted for the ground level 4780 cm^{-3} for N_{tot} , 3630 cm^{-3} for N_{10} , 1990 cm^{-3}
286 for N_{50} , and 820 cm^{-3} for N_{100} during the simulated period. The highest N_{tot} average concentrations
287 (more than 15000 cm^{-3}) were predicted over Bulgaria, southern Romania, Turkey, Poland,
288 Holland, Portugal, Northern Spain, Eastern UK and Russia. On the other hand, the highest N_{50} and
289 N_{100} are predicted over the Mediterranean, mainly in areas near Southern Spain, Southern Italy,
290 and the Balkans. The N_{tot} and N_{10} are high in areas of frequent nucleation events and areas with
291 high particle number emissions, whereas the N_{50} and N_{100} levels are affected significantly by
292 secondary particulate matter production. The high photochemical activity over the Eastern
293 Mediterranean leads to the corresponding high levels of N_{50} and N_{100} during this period.

294

295 3.2 Evaluation of PMCAMx-UF predictions

296 3.2.1 Comparison of PMCAMx-UF predictions to ground aerosol number observations

297 The prediction skill metrics of PMCAMx-UF, for the daily average ground measurements
298 from the 26 stations, are summarized in Tables 1 and 2 for both the base case and the case in which
299 the ELVOCs are neglected.

300 For the base case simulation, the model has a tendency to overestimate the N_{10} levels. The
301 normalized mean bias (NMB) for the daily average concentrations is 23% and the normalized
302 mean error (NME) 63%. The N_{10} was overpredicted in 18 sites, underpredicted in 7 and there was
303 no bias in one. The NMB in 8 sites (Prague-Suchdol, Ispra, Melpitz, Patras, K-Pusztza, Hohen-
304 peissenberg, Hyytiala and San Pietro Capofiume) was less than $\pm 15\%$, and for another 8 stations
305 between $\pm 15\%$ and $\pm 40\%$ (Annaberg-Buchholz, Cabauw, Dresden Nord and Winkelmannstrasse,
306 Finokalia, Giordan Lighthouse, Kosetice, Montseny and Varrio). The highest discrepancies with
307 the measurements of N_{10} were found in Aspvreten, Birkness II, Usti n.L.-mesto, Vavihill, Vielsalm,
308 Zugspitze-Schneefernerhaus, Waldhof, Costa Navarino, and Thessaloniki with NMB higher than
309 $\pm 40\%$.

310 The model performed better for N_{100} . There was little bias in the corresponding predictions
311 on average (the NMB was -10%) and the NME was 45%. The NMB for 10 sites (Cabauw, Giordan
312 Lighthouse, Hyytiala, Kosetice, Melpitz, Patras, Prague-Suchdol, Vielsalm, Waldhof and
313 Zugspitze) was less than $\pm 15\%$ and for another 12 (Annaberg-Buchholz, Birkenes II, Dresden
314 Nord and Winkelmannstrasse, Finokalia, Hohenpeissenberg, Ispra, K-Puszt, Montseny, Costa
315 Navarino, San Pietro Capofiume, Usti n.L-mesto. and Vavihill) between $\pm 15\%$ and $\pm 40\%$ (Table
316 2). The absolute NMB for N_{100} exceeded 40% only in Aspvreten, Varrio and Thessaloniki.

317 3.3.2 Evaluation of aerosol composition predictions

318 The PMCAMx-UF predictions can be evaluated during that period using available PM_{10}
319 measurements from Aerosol Mass Spectrometers at four stations (Bologna and San Pietro
320 Capofiume, in Italy and Finokalia and Patras, in Greece) that were part of the PEGASOS
321 campaign.

322 In Italy and Greece, the model reproduces the observations of the PM_{10} concentrations of
323 the major inorganic aerosol components (sulfate, ammonium, nitrate) reasonably well (Table 3).
324 The model tends to underpredict the organic aerosol concentrations in Patras and Bologna, while
325 it overpredicts the OA in Finokalia and San Pietro Capofiume (Table 4). The OA NMB is -2% and
326 the NME is 38%, with the Finokalia site presenting the higher NMB value (50%) and San Pietro
327 Capofiume, Bologna the lower ($\pm 20\%$) (Table 4).

328 For the rest of Europe, $PM_{2.5}$ filter measurements have been used, available in the European
329 Supersites for Atmospheric Aerosol Research (EUSAAR) and EBAS databases
330 (<http://ebas.nilu.no/>) for stations that had available data for more than 15 days during the simulated
331 period (6 additional stations in Europe: Payerne, Melpitz, Montseny, Ispra, Diabla Gora, and
332 Iskrba; Table 5). For the calculation of OA mass concentration, we assumed OA:OC=1.8
333 (Kostenidou et al., 2015). For these sites, the model has a tendency towards overestimating the
334 $PM_{2.5}$ OA concentration for 4 out of 6 stations, presenting an average NMB of 20% and NME of
335 62% (Table 5).

336 3.3.3 Comparison of PMCAMx-UF predictions to Zeppelin measurements

337 One of the challenges of the PMCAMx-UF evaluation using airborne measurements is that
338 the model predictions are available every 15 min while the corresponding measurements by the
339 Zeppelin were taken every 3 min in different heights. For comparison purposes, the model output

340 was interpolated to the times of the Zeppelin measurement periods. PMCAMx-UF reproduced
341 more than 75% of the 2000 3-min N_{10} and N_{100} measurements by the Zeppelin with a factor of 2
342 (Figure S1). The vertical profiles shown in Fig.2, are averages of different flights that collected
343 data in different days and different altitudes each time. The number of samples at different altitudes
344 changed for each flight creating additional variability in the measured profiles.

345 To facilitate the comparison between measurements and predictions the corresponding
346 average profiles (matched in space and time) were calculated using 80 m altitude bins for all the
347 PEGASOS flights. PMCAMx-UF reproduced on average the N_{10} measurements over Po Valley at
348 the lower 160 m and above 400 m, but underestimated the higher N_{10} levels measured in the
349 residual layer at heights between 160-400 m at several of the flights that started several hours
350 before sunrise (Fig. 2a). The average measured N_{10} at all heights was $6,000 \text{ cm}^{-3}$, while the
351 predicted concentration was equal to $4,700 \text{ cm}^{-3}$.

352 PMCAMx-UF reproduced well the N_{100} concentration at all heights (Fig 2b). The model
353 also reproduced 80% of the 3-min N_{100} Zeppelin measurements within a factor of 2. The measured
354 average N_{100} at all heights was $1,500 \text{ cm}^{-3}$ and the average predicted by PMCAMx-UF was $1,800$
355 cm^{-3} . The ability of the revised model to reproduce reasonably well the high-time resolution (3-
356 minute) Zeppelin measurements at multiple altitudes and locations is encouraging.

357

358 3.2 Effect of ELVOC production on particle number and OA concentrations

359 An additional simulation was performed neglecting the production of ELVOCs from
360 terpenes (case 2). The addition of ELVOCs, increased the $\text{PM}_{2.5}$ OA mass by approximately as
361 much as $0.5 \mu\text{g m}^{-3}$ in Central/Eastern Europe and Russia, accounting for approximately 10-15%
362 of the OA (Fig. 3). In these areas a combination of high terpene emissions and high photochemical
363 reaction rates existed during the simulated period. The highest relative predicted increase of OA
364 was 15-25% in northern Europe. In central Europe the ELVOC formation increased average OA
365 by approximately 10%.

366 The average fractional increase of N_x , due to the production of ELVOCs is calculated as:

$$367 f_{N_x} = \frac{N_x(\text{with ELVOCs}) - N_x(\text{without ELVOCs})}{N_x(\text{without ELVOCs})} \quad (1)$$

368 where, x , is 10, 50, 100 nm or zero (total number). Rather surprisingly, the average fractional
369 change for all number concentrations (N_{tot} , N_{10} , N_{50} and N_{100}), is small ranging between 1% and -
370 4% (Fig. 4) (N_{tot} : -8 cm^{-3} or -0.14% , N_{10} : 40 cm^{-3} or -1.14% , N_{50} : 60 cm^{-3} or 3 %, N_{100} : 35 cm^{-3} or

371 4%). One reason for the small average change is that both increases and decreases are predicted
372 for different areas in Europe. These mixed results are due to the fact that the ELVOC condensation
373 accelerates the growth of new and preexisting particles to larger sizes, but at the same time
374 accelerates their losses due to the increase of the coagulation sink and decreases the nucleation
375 rate due to the increase of the condensation sink.

376 The formation of ELVOCs resulted in a predicted decrease of N_{tot} by 20% (300-600 cm^{-3})
377 in parts of the Nordic countries and by 5% in central Europe (Fig. 4). The decreases are predicted
378 for most Europe with the exception of a few areas in which increases are predicted (northern
379 Iberian Peninsula, parts of France, areas in the Balkans with high sulfur dioxide levels, etc.) (Fig.
380 5). The predicted N_{10} increased by 5-15% (150-400 cm^{-3}) over Finland, northwestern Russia,
381 France, Ireland and northern Portugal. At the same time there were small decreases of a few percent
382 over several areas in Europe especially in the south and in the east as well over the Baltic Sea. N_{50}
383 increased over almost of Europe by 50 to 300 cm^{-3} . This N_{50} increase corresponds to 20-40% over
384 Scandinavia and northwestern Russia, and 10% for central Europe. Finally, the ELVOCs caused
385 an increase in N_{100} of 20-50% over Scandinavia and 10-20% increases over central Europe. The
386 absolute corresponding N_{100} changes in these areas are 100-200 cm^{-3} .

387 The corresponding changes of the number concentrations for particles with diameters
388 between 1 and 10 nm (N_{1-10}), 10 and 50 nm (N_{10-50}) and (iii) 50 and 100 nm (N_{50-100}) are
389 summarized in Fig. S2. These figures illustrate the complex effect of the ELVOCs on different
390 parts of the aerosol number distribution. Decreases in the concentrations of the 1-10 nm particles
391 (decreasing nucleation rate due to increased condensation sink, increasing coagulation with larger
392 particles), increases in the concentrations of the particles larger than 100 nm (due to accelerated
393 growth of the sub-100 nm particles to larger sizes) and both increases and decreases in the 10-50
394 nm size range depending on the magnitude of the different competing processes in each area. The
395 effect of the ELVOCs in this PMCAMx simulation is clearly a lot more complex than a uniform
396 increase of particle number concentrations.

397 The results in the Hyttiala station in Finland were examined in more detail because the
398 predicted number concentrations in Finland are quite sensitive, according to PMCAMx-UF, to the
399 addition of the ELVOCs. The predicted N_3 , N_{10} , N_{50} and N_{100} concentrations for the base case are
400 in reasonable agreement with the field measurements in this area (Figure S3), with a tendency of
401 the model to overpredict the N_3 levels during a few nucleation events. For all concentrations the

402 simulation with the ELVOCs (base case) reproduces the measurements better than the simulation
403 in which they are neglected. The condensation sink (CS) for Hyytiala increases by a few percent
404 due to the additional mass of the ELVOCs (Figure S3). The average measured and predicted
405 number size distributions in Hyytiala site (Finland) are shown in Figure S4. The addition of the
406 ELVOCs leads to increased levels in the part of the size distribution above 50 nm. A decrease of
407 the concentration of particles with diameter below 7 nm is predicted due to the addition of the
408 ELVOCs because of both increased coagulation losses but also lower nucleation rates.

409 The ELVOC addition played a minor role on the overall performance of PMCAMx-UF. The
410 NMB for N_{10} decreased (in absolute terms) by 1%, it increased by 5% for N_{100} due to the addition
411 of the ELVOCs in the simulation (Table 1-2). The addition of the ELVOCs affects mainly the
412 PMCAMx-UF predictions in northern Europe and especially Finland, where the predictions of
413 N_{100} significantly improve. In Hyytiala site the NMB decreases from -34% to -14% and in Varrio
414 drops from -72% to -49%. The corresponding normalized mean errors changed by 1-2%. These
415 small changes in the performance metrics are consistent with the small overall changes caused by
416 the ELVOC addition.

417 The small change in the OA mass concentration due to the addition of the ELVOCs has a
418 modest impact on the performance of PMCAMx-UF for OA (Table S6 and S7). For example, the
419 PM_{10} OA bias improves from -6% to 2% while the $PM_{2.5}$ OA bias increases from 15% to 20%. The
420 changes in normalized error are 1% or less.

421

422 3.3 Effect of IVOCs on particle number concentrations

423 The emissions of IVOCs ($C^* \geq 10^{-3} \mu\text{g m}^{-3}$) were set to zero in a sensitivity test (Case 3) to
424 quantify their effect on the predicted particle number concentration and size distribution. The
425 SOA formed by the IVOCs (SOA-iv) exceeds $1 \mu\text{g m}^{-3}$ in southern Europe, over the Mediterranean
426 Sea, but also in large areas over central and eastern Europe (Fig. 6). The high SOA-iv levels over
427 the Mediterranean are due to the oxidation of IVOCs emitted from large wildfires that occurred
428 during the simulation period. The corresponding SOA-iv is 10-25% of the total OA over
429 continental Europe and even higher (about 60%) over parts of the marine atmosphere.

430 According to PMCAMx-UF the addition of the emissions of IVOCs and their aging
431 reactions lead to a reduction of N_{tot} by 5-10% and N_{10} by 5% (Fig. 7) for continental Europe. On
432 the other hand, this addition of IVOCs leads to an increase of N_{50} by 5% and N_{100} by 5-10% mainly

433 in central Europe and the Mediterranean Sea (Fig. 7). The corresponding changes of the number
434 concentrations for the various size ranges N_{1-10} , N_{10-50} and N_{50-100} are summarized in Fig. 8. The
435 predicted N_{1-10} decreases approximately 15-20% for most of Europe except for the Scandinavian
436 peninsula due to the IVOCs. N_{10-50} decreases 10-15% mainly in southern Europe and N_{50-100}
437 changes less than $\pm 5\%$ or $\pm 100 \text{ cm}^{-3}$ in the simulated domain.

438 The atmospheric oxidation of the emitted IVOCs produces semi-volatile organic
439 compounds, which condense preferentially on particles in the accumulation mode and not so much
440 on the smallest particles due to the Kelvin effect. This results in an increase of both the
441 condensation and coagulation sinks, which then lead to a decrease of the nucleation rate but also
442 on the coagulation rate of the smaller with the larger particles.

443 The effect of the addition of the IVOCs on the performance of PMCAMx-UF is modest and
444 mixed. The NMB for N_{10} increased by 4% (from 23% to 27%) and decreased by 5% for N_{100} (from
445 10% to 5%) (Table S5). The corresponding NME for both N_{10} and N_{100} changed slightly
446 (approximately 1%). The modest overall changes on the number distribution of the ultrafine
447 particles caused by the addition of IVOCs and the corresponding aging reactions are consistent
448 with the small changes in the PMCAMx-UF performance metrics.

449 The addition of the IVOCs and the resulting SOA-iv from their oxidation also had mixed
450 results in the PMCAMx-UF performance for OA in Europe. This added SOA removed the
451 underprediction of OA against the AMS measurements in Italy and Greece; the NMB changed
452 from -18% when IVOCs were neglected to 2% when IVOCs were included (Table S8). The NME
453 increased a little (from 35% to 35%) with the IVOC addition. The performance against the OA
454 measurements in the other European sites became a little worse when IVOCs were included in the
455 model (Table S9). The small underprediction (NMB=-8%) in OA became a larger overprediction
456 (NMB=20%) and the NME increased from 50% to 62%. These results are characteristic of the
457 uncertainties in primary OA emissions but also SOA production from the various VOCs and
458 IVOCs emitted by anthropogenic and biogenic sources.

459

460 **4. Conclusions**

461 A new version of PMCAMx-UF was developed with the ability to simulate the formation
462 and dynamic condensation of ELVOCs during the oxidation of the monoterpenes and the
463 emissions and multi-generational chemistry of IVOCs. The model was applied to the PEGASOS

464 summer intensive period campaign during the summer of 2012. The available measurements
465 included both ground stations across Europe and airborne measurements from a Zeppelin over the
466 Po Valley.

467 The number concentration predictions of PMCAM_x-UF, are compared against ground
468 measurements from 26 stations in Europe. The model tends to overestimate daily average N_{10} with
469 a normalized bias of 35% and an average error of 64%. PMCAM_x-UF performed well for N_{100}
470 with a low bias (-2 %) and an error of 41%. The performance of the model in the lowest 1 km of
471 the atmosphere above Po Valley for both N_{10} and N_{100} was even better than its average performance
472 over Europe. The model's predicted PM₁ and PM_{2.5} concentrations and composition had NMB of
473 15% and errors less than 60% depending on the PM component. These results suggest that
474 PMCAM_x-UF does a reasonable job reproducing the aerosol mass and number concentrations over
475 Europe during the simulated period.

476 The ELVOCs produced by the monoterpene oxidation contributed, according to the
477 PMCAM_x-UF predictions on average around $0.5 \mu\text{g m}^{-3}$ and accounted for 10-15% of the PM_{2.5}
478 OA. The highest relative predicted increase of OA was 15-25% in northern Europe, while the
479 ELVOC formation increased average OA by approximately 10% in central Europe.

480 The ELVOC production by monoterpenes led to surprisingly small changes of the average
481 number concentrations over Europe. The total number concentration decreased by 0.2%, the N_{10}
482 decreases by 1.1%, while N_{50} increased by 3% and N_{100} by 4% due to this new SOA source. One
483 of the reasons for these small average increases is the nonlinearity of the system leading to both
484 increases and decreases in different parts of Europe. Even if ELVOCs accelerate the growth of the
485 newly formed particles to larger sizes increasing in this way their lifetime, at the same time they
486 increase the aerosol mass and surface area as they mostly condense on the accumulation mode.
487 Therefore, they increase the condensation sink, decreasing the sulfuric acid supersaturation and
488 the corresponding nucleation rate. They also increase the coagulation sink and thus accelerate the
489 removal of all nanoparticles.

490 Locally the effects of the ELVOC production could be higher. For example, it is estimated
491 that the ELVOC productions leads to a decrease of the total particle concentration N_{tot} by 20% in
492 parts of the Nordic countries and by 5% in central Europe. At the same time, the predicted N_{10}
493 increased by 5-15% ($150\text{-}400 \text{ cm}^{-3}$) over Finland, northwestern Russia, France, Ireland and
494 northern Portugal due to these secondary organic compounds. The predicted N_{50} increased almost

495 everywhere in continental Europe by 50-300 cm⁻³. This is 10% increase of N_{50} over central Europe
496 and 20-40% over Scandinavia and northwestern Russia.

497 The addition of IVOC emissions and their aging reactions led to surprising reduction of the
498 total number of particles (N_{tot}) and N_{10} by 10-15 and 5-10%, respectively, and to an increase of the
499 concentration of N_{100} by 5-10%. In this case semi-volatile organic mass is produced, which
500 condenses preferentially on particles in the accumulation mode, increasing the condensation and
501 coagulation sinks and leading to a decrease in the concentration of the sub-10 nm particles.

502

503 **Data and code availability.** Field measurement data are available in ebas.nilu.no and
504 <https://actris.nilu.no/>. The Zeppelin-relevant, San Pietro Capofume and Bologna data are available
505 in <https://doi.org/10.5281/zenodo.4660145> (Lampilahti et al. 2021). The field datasets for Patras,
506 Thessaloniki and Costa Navarino can be obtained after request to the authors. The PMCAMx-UF
507 is available from the authors (spyros@chemeng.upatras.gr).

508

509 **Supplement.**

510

511 **Author contributions.** DP wrote the code, conducted the simulations, analyzed the results, and
512 wrote the paper. SNP was responsible for the design of the study and the synthesis of the results
513 and contributed to the writing of the paper.

514

515 **Competing interests.** The authors declare that they have no conflict of interest.

516

517 **Acknowledgments:** The authors would like to thank the PEGASOS team and the members and
518 personnel of ACTRIS measurement sites. The ACTRIS project has received funding from
519 the European Union Seventh Framework Programme (ACTRIS, FP7/2007-2013, grant agreement
520 no. 262254) and the ACTRIS-2 project has received funding from the European Union's Horizon
521 2020 research and innovation programme under grant agreement No 654109. We would like to
522 especially thank: Pasi Aalto, Andres Alastuey, Benjamin Bergmans, Wolfram Birmili, Miroslav
523 Bitter, Raymond Ellul, Markus Fiebig, Harald Flentje, Spiridon Bezantakos, George Biskos,
