13 Abstract: By synthesising remote-sensing measurements made in the central Arctic into a model-gridded Cloudnet cloud 14 product, we evaluate how well the Met Office Unified Model (UM) and European Centre for Medium-Range Weather 15 Forecasting Integrated Forecasting System (IFS) capture Arctic clouds and their associated interactions with the surface energy 16 balance and the thermodynamic structure of the lower troposphere. This evaluation was conducted using a four-week 17 observation period from the Arctic Ocean 2018 expedition, where the transition from sea ice melting to freezing conditions 18 was measured. Three different cloud schemes were tested within a nested limited area model (LAM) configuration of the UM 19 - two regionally-operational single-moment schemes (UM_RA2M and UM_RA2T), and one novel double-moment scheme 20 (UM_CASIM-100) - while one global simulation was conducted with the IFS, utilising its default cloud scheme 21 (ECMWF_IFS).

- Consistent weaknesses were identified across both models, with both the UM and IFS overestimating cloud occurrence below
 3 km. This overestimation was also consistent across the three cloud configurations used within the UM framework, with >90%
 mean cloud occurrence simulated between 0.15 and 1 km in all model simulations. However, the cloud microphysical structure,
 on average, was modelled reasonably well in each simulation, with the cloud liquid water content (*LWC*) and ice water content
 (*IWC*) comparing well with observations over much of the vertical profile. The key microphysical discrepancy between the
 models and observations was in the *LWC* between 1 and 3 km, where most simulations (all except UM_RA2T) overestimated
 the observed *LWC*.
- 29 Despite this reasonable performance in cloud physical structure, both models failed to adequately capture cloud-free episodes:
- 30 this consistency in cloud cover likely contributes to the ever-present near-surface temperature bias simulated in every
- 31 simulation. Both models also consistently exhibited temperature and moisture biases below 3 km, with particularly strong cold
- 32 biases coinciding with the overabundant modelled cloud layers. These biases are likely due to too much cloud top radiative

cooling from these persistent modelled cloud layers and were interestingly consistent across the three UM configurations tested, despite differences in their parameterisations of cloud on a sub-grid-scale. Alarmingly, our findings suggest that these biases in the regional model were inherited from the driving model, thus triggering too much cloud formation within the lower troposphere. Using representative cloud condensation nuclei concentrations in our double-moment UM configuration, while improving cloud microphysical structure, does little to alleviate these biases; therefore, no matter how comprehensive we make the cloud physics in the nested LAM configuration used here, its cloud and thermodynamic structure will continue to be overwhelmingly biased by the meteorological conditions of its driving model.

40 1 Introduction

41 The Arctic is warming at more than twice the global average rate (Serreze and Barry, 2011; Cohen et al., 2014), with recent 42 evidence suggesting the rate of warming could be up to three times the global average (AMAP 2021). Coupled general 43 circulation models (GCMs) fail to agree on the magnitude of recent warming and exhibit large biases in surface temperature 44 and energy balance (Boeke and Taylor, 2016) driven largely by model parameter uncertainties on a decadal scale (Hodson et 45 al., 2013). Biases in such surface properties are also present in atmosphere-only versions of these models with fixed ocean and 46 sea ice boundaries, indicating that there is an important atmospheric source of disparity between models and reality (Bourassa 47 et al., 2013). Arctic clouds have a net warming effect at the surface (Boucher et al., 2013) and are likely a contributing factor 48 to the spread of surface energy balance estimates obtained from these models, with a large spread in cloud fractions, liquid 49 water paths (LWP), and ice water paths (IWP) identified in past phases of the Coupled Model Intercomparison Project (CMIP; 50 Karlsson and Svensson, 2011; Boeke and Taylor, 2016). Early results from the most recent CMIP indicate that high latitude 51 discrepancies in cloud fraction are still prevalent in recent revisions of these models (Vignesh et al., 2020).

With accelerating Arctic warming, we need to build suitable numerical models to confidently predict how the atmosphere will change both on short weather prediction and longer climate time scales (**Jung et al., 2016**). Models such as the Met Office Unified Model (UM) and European Centre for Medium-Range Weather Forecasting (ECMWF) Integrated Forecasting System (IFS) are commonly used for assessing future Arctic change; however, recent work has shown that, like other large-scale models, both exhibit surface energy balance discrepancies with comparison to high Arctic observations. In both the UM and the IFS, these biases have largely been attributed to incorrect cloud cover (**Birch et al., 2012**; **Sotiropoulou et al., 2016**; There tal. **2021**)

- 58 Tjernström et al., 2021).
- 59 Several studies have considered why such large-scale models fail to reproduce observed cloud cover in the high Arctic.
- 60 Observations have shown that during summer, Arctic clouds experience episodes of extremely low concentrations of cloud
- 61 condensation nuclei (CCN; < 10 cm⁻³) approximately 10—30% of the time (**Mauritsen et al., 2011**; **Tjernström et al., 2014**),
- 62 highlighting that model capability to reproduce cloud free conditions in the Arctic is likely dependent upon representing these
- 63 low CCN numbers (Birch et al., 2012; Stevens et al., 2017; Hines and Bromwich, 2017). Such conditions are difficult to
- 64 simulate with large-scale numerical models utilising single-moment microphysics schemes with assumed constant droplet
- number concentrations, N_d . Both the IFS and the UM make such assumptions in their current global operational configurations:
- 66 while climatological aerosol concentrations are referenced in the calculations of the first and second indirect effect, droplet
- 67 number cannot evolve independently of cloud liquid mass.

- 68 The operational single-moment microphysics scheme within the UM was found to hinder its ability to reproduce tenuous cloud
- 69 periods during the Arctic Summer Cloud Ocean Study (ASCOS); when clouds were modelled, the model produced too thin 70 cloud layers in a boundary layer (BL) that was often too well-mixed and too shallow (Birch et al., 2012). The prevalence of
- 71 too much low-level cloud caused surface energy balance, and hence surface temperature, biases. The new Cloud-Aerosol
- 72 Interactive Microphysics (CASIM) double-moment scheme in the UM has enabled improvements in its representation of Arctic
- 73 clouds; Stevens et al. (2017) noted it improved the surface net longwave radiation (LW_{net}) in both cloudy and cloud-free
- 74 conditions. Specifically, inclusion of aerosol processing within CASIM successfully led to cloud dissipation when modelling
- 75 the CCN-limited clouds observed during the ASCOS campaign, indicating that this explicit description of double-moment
- 76 microphysics (rather than a simplified cloud physics description) is key to modelling these clouds in the high Arctic.
- 77 Like the UM, the IFS also failed to capture episodic cloud-free periods observed during ASCOS, leading to similar surface
- 78 energy biases (Sotiropoulou et al., 2016). The updated IFS cloud scheme, used operationally since 2013, has improved its
- 79 ability to capture mixed-phase Arctic clouds in recent revisions; however, Sotiropoulou et al. (2016) reported that the IFS still
- 80 exhibits a persistent positive near-surface temperature bias, despite the improvement to its representation of these clouds. These
- 81 Arctic surface biases persist in version Cy45r1 of the model, as shown by Tjernström et al. (2021). Given that reanalysis
- 82 products created using the ECMWF IFS (e.g., ERA5; Hersbach et al. 2020) are widely used, both to produce lateral boundary
- 83 conditions for process studies with numerical weather prediction (NWP) models and to analyse Arctic atmospheric structure,
- 84 we must understand the root of these biases and make recommendations for process improvements.
- 85 Here, we evaluate the performance of recent revisions of both the UM and IFS focusing on their ability to capture clouds and 86 the thermodynamic structure of the BL, highlighting common process relationships between the models which may explain 87 differences from observations. To achieve this, we compare these models with recent high Arctic observations made during the 88
- Arctic Ocean 2018 (AO2018; Vüllers et al., 2021) expedition, where a suite of remote-sensing instrumentation was active
- 89 aboard the Swedish icebreaker Oden measuring summertime cloud and BL properties in the high Arctic. We use Cloudnet
- 90 (Illingworth et al., 2007) to compare observations with cloud properties simulated by the models, to test the respective
- 91 components in each model simulation with a focus on evaluating the relative contributions of the following on cloud structure:
- 92 1. The choice and use of large-scale cloud schemes at high resolution
- 93 2. The cloud microphysics scheme chosen to represent resolved clouds
- 94 3. Representative CCN concentrations, and thus droplet number concentrations, as a function of altitude
- 95 4. The global model analyses used to produce boundary conditions for high resolution nested configurations
- 96 By testing these hypotheses with two different atmospheric models, operating on different grid configurations, we assess
- 97 whether representative CCN concentrations are indeed the key model development still required to suitably capture Arctic
- 98 clouds, or whether other factors are restricting model performance in the high Arctic.

99 2 Data and methods

100 2.1 Arctic Ocean 2018 expedition

During the AO2018 expedition, *Oden* drifted with an ice floe near the North Pole from 14 August to 14 September 2018 (Fig. 1). Campaign details, instrumentation, and meteorological measurements from the AO2018 expedition are summarised in
Vüllers et al. (2021). Here, we use a subset of the measurements for direct comparison with our model simulations. Key acronyms, abbreviations, and parameters referenced in this study are listed in Table 1.

105 Radiosondes (Vaisala RS92) launched at 0000, 0600, 1200, 1800 UTC, provide in situ thermodynamic profiles with a 0.5°C 106 and 5% manufacturer specified uncertainty associated with temperature and humidity sensors, respectively. The radiosonde 107 data were distributed via the global telecommunications system and assimilated operationally at the Met Office and ECMWF. 108 Remote sensing measurements from a Metek MIRA-35 Doppler cloud radar, a Halo Photonics Streamline Doppler lidar, and 109 an RPG HATPRO microwave radiometer were processed through the Cloudnet algorithm (Illingworth et al., 2007) following 110 the data preparation steps of Achtert et al. (2020). A Vaisala PWD22 present weather sensor (PWS) measured visibility, precipitation type, precipitation intensity, and cumulative amount; near surface temperature and relative humidity (RH) were 111 112 obtained from an aspirated Rotronic HMP101 sensor. Broadband downwelling solar and infrared radiation were measured on board the ship by Eppley PSP and PIR radiometers. 3-hourly albedo estimates from surface images were used to calculate 113 114 upwelling shortwave radiation (Vuellers et al., 2021).

115 2.2 Cloudnet

128

129

130

131

132

116 Cloudnet is used to directly compare between our measured and modelled cloud properties (Illingworth et al., 2007). Cloudnet 117 ingests Doppler cloud radar and lidar, ceilometer, microwave radiometer, and radiosonde data to derive cloud fractions and 118 cloud water contents on a chosen model grid. A comprehensive description of the algorithm is beyond the scope of this paper 119 and is provided by Illingworth et al., 2007 (and references therein), but essentially the algorithm first homogenizes 120 observational data to a common time resolution of 30 s and interpolates data to the radar height grid. Radar reflectivity (Z_e) and 121 lidar backscatter (β) profiles are used to determine cloud boundaries. Cloudnet takes advantage of the lidar's sensitivity to 122 small particles, such as cloud droplets and aerosol, and the radar's sensitivity to large particles, such as ice particles, rain, and 123 drizzle. Cloud phase is determined using Z_{e_i} , β_i , and thermodynamic information from the radiosondes. Cloud ice water content (IWC) is derived using Z_e and temperature (**Illingworth et al., 2007**), while liquid water content (LWC) is derived by 124 partitioning LWP measured by the radiometer to the identified liquid cloud layers from the lidar. Additionally, an 125 126 adiabatic LWC is calculated from temperature and humidity profiles and the identified cloud top and base height from radar 127 and lidar measurements.

Cloudnet has already been utilised to study Arctic cloud properties using measurements made aboard *Oden* both during this campaign (**Vüllers et al., 2021**) and during the *Arctic Clouds in Summer Experiment* in 2014 (**Achtert et al., 2020**). Potential errors associated with the Cloudnet procedure are described in **Achtert et al. (2020**). One particular limitation relevant to this study is the minimum detection height of 156 m (lowest radar range gate). Low level clouds/fog below this height are hence missed by Cloudnet (**Vüllers et al., 2021**) and not included in model comparisons. This limitation also results in problems with

133 the LWC derived from radiometer measurements; therefore, we use the calculated LWC under adiabatic assumption in this

- 134 study (for further details see Appendix A)
- 135 For comparisons with models, cloud fraction by volume (C_V), adiabatic LWC, and cloud IWC from observations are averaged
- to a reference model grid; here, we use the UM grid, but we could have equally chosen that of the IFS (**Fig. S1**). Cloud properties
- are calculated using measurement profiles alongside model wind speed and grid-box size, where changes in cloud properties
- 138 over time are assumed to be driven primarily by advection and not microphysical changes (**Illingworth et al., 2007**). This
- procedure is applied for C_V , LWC, and IWC, with C_V defined as the fraction of pixels in a 2D slice which are categorised as
- 140 liquid, supercooled liquid, or ice (**Illingworth et al., 2007**).

141 2.3 Models

A summary of each model simulation is included in **Table 2** and detailed in the following sections. 36-hour forecasts were performed with each model, initialised each day at 1200 UTC with the first 12 hours of spin up discarded, thereby producing daily forecast products (0000 UTC – 0000 UTC) with hourly diagnostics for analysis. This is common practice for such forecasts to ensure discrepancies due to spin up are avoided, while maintaining meteorology close to reality; however, as noted by **Tjernström et al. (2021)**, model error growth is often a function of forecast time and thus the findings of this study may be related to the time window chosen for each model forecast.

148 Column diagnostics from the grid cell closest to the position of *Oden* were extracted from the model domain, updated hourly
149 to account for the ship's drifting position. These variables (e.g., temperature, humidity, cloud fraction, condensate variables,
150 wind versus time) were then used for comparisons with alike variables constructed using Cloudnet (Illingworth et al., 2007)
151 with measured data (see Sect. 2.1).

152 2.3.1 Integrated Forecasting System (IFS; ECMWF_IFS)

153 Cycle 46r1 (Cy46r1) of the IFS (used operationally from Jun 2019 to Jun 2020) was used to create global meteorological 154 forecasts. The IFS uses a spectral formulation with a wave-number cut off corresponding to a horizontal grid size of 155 approximately 9 km (**Fig. 1b**). It has 137 levels in the vertical up to 80 km, the lowest at ≈10 m with 8 levels below ≈200 m 156 and 20 below 1 km. IFS forecasts were initialised from ECMWF operational analyses. Operational forecasts produced at the 157 time of the campaign (with Cy45r1) were recently evaluated on a 3-day lead time from a statistical viewpoint for this expedition 158 (**Tjernström et al., 2021**); in contrast, lead-time averaged verification was conducted in this study using a 1-1 comparison of 159 a concatenated timeseries of forecast values (T+13—T+36) with hourly observations.

160 Cloud properties are parameterised following Forbes and Ahlgrimm (2014). This cloud scheme was implemented in Cy36r4

- and has been previously evaluated for Arctic clouds by **Sotiropoulou et al. (2016)** using Cy40r1. Five independent prognostic
- 162 cloud variables are included (grid box fractional cloud cover, and specific water contents for liquid, rain, ice, and snow).
- Heterogeneous primary ice formation is diagnosed following **Meyers et al.** (1992), with a mixed-phase cut-off of -23 °C. Liquid cloud formation occurs when the average relative humidity within a grid box exceeds a critical threshold, RH_{crit} ,
- representing sub-grid-scale variability of moisture. This threshold is 80% in the free troposphere, increasing towards the surface

166 in the boundary layer (**Tiedtke, 1993**). Once formed, cloud liquid mass is distributed across a fixed cloud droplet number 167 concentration, N_d , of 50 cm⁻³ over the ocean (and 300 cm⁻³ over land) to act as a threshold for autoconversion from liquid to 168 rain. For interactions with the radiation scheme, the IFS follows **Martin et al. (1994**) for estimating droplet number, using the 169 prognostic specific liquid water content and a prescribed CCN profile. CCN concentrations are calculated as a function of the 170 near-surface wind speed but decreases with altitude to represent the vertical distribution of aerosol within and above the BL. 171 Further details regarding the cloud scheme can be found in the ECMWF documentation (**IFS Documentation – Chapter 7:**

172 Clouds and large-scale precipitation, <u>https://www.ecmwf.int/node/19308</u>).

173 The IFS is coupled to a 0.25° resolution dynamic sea-ice model (Louvain-la-Neuve Sea Ice Model, LIM2) which provides sea 174 ice fractions to the IFS and the surface flux tiling scheme (**Buizza et al., 2017; Keeley and Mogensen, 2018**). The surface 175 energy balance over the sea ice fraction is, however, calculated separately from LIM2 using an albedo parameterisation 176 following **Ebert and Curry (1993)** with fixed monthly climatology values interpolated to the actual time, and a heat flux 177 through the ice calculated using a constant sea-ice thickness of 1.5 m.

178 2.3.2 Unified Model (UM)

179 The UM was operated as a high-resolution LAM with a 1.5 km \times 1.5 km grid (grid is shown in Fig. 1). A rotated pole 180 configuration provided approximately equal spacing between grid points towards 90 °N. The LAM contained 500 × 500 grid 181 boxes, spanning from 83.25 °N to 90 °N centred on the 30 °E meridian. In the vertical, there were 70 vertical levels up to 40 182 km, with 24 levels within the lowest 2 km of the domain (Grosvenor et al., 2017). Lateral boundary conditions were generated 183 hourly from UM global model 36-hour forecasts at N768 resolution (corresponding to approximately 17 km at 90 °N with the rotated pole) using the Global Atmosphere 6.1 configuration (Walters et al., 2017; Table 2). Three configurations of the UM 184 185 LAM were tested for the main body of this study, each using different combinations of cloud microphysics and large-scale 186 cloud schemes. Details on the pertinent microphysical processes represented in each simulation are listed in Table 3.

187 2.3.2.1 Regional Atmosphere model configurations (UM_RA2M and UM_RA2T)

Version 2 of the Regional Atmosphere model within the UM framework has two standard configurations: the mid-latitude configuration (UM_RA2M) and the tropical configuration (UM_RA2T). Both are used operationally in their respective geographical regions. The key difference between these configurations can be found in their turbulent mixing processes: UM_RA2M employs weak turbulent mixing to encourage heterogeneity in model fields to facilitate the triggering of small convective showers; however, while this weak mixing works well to reproduce conditions often experienced in the midlatitudes, it triggers convection too early in the tropics. Therefore, these two standard Regional Atmosphere configurations were designed separately to account for these subtle differences in convection initiation on km-scales (**Bush et al., 2020**).

Neither configuration has been previously evaluated for use in the Arctic. Note that both UM_RA2M and UM_RA2T use the
default Regional Atmosphere surface albedo thresholds, giving a 50% albedo at an ice surface temperature of 0 °C and
increasing to 80% at -10 °C. Gilbert et al. (2020) tested both configurations for polar cloud modelling over the Antarctic

198 Peninsula, finding that the mid-latitude scheme performs better than the tropical configuration for capturing polar cloud liquid

water properties and associated radiative interactions (with the surface albedo modelled to within 2% of observed values),whereas the tropical scheme enabled a too-efficient ice phase (and associated liquid depletion).

- 201 Both UM_RA2M and UM_RA2T include the Wilson and Ballard (1999) description of large-scale precipitation to simulate
- resolved cloud microphysics. This microphysics scheme describes prognostic liquid and ice mixing ratios (q_{liq} and q_{ice} ,
- respectively), with an assumed fixed N_d profile calculated from an aerosol climatology and tapered to 50 cm⁻³ towards the
- surface (between 150 m and 50 m). A single ice species (encapsulating pristine crystals, aggregates, and snow particles) is
- represented, with an assumed particle size distribution based on **Field et al.** (2007).

UM_RA2M uses the Smith (1990) large-scale cloud scheme to parameterise sub-grid-scale fluctuations in humidity and cloud,
 designed to ensure coarse grid GCMs do not have entirely cloudy grid boxes. It diagnoses cloud fraction and condensate

variables for input to the microphysics scheme, referencing a prescribed RH_{crit} profile (based on a symmetric triangular

- 209 probability density function of sub-grid-scale variability in temperature and moisture) to permit condensation below 100 %
- 210 humidity (Wilson et al., 2008). Condensation cannot occur within a grid box until the grid box mean *RH* exceeds a prescribed
- 211 altitude-dependent *RH_{crit}* (described in **Table 3**).

212 In UM_RA2T, the prognostic cloud fraction and prognostic condensate (PC2; Wilson et al., 2008) large-scale cloud scheme

is used, designed to address the over-sensitive diagnostic links between cloud fraction and cloud condensate in Smith (1990).

Total, liquid, and ice cloud fractions are included as prognostic variables in PC2, allowing cloud fractions and condensate to

- vary through other interactions (such as BL processes and cloud microphysics) and not simply diagnosed from temperature and
- humidity as in Smith (1990) (Wilson et al., 2008). PC2 prognostic variables are advected by the wind and continually updated
- 217 following incremented sources and sinks in the model, with the additional inclusion of sub-grid-scale turbulent production of
- 218 liquid in mixed-phase cloud from an analytical model of sub-grid-scale moisture variability (Furtado et al., 2016). Differences

between the methods of representing cloud fraction in the PC2 and Smith schemes are detailed in the **Supporting Information**.

220 2.3.2.2 Regional Atmosphere with Cloud-Aerosol Interactive Microphysics scheme (UM_CASIM-100)

UM_CASIM-100 uses the CASIM scheme (detailed by Hill et al., 2015) coupled with the Smith (1990) large-scale cloud scheme (as in Grosvenor et al., 2017). Stevens et al. (2017) previously tested the CASIM scheme within the UM nesting suite in an Arctic cloud case study, showing that it performed well in capturing cloud dissipation; however, the authors did not include sub-grid-scale contributions from Smith (1990) in that study.

CASIM utilises prescribed lognormal aerosol distributions to provide a double-moment representation of cloud particle processes and is the only double-moment setup included in this study. Particle size distributions of five hydrometeors (liquid droplets, ice, snow, graupel, and rain) are each described by a gamma distribution, with prognostic mass mixing ratios and

- number concentrations. Ice number concentrations are diagnosed via a temperature-number concentration parameterisation
- 229 (Cooper, 1986), but require liquid to be present before ice can form; a relationship thought to be important in Arctic mixed-
- phase clouds (e.g., de Boer et al., 2011; Young et al., 2017). Droplet activation follows Abdul-Razzak and Ghan (2000),
- 231 referencing a fixed soluble accumulation mode aerosol number concentration profile of 100 cm⁻³. This profile was

approximated based on aerosol concentration profiles previously measured during summertime in the central Arctic (Kupiszewski et al., 2013).

- 234 CASIM offers user flexibility regarding aerosol processing, as described by Miltenberger et al., (2018). Here we do not impose
- wet-scavenging processes, likely important for capturing cloud-free conditions, for consistency with the simpler single-moment
 liquid microphysics schemes used in the other simulations; however, use of this option will be explored in future work.
- 237 For our CASIM simulation, we adapt the warm ice temperature albedo of the LAM to 72% (at 0 °C), with 80% albedo achieved
- 238 at -2 °C, to match the parameterisation limits currently used in the Joint UK Land Environment Simulator surface scheme of
- the Global Atmosphere 6.0 global model (under the assumption that snow is present on the sea ice surface). For the drift period,
- 240 we know that snow was indeed present on the surface from first-hand knowledge and surface imagery; therefore, we use this
- 241 simulation to test the effect of such an increased albedo at warmer surface ice temperatures on the modelled surface energy
- balance. An example simulation utilising the CASIM scheme with the default Regional Atmosphere albedo settings used in
- 243 UM_RA2M and UM_RA2T, to demonstrate the radiative impact of CASIM alone, is described in the Supporting Information
- 244 (Sect. S2).

245 2.4 Comparison methodology and compared parameters

- 246 C_V , q_{liq} , and q_{ice} from each model simulation were ingested by Cloudnet to calculate *LWC* and *IWC*. Within these calculations, 247 Cloudnet filters model data for values outside the range observable by the instrumentation used; for example, q_{ice} data are 248 filtered for values which would be beyond the observable range of the radar.
- We use an additional metric alongside C_V based on total condensate for comparisons between our measured and modelled clouds; a total water content (*TWC*) mask where the grid-box is considered cloudy; this mask is set to 1, when $TWC \ge 1 \times 10^{-7}$ for 6 kg m⁻³ below 1 km, and $TWC \ge 1 \times 10^{-7}$ kg m⁻³ above 4 km, with vertical interpolation in between (following **Tjernström et al., 2021; Fig. S3**). While this mask will not capture fractional cloud at cloud boundaries, averages of this mask are directly comparable between the observations and models. It acts as a comparison metric based solely on cloud water contents, which
- are prognostic in every simulation, and does not depend on a specific definition of e.g., cloud fraction.
- In addition to a full overview of model performance over the drift, we further split our data into sub periods to aid our interpretation of the comparisons between the measurements and models. The sea ice melt/freeze transition was captured by the measurements; **Vüllers et al. (2021)** identified the sea ice freeze onset date as 28 Aug and defined sub-periods throughout the drift based on consistent meteorology (see **Fig. 2g**). We concentrate on the sea ice melt and freeze periods separately and on shorter episodes within these periods; one during the sea ice melt (14—18 Aug) and one during the freeze (4—8 Sept).
- 260 3 Results

261 3.1 Surface radiation

Figure 2 shows measured and modelled time series of net surface shortwave (SW_{net}) radiation, LW_{net} , and the combined surface net radiation (R_{net}) during the AO2018 drift period. All radiative quantities are defined as positive downwards.

264 All models overestimate SW_{net} (Fig. 2a) with respect to measurements, with ECMWF_IFS and UM_CASIM-100 in better 265 agreement with observations than UM_RA2M and UM_RA2T. From Fig 2d, all simulations fail to capture strong longwave

266 net emission likely related to cloud-free episodes (e.g., 20-21 Aug) and sporadically predict such cloud-free conditions (and

267 net longwave emission) when clouds were observed (e.g., 2 Sep).

- 268 Considering the melt and freeze periods separately, the measured R_{net} is often negative after 28 Aug (Fig. 2g) driven by LW_{net} , 269 while SW_{net} decreases with the declining solar elevation angle (Fig. 2a). In contrast, the models' net radiation is not typically negative until after 8-9 Sep, excluding a short negative period at 2 Sep driven by the lack of modelled cloud (as suggested by 270 271 strong net longwave emission; Fig. 2d). This delay would likely affect the freeze onset if the models were fully coupled to a
- 272 sea ice model; as such, this feedback may be active within the (simple) coupled atmosphere-sea ice system of the IFS.
- 273 Probability Density Functions (PDFs) of these data, split between melt and freeze periods (Fig. 2b-c, e-f, h-i), reveal some 274 clear distinctions in model capability. SWnet PDFs vary substantially between the models during the melt period (Fig. 2b); no 275 simulation captures the observation distribution well. Observed SW_{net} from the ship has a median of +18.2 W m², with each 276 simulation producing medians at greater values (UM_CASIM-100 = +18.7 W m⁻²; ECMWF_IFS = +21.6 W m⁻²; UM_RA2M 277 = +40.5 W m⁻²; and UM_RA2T = +41.9 W m⁻²). While the medians for UM_CASIM-100 and ECMWF_IFS are in good 278 agreement with observations, both exhibit a too-narrow distribution. These too-narrow distributions - which also all lack a very 279 high positive tail - suggest that the modelled cloud cover is too consistent, likely related to the lack of cloud-free episodes 280 indicated by the LWnet data (Fig. 2d). Median SWnet of both the UM_RA2T and UM_RA2M PDFs is much too high, with 281 non-negligible occurrences > +50 W m⁻². The improvement of UM_CASIM-100 over UM_RA2T and UM_RA2M indicates 282 that both the surface albedo used by default in the Regional Atmosphere configurations is too low and the updated cloud physics 283 description of CASIM improves the modelled cloud-radiation interactions. A trial simulation utilising the cloud physics setup 284 of UM_CASIM-100 alongside the default Regional Atmosphere surface albedo parameterisation inputs (as used in UM_RA2M 285 and UM_RA2T) shows that the double-moment cloud physics representation alone does improve radiative properties with 286 comparison to the standard configurations (see Supporting Information); however, the combination of improved cloud-287 radiation interactions and an updated surface albedo (as shown here in UM_CASIM-100) provides the best agreement between 288 the UM and our observations.
- During the freeze period, measurement estimates of SW_{net} peak at +7.9 W m⁻², while ECMWF_IFS, UM_CASIM-100, 289
- UM_RA2M, and UM_RA2T have maxima at +10.0, +10.4, +25.0, and +26.6 W m⁻² respectively (Fig. 2c). The peak modelled 290
- SWnet remains too high in all simulations but, in contrast to the melt period, all PDFs are now too broad. ECMWF_IFS and 291 292 UM_CASIM-100 perform best with comparison to observations (both with a positive bias of less than +3 W m⁻² at their peaks).
- 293 However, both UM_RA2M and UM_RA2T have a broad bimodal structure, with the secondary peak in better agreement with
- 294
- the observations than their maxima. Both UM_RA2T and UM_RA2M are largely in better agreement with observations during 295 the freeze period than during the melt; this improved agreement is likely due to either a better representation of incoming
- 296
- shortwave radiation or the surface albedo; the surface temperatures decreases through the transition to sea ice freezing
- 297 conditions, and Fig. S4 indeed shows that the albedo modelled during the freeze for UM RA2M and UM RA2T is in better
- 298 agreement with observational estimates than that modelled during the melt period.

299 During the melt period, LW_{net} aligns well between the measurements and models; however, all simulations produce a narrower 300 PDF than the observations and largely miss the tail < -20 W m⁻² (Fig. 2e) resulting from observed cloud-free episodes at 15— 301 16 Aug, 20 Aug, 22 Aug, and 26 Aug (Fig. 2d). Despite this, each simulation performs well in replicating the median of the 302 PDF, with a maximum model-observation difference of -1.9 W m⁻² (UM_RA2T). As with SW_{net}, model-observation agreement generally improves during the freeze period, with UM_RA2M, UM_RA2T, and ECMWF_IFS producing PDFs 303 304 closely matching the observations, with median values at -9.4, -11.5, and -6.8 W m⁻² respectively compared with an observation peak of --6.5 W m⁻² from the ship estimates. Each of these cases also reproduces the negative distribution tail 305 306 missed by all simulations during the melt (Fig. 2f). UM_CASIM-100 displays a narrower distribution with fewer negative values, yet still performs equally well in reproducing the median of the LW_{net} PDF (with a bias of -5.5 W m⁻²). With the 307 308 exception of the too-narrow UM_CASIM-100 PDF, this improved agreement in LW_{net} indicates that cloud cover is indeed 309 captured better by the models during the freeze, and remaining discrepancies in the SW_{net} comparisons may indeed be related more so to cloud microphysical structure or surface properties. 310

- To investigate this relationship in more detail, we split our radiation data into the periods of consistent meteorology indicated on **Fig. 2g.** In agreement with **Fig. 2**, model SW_{net} and downwelling shortwave radiation (SW_{\downarrow}) biases are at their greatest during period 3 (**Table 4**). All simulations similarly exhibit their greatest LW_{net} biases during period 3 (**Table 4**); less cloud cover was observed during this period with relation to other periods during the drift (**Vüllers et al., 2021**). Both UM_RA2T and UM_RA2M perform best in terms of SW_{\downarrow} during period 3; however, both perform particularly poorly in SW_{net} , indicating that their surface albedo is not representative of observations. During period 4, UM_CASIM-100 performs very well in terms of these SW_1 biases, suggesting the modelled cloud structure was in good agreement with observations. However, ECMWF_IFS
- **318** exhibits the smallest SW_{\downarrow} biases of the four simulations during periods 5 and 6; periods when the sea ice was beginning to
- 319 freeze.
- Each of these simulations highlight that small SW_{\downarrow} biases do not necessarily produce similarly small SW_{net} biases, as both the
- 321 modelled cloud properties and surface albedo need to be representative to remedy the SW_{net} discrepancies. In UM_RA2T and
- 322 UM_RA2M, the surface albedo is poorly captured, as indicated by the consistently high SW_{net} biases; however, ECMWF_IFS
- and UM_CASIM-100 perform better in terms of surface albedo, with UM_CASIM-100 performing the best with the smallest
- SW_{net} biases across the four sub-periods considered. Further discussion of the surface albedo comparison is included in the
- 325 Supporting Information.
- 326 LW_{net} biases do not exceed +5.5 W m⁻² over periods 4—6; however, biases are greater (up to +16.3 W m⁻² during period 3;
- **Table 4**) due to the models' inability to reproduce cloud-free conditions. This relationship with cloud cover influences the surface downwelling longwave (LW_{\downarrow}) biases: with the exception of the standard UM configurations during period 5, all LW \downarrow biases are positive (**Table 4**).
- Combining these radiative components, we find that R_{net} is overestimated by all simulations during the melt (with UM_CASIM-100 and ECMWF_IFS performing better than UM_RA2M and UM_RA2T; **Fig. 2h**), largely driven by too much
- surface SW_{net} when cloud is present in reality, thus indicating that the model surface albedo is too low and thus does not reflect
- enough SW_{\downarrow} . On the other hand, there are also non-negligible occurrences of too much modelled cloud when the conditions

334 should be cloud-free, driving strong LW_{net} biases at these times. While agreement with observations largely improves during

- the freeze period, these discrepancies still exist in the SW_{net} data. While the SW_{net} biases may be strongly influenced by errors in the surface albedo, and thus beyond the scope of this study, the role of cloud structure in SW_1 biases and the LW_{net} emission
- in the surface albedo, and thus beyond the scope of this study, the role of cloud structure in SW_{\downarrow} biases and the LW_{net} emission
- episodes missed by each simulation are driven by the description of cloud: in the following sections, we investigate the cloud
- 338 macro- and microphysical structure and surface properties to explain these radiative differences.

339 3.2 Cloud properties

To evaluate model performance, we use two metrics for cloud occurrence: the model diagnosed cloud fraction, C_V , and the cloud occurrence inferred from cloud water contents, the *TWC* cloud mask. **Figure 3** shows *TWC* and cloud fraction, C_V , calculated from observations using Cloudnet and output by models. *TWC* comparisons indicate that each simulation captures the observed cloud aloft, except for UM_CASIM-100 between 4 and 10 Sep. Below 3 km, observed *TWC* is generally lower in magnitude than the model simulations.

In contrast, all simulations except UM_RA2T fail to reproduce the observed C_V aloft. Low-altitude (below 2 km) cloud cover appears to be captured comparatively better across all simulations. Cloud height simulated by ECMWF_IFS is in reasonable agreement with the observations; however, there are notable periods where the persistence of clouds aloft is not reproduced. For example, the altitude and timing of onset of the (likely precipitating) high clouds at 3—4 Sep is initially captured, but the clouds are not sustained. Cloud layers aloft appear more tenuous also in UM_RA2M and UM_CASIM-100 than in the observations: there are few cases of cloud fractions > 0.5 at altitudes above 3 km.

351 Figure 4a shows mean profiles of C_V over the drift period. Only periods where we have measurement data are included in these 352 profiles for fair comparison. Note that cloud fraction below 0.15 km is not evaluated against observations here due to low-353 altitude measurement limit of the cloud radar. Supporting qualitative interpretation of Fig. 3, model-observation agreement of 354 C_V is best at low altitude (below 1 km); however, all simulations produce too much very low (between 0.15 and 0.5 km) cloud. 355 Modelled near-surface C_V (between 0.15 and 0.5 km) is up to 16% too high (UM_RA2T). However, we can speculate that the 356 frequent fog episodes reported during the ice drift (Vüllers et al., 2021) may be somewhat captured by the models, as indicated by mean values of C_V below 0.15 km of 82%, 72%, 53%, and 39% respectively for UM_RA2T, UM_RA2M, UM_CASIM-357 358 100, and ECMWF_IFS. All simulations except UM_RA2T perform poorly aloft: ECMWF_IFS, UM_RA2M, and 359 UM_CASIM-100 strongly underestimate C_V between 1 km and 8 km, with UM_CASIM-100 and UM_RA2M reproducing less than 20% of the observed C_V at 4.5 km. Only the UM_RA2T C_V profile agrees well at altitude, with particularly good agreement 360 between 0.5 and 2 km. In fact, C_V between 2 km and 5.5 km agrees best with observations out of the four simulations considered. 361

Figure 3 highlights that the observations, UM_RA2T, and (to an extent) ECMWF_IFS have a C_V field scaling largely as either 0 or 1, whereas UM_RA2M and UM_CASIM-100 are more likely to have a fractional cloud cover aloft, thus producing a poor comparison with our observations (**Fig. 4a**). Despite this, qualitative model-observation comparisons of *TWC* indicate that the models are performing well. Further discussion of these differences is included in the **Supporting Information**. In summary, the Cloudnet calculation of C_V from observations is not directly equivalent to our model cloud fractions and such comparisons, in isolation, should be approached with caution in the Arctic. To bypass this issue, we also use a cloud mask built from *TWC*

data to aid interpretation of our results. The observed *TWC* cloud mask (**Fig. 4b**) differs from the mean C_V profile, with a subtle bimodal structure peaking at approximately 0.5 and 4.5 km (with a minimum around 2 km).

- All simulations overestimate cloud occurrence below 2.5 km (Fig. 4b), in contrast to the underestimation between 1 and 2.5
- km shown in the C_V data (Fig. 4a). Mean observed cloud occurrence only reaches 75% between 0.15 km (lowest radar range
- 372 gate) and 0.5 km, while UM_RA2M and UM_CASIM-100 have more than 98% cloud occurrence at 0.2 km. UM_RA2T
- performs slightly better, peaking to only 92% at 0.2 km; however, the improvement is not as significant between UM_RA2T
- and UM_RA2M/UM_CASIM-100 as is suggested by the mean C_V profiles (Fig. 4a). ECMWF_IFS peaks at a slightly higher
- altitude, overestimating cloud occurrence by 33% at approximately 0.5 km (**Fig. 4b**).
- 376 Above 2 km, ECMWF_IFS, UM_RA2M, and UM_RA2T perform similarly; the greatest difference aloft occurs at 4.5 km,
- 377 where there is a minor peak in the mean observed cloud occurrence (up to 41%; Fig. 4b). ECMWF IFS produces only 28%
- 378 cloud cover at this altitude. UM_CASIM-100 cloud occurrence monotonically decreases with altitude above 3.5 km, producing
- 379 only 20% cloud cover at 4.5 km, in agreement with the qualitative findings of Fig. 3. Therefore, with the exception of
- 380 UM_CASIM-100, the TWC cloud masks indicate that modelled cloud occurrence aloft is, in fact, in reasonable agreement with
- 381 observations, in contrast to the trends indicated by the C_V data (Fig. 4a). These data suggest that the C_V comparisons may be
- misleading if used in isolation, likely due to the different methods for representing cloud fractions and associated sub-grid-
- 383 scale variability in models (see **Supporting Information**).
- Averaged in-cloud water content profiles are shown in Fig. 4c—d. Adiabatic *LWC* calculated from observations with Cloudnet
 is shown in Fig. 4c. This adiabatic assumption was used in place of the HATPRO *LWP* due to the data quality issues introduced
 to the latter because of the frequent occurrence of fog at altitudes below the lowest radar range gate (0.15 km; discussed further
- in Appendix A).
- 388 The adiabatic LWC peaks between 0.5 and 1 km then decreases steadily with altitude between 1 and 3 km. All simulations 389 overestimate in-cloud LWC between 1 and 3 km; however, below 1 km, each simulation (except UM_RA2T) performs reasonably well. At 0.5 km, UM_RA2T underestimates by 47 %, while UM_CASIM-100 overestimates by just 10 % and 390 391 UM_RA2M and ECMWF_IFS are in reasonable agreement with observations. UM_RA2T and UM_RA2M have bimodal 392 distributions, with peaks below 0.5 km and around 2 km, perhaps linked to their common use of the Wilson and Ballard (1999) 393 microphysics scheme. The increase in LWC towards the surface in UM_RA2M is suggestive of fog, and UM_RA2M is the 394 only simulation to display this vertical structure. The mean LWC calculated for ECMWF_IFS is consistent with altitude between 0.5 and 2 km; however, there is more variability at 2 km than at lower altitudes, indicating that this may be a more 395 dominant liquid cloud layer at some time periods. Only UM_CASIM-100 displays a similar shape to the observations, yet its 396 397 *LWC* is often greater than the observed *LWC* at all altitudes above 1 km.
- All simulations agree with the Cloudnet-calculated *IWC* above 4 km (**Fig. 4d**); in fact, UM_RA2M performs particularly well
- across the entire vertical profile. ECMWF_IFS and UM_CASIM-100 also agree well for most of the profile apart from slight
- 400 overestimations below 1.5 km (though still within one standard deviation of the observed mean). UM_RA2T overestimates
- 401 below 4 km, producing almost seven times the observed *IWC* (0.019 g m⁻³ versus 0.003 g m⁻³) at 0.5 km. Shaded standard
- 402 deviations also indicate that UM_RA2T is also more variable than both the three other simulations and the measurements,

403 consistent with previous studies showing its ice phase is more active than UM_RA2M in polar mixed-phase clouds (Gilbert
404 et al., 2020).

- 405 Column-integrated metrics and surface measurements provide an additional perspective for evaluating model performance with 406 regards to clouds. Measured LWP and precipitation fluxes are shown alongside corresponding model diagnostics in Fig. 5. 407 Cloudnet-filtered LWP is included in Fig. 5a,b for comparison; these data are HATPRO measurements filtered by Cloudnet for bad points (e.g., strong precipitation events). ECMWF_IFS, UM_RA2M, and UM_CASIM-100 produce LWPs in 408 409 reasonable agreement with measurements throughout the full drift period, with the PDFs of Fig. 5b indicating that these LWPs 410 are overestimated slightly with respect to the measurements/Cloudnet data. UM_RA2M overestimates in some periods, for example the LWP peak during the storm of 12 Sep is 230 g m² more than measured (Fig. 5a). In contrast, UM_RA2T 411 underestimates the LWP overall, with few occurrences of $> 200 \text{ g m}^{-3}$ (Fig. 5b). This underestimation of LWC (Fig. 4c) and 412
- 413 LWP (Fig. 5a, b) by UM_RA2T aligns with its overestimation of IWC below 4 km; with too much ice in mixed-phase cloud,
- 414 liquid is depleted too efficiently via the Wegener-Bergeron-Findeisen mechanism.
- Each simulation broadly captures the notable precipitation events measured (**Fig. 5c**—**d**). UM_CASIM-100 and UM_RA2T reproduce the measured total precipitation flux well and capture the short episodes of increased precipitation at 22 Aug, 3 Sep, and 12 Sep. ECMWF_IFS and UM_RA2M also capture some precipitation events; however, the magnitude of these events is best reproduced by UM_CASIM-100. No simulation reproduces the precipitation intensity measured at 8 Sep. While the key precipitation events are largely captured by the models, with each model producing precipitation as predominantly snow rather than rain, the precipitation rates simulated are low and likely contribute to the lack of cloud-free periods as indicated by the *LW_{net}* comparisons shown previously (**Fig. 2d, e, f**).
- 422 These results therefore indicate that the modelled microphysical stru
- These results therefore indicate that the modelled microphysical structure is positively biased in terms of cloud liquid with respect to observations (**Figs. 4c, d—5**). There is a consistent model-observation bias, with all simulations producing too much
- 424 cloud (Fig. 4a, b) below 2.5 km. In ECMWF_IFS, UM_RA2M, and UM_CASIM-100, this cloud contains too much liquid (as
- 425 indicated by positive biases in *LWC* and *LWP*). Only UM_RA2T underestimates the cloud liquid properties due to its active
- 426 ice phase. Figure 6 links the radiation, LWP, and C_V biases of our four model simulations with respect to observations. C_V
- 427 biases are calculated as the model-observation bias below 3 km, where model data below the height of the lowest radar range
- 428 gate (0.15 km) are excluded from the bias calculation. Here, C_V is used in place of the *TWC* cloud mask as the latter is calculated
- 429 from in-cloud *LWC* and is therefore not strictly independent of *LWP*. These linear regressions demonstrate that the positive
- 430 downwelling radiative biases are indeed tied to too much cloud cover within the models, and too much liquid within the
- 431 modelled clouds. The correlations are weaker for R_{net} , likely due to the additional influence of other factors (e.g., surface
- 432 albedo) on the net radiative properties.

433 3.2.1 Influence of CCN concentration

Each simulation overestimates cloud occurrence below 2.5 km and struggles to maintain cloud-free conditions, problems
previously identified for earlier versions of these models. Both Sotiropoulou et al. (2016) and Birch et al. (2012) commented
on the need for variable, representative cloud nuclei concentrations in the IFS and the UM to enable cloud-free periods to be

437 captured. A fixed accumulation-mode aerosol number and mass concentration profile was used in UM_CASIM-100; however,

438 such consistency with altitude is unlikely to occur in reality. While the concentration chosen was based on previous 439 measurements in the Arctic (**Kupiszewski et al., 2013**), aerosol number concentrations are typically very low and 440 heterogeneous within the BL during the Arctic summer (**Mauritsen et al., 2011**; **Tjernström et al., 2014**) yet long-range 441 transport provides comparatively greater, more homogeneous concentrations aloft.

442 An additional simulation with the CASIM scheme was tested, using a more representative CCN vertical profile guided by 443 output from the UK Chemistry and Aerosol (UKCA; Morgenstern et al., 2009; O'Connor et al., 2014) global model. Details 444 on the UKCA model configuration used to obtain these aerosol data are included in the Supporting Information. Using 445 representative aerosol profiles as input to the CASIM scheme (with lower CCN concentrations within the lower troposphere 446 and greater concentrations within the free troposphere; denoted UM_CASIM-AeroProf) can affect the SW_{\downarrow} as expected via the 447 associated influence on N_d and q_{liq} (Fig. 7). Low altitude (below 1 km) clouds have a significantly lower N_d , < 25 cm⁻³, in 448 UM_CASIM-AeroProf than in UM_CASIM-100. This low N_d is expected from periodic episodes of low CCN in the Arctic 449 BL (Mauritsen et al., 2011); cloud residual concentrations of up to 10 cm⁻³ were measured on board Oden during the AO2018 450 expedition (Baccarnini et al., 2021). However, despite the differences in N_d between these two CASIM simulations, q_{iiq} does 451 not differ much as the simulated clouds are not heavily precipitating (and thus cloud lifetime is largely unaffected).). This 452 similarity is also displayed in the diagnosed cloud fractions, related to the comparatively unaffected q_{liq} . Despite the 453 consistency in cloud fractions and q_{lia} , the cloud albedo is subtly lowered (as fewer CCN are available) in UM_CASIM-454 AeroProf, as shown by the SW_1 comparisons in **Fig. 7a**—**b**.

455 3.3 Thermodynamic structure

Differences between modelled and observed cloud properties are likely related to the thermodynamic structure of the atmosphere and how well this is modelled. **Figure 8** shows temperature (T) and water vapour specific humidity (q) from radiosondes and anomalies of each simulation with respect to these measurements. The altitude of the main inversion base identified from the radiosondes is shown in black.

- 460 Each simulation is typically too cold with respect to observations at altitudes just above the main inversion (left column; Fig. 461 8): this anomaly is a consistent feature throughout the drift period and across models, however it is most prominent at the 462 beginning of the drift. These trends indicate that the altitude of the modelled temperature inversion capping the BL is too high, 463 likely driven by too much BL mixing and the associated too-deep cloud layers modelled in each simulation (Fig. 4b). Below 464 the observed inversion, the simulations are typically warmer than measured; for example, at 18 Aug all UM simulations have 465 a particularly strong bias (> 3 K) below the observed main inversion, with ECMWF IFS exhibiting a similar, but smaller, bias. 466 Above approximately 3 km the T biases are typically smaller in magnitude and variable in sign. All UM simulations display 467 similar differences with respect to the radiosonde measurements; for example, each UM simulation exhibits a strong T bias up 468 to 4.4 K at 6.5 km during 9 Sep.
- q biases are typically small throughout much of the atmospheric column (*right column*; Fig. 8), with some instances of larger
 biases. These stronger biases are not confined to the lowest 3 km as with the temperature data. Radiosonde humidity data up to
 22 Aug are variable aloft, and this noise affects the biases calculated over this period. However, a strong moisture bias of >

- 472 0.90 g m⁻³ is evident between 2 km and 4 km over 20—22 Aug in all UM simulations. Similarly, the dry bias (of up to 1.86 g m⁻³) across the UM simulations from 2—4 Sep is notable and is also present, to a lesser extent, in ECMWF_IFS (up to 0.82 g
- 474 m⁻³).
- 475 When these data are simplified into median profiles (Fig. 9), the characteristic biases exhibited by the models become clearer.
- 476 Figure 9(a, c) shows that the T biases are small above 4 km, with all UM simulations exhibiting a slight warm bias and
- 477 ECMWF_IFS exhibiting a slight cold bias. Similarly, moisture biases are negligible above 4 km in all simulations (Fig. 9b, d).
- 478 However, below 4 km strong biases emerge.
- From the surface up to 0.5 km, there is a decreasing positive *T* bias in all simulations. However, the positive surface *T* bias is reduced during the freeze period for UM_RA2M and UM_RA2T (from +0.28/+0.31 K to +0.20/+0.14 K, respectively) while it intensifies from +0.52 K (+0.46 K) to +0.90 K (+0.56 K) for ECMWF_IFS (UM_CASIM-100) (**Fig. 9c**).
- 482 During the melt period, all simulations underestimate the temperature between 1 and 3 km, yet there is a clear bimodal structure 483 evident in each profile with secondary negative peaks at lower altitudes (Fig. 9a). ECMWF_IFS remains too cold across a 484 deeper layer than the UM simulations, between 0.4 and 3 km. Both the IFS and the UM exhibit strong (up to -1.54 K) biases 485 at 1.75 km. The negative *T* bias layers at lower altitudes differ in height between the models, with ECMWF_IFS reaching – 486 0.94 K at 0.85 km while the UM simulations exhibit negligible positive biases at this height. The secondary peak in the UM 487 simulations is in fact lower in altitude, at 0.4—0.5 km. *T* biases are smaller than during the melt period, reaching up to -1.06 488 K (ECMWF_IFS) between 0.65 km and 1 km, and the negative bias peak at 2 km seen previously is no longer present (Fig.
- 489 **9**c).
- 490 Similarly, each simulation exhibits a positive q bias towards the surface. These biases change little between the melt and freeze
- 491 periods (Fig. 9b, d); ECMWF_IFS produces the greatest bias in both periods (+0.31 g m⁻³ during both the melt and freeze),
- while UM_RA2T produce the lowest (+0.24 g m⁻³ and +0.10 g m⁻³ during the melt and freeze, respectively). ECMWF_IFS is
 too dry, as well as too cold, between 0.5 and 4 km, while the UM simulations are typically too moist (though variable; Fig.
- 494 **9b**).

There is less variability in the *q* biases during the freeze period. The UM simulations in particular exhibit only small *q* biases
above 0.5 km (Fig. 9d). ECMWF_IFS performs well above 2 km; however, similar to trends identified during the melt, it is
again too dry between 0.5 and 2km.

498 Figure 10 similarly shows the median T and q biases modelled by UM_CASIM-100 and UM_CASIM-AeroProf over the 499 whole AO2018 drift period. Even though the clouds are likely more representative of the high Arctic environment in 500 UM_CASIM-AeroProf than UM_CASIM-100, the thermodynamic biases are largely unchanged from the approximated 501 aerosol input of UM_CASIM-100. We speculate that these biases would perhaps differ more so if the modelled clouds were 502 precipitating strongly in either simulation, thus affecting q_{lig} and cloud lifetime. However, considering each of the UM LAM 503 configurations shown here, there is little variability in their thermodynamic biases despite the differences in their representation 504 of aerosol inputs, cloud microphysics, and large-scale cloud scheme. Interestingly, these biases are shared by the UM global 505 model (UM_GLM, shown in grey; Fig. 9) used to generate lateral boundary conditions for each LAM. UM_GLM exhibits

506 similar biases as its high-resolution LAM counterparts, suggesting that these thermodynamic biases are sourced from the 507 driving model itself.

508 3.3.1 Influence of the UM driving model

509 To investigate how much the large-scale forcing is influencing the UM biases, an additional test was performed over a subset

510 of the drift (31 Aug to 5 Sep) using ERA-Interim to initialise the UM global model (labelled UM_RA2M-ERAI-GLM; Fig

511 11). This test was designed to evaluate whether the initial conditions of the global driving model, and therefore the associated

512 data assimilation (DA) systems used to derive the operational analyses used for initialisation, are largely responsible for the

513 LAM thermodynamic biases we have found in this study. For this test, we used the UM_RA2M configuration for the LAM,

514 and all global model physics options remained the same as in previous simulations (as described in Table 2); the only difference

- 515 was in the initial conditions of the global model.
- 516 We find that UM_RA2M-ERAI-GLM exhibits T and q biases following ECMWF_IFS between the surface and 3 km, inheriting

517 the ECMWF_IFS near-surface temperature bias discussed previously (Fig. 11a). Over this short time period, the UM

518 simulations do not have this bias. Above 3 km, UM_RA2M-ERAI-GLM follows UM_RA2M and UM_GLM, exhibiting a

519 slight warm bias (0.45 K at 5.5 km) in contrast to the cold bias of ECMWF_IFS (-0.65 K at the same altitude).

520 These results confirm that the UM LAM biases within the lower atmosphere shown in Figs. 8 and 9 are driven by biases in the 521 large-scale forcing from the global model, which may be a result of the model physics itself or the DA used to produce the 522 operational analyses. Given that the Arctic lacks good observational data coverage, DA systems still rely heavily on their model 523 components when creating the analysis products used for model initialisation; therefore, improved observational data coverage 524 may improve these biases in the DA systems and thus global model initial conditions. In the meantime, a different LAM 525 configuration, with a larger nested domain with lateral boundaries further from the science region of interest may break the 526 relationship between global model and LAM biases shown here.

527 Links between cloud properties and thermodynamic biases 3.4

528 To better understand how the model thermodynamic biases relate to cloud properties in each simulation, we split our drift period further into four subsections – periods 3 to 6, as illustrated in Figs. 2 and 8 – to study periods of consistent meteorology. 529 530 Mean equivalent potential temperature (θ_e) and q profiles measured by radiosondes during these periods are shown in Fig. 12. 531 Of the four periods considered, period 3 had cloud-free conditions most often. Periods 5 and 6 were similar; both were cloudy

532 and influenced synoptically by three different low-pressure systems over their duration.

533 Cloud properties and thermodynamic biases during periods 3 and 6 are shown in Fig. 13 (with similar analysis for periods 4 534 and 5 included as Fig. S7). As mentioned previously, mean observed cloud occurrence was lower for period 3 than in any other period during the drift. All simulations overestimate the TWC cloud mask below 2 km, with each UM case producing a bimodal 535 536 mean profile peaking below 0.5 km and at 1.8 km (Fig. 13a). Such bimodality is less clear with ECMWF_IFS; it exhibits a 537 lower layer with cloud top at 1 km and a more prominent than a secondary layer at 1.6 km, although the separation of these 538 layers is not as distinct as in the UM cases. The secondary layer at 1.6 km has a greater LWC than the lower layer, with a peak

of 0.14 g m⁻³ (**Fig. 13b**). The bimodal cloud structure is also liquid dominated in the UM simulations, where both peaks reach around 0.1 g m⁻³ (and even exceed this magnitude in the 1.8 km layer), across all three configurations.

- 541 Considering the corresponding median *T* biases (Fig. 13d), there are clear correlations between negative biases and modelled
- cloud height, suggesting that cloud top *LW* cooling is a contributing source of these biases. The lower layer (0.75 km) bias in
- 543 ECMWF_IFS is particularly striking, reaching -4.45 K, and corresponds with the top of a large fraction of liquid-dominated
- cloud (**Fig. 13a, b**). The mean *LWC* modelled at this altitude is over three times greater than was observed, with cloud frequency
- overestimated by 73%. q biases (Fig. 13e) are negligible for ECMWF_IFS between 0.75 and 1 km, yet positive below and
- above this altitude range. The coinciding overestimation of cloud at these heights indicates that the IFS has simulated too much
- condensation, driven by the availability of too much moisture. Similarly, all UM simulations exhibit a moist bias between 0.5and 1.6 km, between the modelled cloud layers, and exhibit small dry biases where too much cloud is modelled (e.g., 0.5 km).
- 549 These results indicate that both models have an excess of water vapour, particularly below 3 km, where negligible/dry biases
- 550 with comparison to observations are in fact an artefact of too much condensation and resulting cloud cover. This excessive
- cloud cover, on the other hand, has a negative effect on the temperature bias profile, resulting in strong cold biases.
- The models are in good agreement with the observed *LWC* during period 6, with the exception of UM_CASIM-100 which produces double the observed *LWC* at 0.7 km (**Fig. 13g**). In particular, ECMWF_IFS performs well below 2.5 km in terms of
- 554 *LWC*, *IWC*, and cloud occurrence, with the largest difference in the latter occurring at approximately 0.7 km (100% in
- ECMWF_IFS in comparison to 79% observed). Consequently, the T biases are smaller during period 6 than period 3 for
- ECMWF_IFS. However, these *T* biases are still present (**Fig. 13i**), peaking at -0.96 K at 0.65 km, likely caused by this minor
- 557 overestimation in cloud cover, albeit with representative microphysics.
- The magnitude of the *T* biases for the UM simulations is similar between both periods, likely caused by this model producing up to 100 % cloud cover at low altitude. All UM simulations exhibit stronger *T* and *q* biases below 1 km than ECMWF_IFS during period 6 (**Fig. 13i**—**j**). Strong negative *T* biases accompany the overestimation of cloud cover in each UM case, and the improved model-observation agreement of *LWC* by UM_RA2M and UM_RA2T does little to alleviate these biases with comparison to the overestimated *LWC* of UM_CASIM-100. Simply, there is too much low-altitude (below 1 km) cloud causing
- too much cloud-top radiative cooling in the model, no matter which representation of cloud microphysics or large-scale cloudis used.
- 565 However, while the q biases were negligible when ECMWF_IFS exhibited particularly strong T biases during period 3, q
- biases for the UM become notably negative for the same effect during period 6; this is the largest dry bias simulated over the
- four periods considered (with periods 4 and 5 included in the **Supporting Information**). The surface q bias for the UM
- 568 simulations is smaller during period 6 than during period 3, and the tropospheric q bias is positive less often, suggesting the
- 569 positive moisture bias hypothesised previously (leading to too much condensation and cloud cover) is not ubiquitous in the
- 570 model. In fact, results shown in Fig. 13, and Fig. S7 for periods 4 and 5, suggest that either the increased synoptic activity or
- 571 freezing sea ice conditions (or both) of periods 5 and 6 acts to reduce this moist bias in the UM.
- 572 In summary, both models exhibit strong negative T biases at altitudes coinciding with too much liquid-dominated cloud (e.g.,
- 573 Fig. 13a, b, d), likely caused by the consequent enhancement of cloud-top radiative cooling. q biases improve where cloud is

574 modelled during the melt period (Fig. 13a, e), suggesting that the q field was perhaps too moist below 3 km to begin with,

leading to too much condensation and excessive cloud cover. However, this hypothesis does not appear to be valid during the freeze nor at altitude, as indicated by the negative q biases above 2.5 km which occur where more cloud was observed than

577 modelled: for example, 2.5 to 4 km during period 3 for all simulations (**Fig. 13a, e**), or 2.5 to 3.5 km for the UM simulations

578 during period 6 (Fig. 13f, j). In these instances, our models produce too little cloud as they are too dry to facilitate cloud

formation. With underestimated cloud formation, the models are also slightly too warm (approximately 0.3 K) due to the

580 missing radiative cooling occurring at these altitudes in reality.

581 While the model *T* biases align well with their overestimation of cloud cover, our analysis thus far does not account for the
582 height of the capping inversion. Therefore, incorrect placement of cloud in the models, or a too-deep or too-shallow modelled
583 BL, could be contributing to these biases and thus could affect the interpretation of our results.

Figure 14 shows the strongest temperature inversion base identified from each model simulation and the radiosonde measurements. In each dataset, the strongest inversion below 3 km was identified (following Vüllers et al., 2021); if a weaker inversion was modelled at a lower altitude which was closer to the inversion base identified from the radiosonde, the model inversion height was adjusted accordingly. In keeping with previous analysis, radiosonde and IFS data were interpolated to the UM vertical grid for fair comparison; this procedure smooths some high-altitude detail in the radiosonde profiles, such that the strength of some higher-altitude inversions is reduced causing weaker low-altitude inversions to be identified as the primary inversion instead.

591 These results indicate that the strongest (unadjusted) inversion in each simulation is often too high (grey points, Fig. 14), and 592 weaker inversions at lower altitude are typically in better agreement with identified inversions from radiosondes. Low inversion 593 bases (below approximately 0.5 km) are consistently overestimated in each simulation, particularly during the melt period (not 594 shown), supporting our previous deduction that the model inversions were often too high. The detection algorithm does fail to 595 capture some inversions, predominantly during the freeze period, and instead underestimates the modelled inversion base 596 during this time window with comparison to measurements (lower right-hand points in each panel).

597 Modelled and observed temperature profiles were scaled using these identified inversions to remove the differences in inversion 598 height from our interpretation of the model biases (Fig. 15). When averaged over the full drift, the models are largely biased 599 warm below the inversion and cold above (up to 3 km; Fig. 15a), with the exception of UM_CASIM-100 which also exhibits 600 a subtle cold bias just below the inversion. This warm below/cold above signal is more consistent between the models during 601 the melt period (Fig. 15b). Above the inversion, ECMWF_IFS exhibits a stronger cold bias than the UM simulations. The 602 shape of the scaled profile is rather consistent between the melt and freeze with ECMWF_IFS; the model is consistently too 603 warm below the inversion, and too cold above, with comparison to radiosonde measurements. However, the UM simulations, 604 particularly UM_RA2M, are partially biased cold below the inversion during the freeze. As previously mentioned, biases during 605 the freeze period must be interpreted with caution as the inversion detection algorithm performed less well during this time 606 window, with several modelled inversions missed. However, these scaled T bias profiles support our previous hypothesis that 607 cloud longwave cooling is producing colder thermodynamic conditions in the models than were observed, irrespective of the

- differences between modelled and observed inversion heights. Similarly, the warm surface bias indicated previously can beinterpreted to span most of the lower troposphere below the main inversion base, rather than solely near the surface.
- 610 4 Discussion
- 611 4.1 Surface radiative balance

612 4.1.1 Shortwave

The small SW_{\downarrow} biases exhibited by the standard UM configurations concurrent with a more significant SW_{net} bias indicate that the modelled surface albedo is likely too low. While the observed albedo may be biased high due to its calculation from a spatially small sample of sea ice (directly surrounding the ship), the UM surface albedo parameterisation has previously been shown to be too low in the high Arctic (**Birch et al., 2009; 2012**). The temperature and albedo limits used in the standard Regional Atmosphere parameterisation have been increased since **Birch et al. (2009, 2012**); however, it is clear from **Fig. 2** that the snow-on-sea-ice parameterisation limits tested here with ECMWF_IFS and UM_CASIM-100 (currently used in the Global Atmosphere model configuration) produce a better comparison with our high Arctic measurements.

620 4.1.2 Longwave

621 The root of the LW error in each simulation is likely the >90% liquid-dominated low cloud occurrence which is not 622 representative of the observations (Fig. 4b). This problem has been previously identified in the high Arctic with both models 623 used in this study (Birch et al., 2012; Sotiropoulou et al., 2016) and recent model improvements/microphysical changes have 624 not sufficiently improved model performance in this regard. The positive LW biases are consistent with the too-warm surface 625 T biases in all simulations (Figs. 9, 10), which is also consistent with previous findings with both models (Birch et al., 2009; Sotiropoulou et al., 2016) and with the ERA-Interim reanalysis product (Jakobson et al., 2012; Wesslén et al., 2014). Figures 626 627 9 and 10 suggest that the UM simulations are perhaps better at capturing the near-surface T over the freeze, while ECMWF_IFS 628 consistently has a warm surface bias regardless of season. Tjernström et al. (2021) suggest that surface is actually warmed by 629 the atmosphere in the IFS, not the opposite, as indicated by the enhanced downward sensible heat flux, in combination with 630 diminished SW_{\downarrow} with comparison to observations.

Given these results, we suggest that excessive cloudiness is likely a contributing factor to the warm surface bias in all simulations. In particular, it is noteworthy that UM_CASIM-100 performs most poorly of the UM simulations. This result is disappointing given the improvement of UM_CASIM-100 over the standard Regional Atmosphere configurations in both SW_{\downarrow} and SW_{net} . Including CASIM aerosol processing through wet scavenging – thus enabling cloud dissipation (e.g., **Stevens et al., 2017**) – may rectify this issue, or the representation of prognostic ice nucleating particles in place of a simple diagnostic relationship between temperature and cloud ice number concentrations (e.g., **Varma et al., 2021**). These pathways will be explored in future work; however, it is highly likely that other meteorological factors and incorrect model processes are

638 contributing to this warm surface bias across all of our simulations, in addition to cloudiness.

639 4.2 Lower troposphere

640 4.2.1 Temperature

641 Temperature biases are strongest within the lowest 3 km of our model domains (Figs. 9, 13); this is also the altitude range over 642 which the models overestimate cloud occurrence. With too much cloud, cloud top radiative cooling likely lowers the 643 temperature too efficiently; this, coupled with incorrect cloud positioning (e.g., period 3; Fig 13), gives a cold bias with respect 644 to our observations, above the observed main capping inversion. Where the liquid (and ice) phase is modelled more effectively 645 -e.g., ECMWF_IFS during period 6 (Fig. 13) – the associated median biases are smaller ($< \pm 1$ K), supporting this conclusion.

646

The dipole in T errors shown in Figs. 8 and 9, with a positive bias towards the surface below a negative bias between 0.5 and 647 3 km, suggests that heat and moisture are not being sufficiently transported upwards from the surface or downwards from

648 cooling at cloud top. This T bias is present in all simulations during both the melt and freeze periods and could result from the

649 models failing to reproduce the structure of more than one strong observed inversion, instead exhibiting comparatively smooth

- 650 T profiles. As shown by Fig. 14, low-altitude T inversions are often overestimated by the models, particularly during the melt
- 651 period (not shown): this too-deep surface mixed layer likely results in incorrect cloud placement, leading to thermodynamic
- 652 model-observation biases on a 1-to-1 comparison. Our scaled thermodynamic analysis (Figs. 14, 15) indicates that, while the
- 653 models are often incorrectly placing the temperature inversion (consistent with previous findings; Birch et al., 2012), the
- 654 relationship between too much cloud and strong negative T biases suggested by Fig. 13 appears to be robust under these scaled
- 655 height adjustments by the inversion base, and that the simulations are still largely too warm below the inversion.

656 Both Sotiropoulou et al. (2016) and Tjernström et al. (2021) found a similar vertical structure of the temperature biases with 657 the IFS model, with positive biases within the lower 0.5 km of the atmosphere and a consistent cold bias present around 1 km. 658 Tjernström et al. (2021) found that this cold bias intensifies with time during 3-day forecasts, indicating that it is made worse 659 by processes within the model. They hypothesised the mid-level convection parameterisation triggering too-efficiently within 660 the IFS could be transporting water vapour out of the BL, resulting in too much condensation to form cloud. While our UM 661 LAM simulations do not employ such a convection scheme, the global driving model does: this parameterisation acts in addition 662 to shallow convection, e.g., representing convection in mid-latitude storms, or above the BL where the surface layer is stable. 663 Given the apparent close relationship between the biases exhibited by the LAM and global model (Fig. 9, 11), we conducted a 664 short 6-day test with the global mid-level convection scheme switched off; this test caused over an order of magnitude increase 665 in the UM_GLM cold biases shown in Fig. 11 (not shown). Given the short duration and extreme "on-off" nature of this test, 666 these results do not provide conclusive evidence that the mid-level convection scheme is not contributing to the thermodynamic 667 biases shown here. Further investigation into vertical transport and mixing of scalars (temperature, moisture and clouds) is 668 needed to confirm the origin of these thermodynamic biases. Specifically, more investigation into vertical transport and mixing 669 of scalars (temperature, moisture and clouds) is needed; however, this investigation is beyond the scope of this paper.

670 4.2.2 Moisture

- 671 During the melt period, our results indicate that the UM is particularly moist throughout much of the troposphere (Fig. 9b),
- 672 suggesting that the melting ice is enabling a too-great moisture source from the surface to the atmosphere. However, this

tropospheric bias appears to be rectified during the freeze, while the surface bias remains (Fig. 9d); therefore, the hypothesised
melting ice source is likely not the only contributor of this moisture bias. Latent heat fluxes measured during the expedition
indicate no significant change between the melt and freeze periods (not shown); therefore, the hypothesised increased moisture

676 flux during the melt is unlikely.

Given the close relationship between our UM LAM and global model biases (**Figs. 9, 11**), increased poleward moisture transport introduced at the lateral boundary conditions from the mid-latitudes could partly explain these biases. This phenomenon has been previously identified to be a consequence of climate change and may promote increased cloudiness in the polar regions (e.g., **Held and Soden, 2006**; **Vavrus et al., 2009**; **Allen et al., 2012**; **Bender et al., 2012**). The moist surface bias is also present over both the melt and freeze in ECMWF_IFS; however, ECMWF_IFS is routinely too dry between 0.5 and 4 km, in contrast to the UM. Instead, the IFS traps too much moisture in the lowest 0.5 km, suggesting that the upward transport of moisture may be insufficient, the cloud sink above 0.5 km is too great, or there are consistent biases introduced via

- assimilation of data other than the radiosonde data (e.g., satellite).
- The moist bias exhibited by ECMWF_IFS towards the surface has previously been highlighted by Sotiropoulou et al. (2016),

686 who suggested that this problem may explain why this model struggles to reproduce humidity inversions above the BL. There

are instances where negative T biases coincide with negative q biases at altitudes just above the main temperature inversion

688 (for example, at 27 Aug; Fig. 9). Moisture inversions have often been observed during the Arctic summertime (Sedlar et al.,

2012; Nygård et al., 2014); ECMWF_IFS fails to reproduce such inversions observed during AO2018. This dry bias above

the observed capping inversion around 27 Aug is not as strong in the UM simulations, but the UM does successfully reproduce

- a small humidity inversion.
- 692 4.3 Cloud macro- and microphysics

The UM simulations have >98% cloud occurrence around 0.2 km over all four periods. Reduced SW_{\downarrow} biases with respect to the standard Regional Atmosphere configurations indicate that UM_CASIM-100 does improve agreement with our high Arctic observations (**Table 4**). In particular, the comparison between UM_CASIM-100 and UM_RA2M (which use the same largescale cloud scheme and differ only in their representation of resolved cloud physics) shows that the new CASIM scheme reproduces the observed Arctic clouds better on a microphysical level.

The ice phase differs more between the models than the liquid phase, likely due to its strong relationship with temperature: UM_RA2M and UM_RA2T use the **Fletcher (1962)** parameterisation for primary ice formation, while ECMWF_IFS uses **Meyers et al. (1992)** and $UM_CASIM-100$ uses **Cooper (1986)**. Each of these parameterisations is inherently temperaturedependent, with **Meyers et al., (1992)** producing the largest ice number concentration, and **Fletcher (1962)** producing the smallest. Given that each simulation does not reproduce the observed temperature profile well below 3 km, the onset of ice nucleation (occurring below a threshold of -10 °C in the UM, for example) will be affected. If ice production is triggered

704 prematurely, cloud liquid properties should be dampened via the Wegener-Bergeron-Findeisen mechanism; evidence of this

can be seen in UM_RA2T during period 3, where an overestimation of ice below 2 km corresponds with a smaller mean LWC

than the other simulations (**Fig. 13b—c**).

707 When considering the drift as a whole, IWC is overestimated by all simulations (except UM_RA2M) below 1.5 km, where our 708 T and q biases are at their greatest. To test whether the method of parameterising primary ice itself has any effect on these 709 biases, we used the Fletcher (1962), Cooper (1986), and Meyers et al. (1992) parameterisations over a short test period within 710 the CASIM framework; however, we found little difference in the tropospheric ice with the different parameterisation methods 711 (Fig. S8). Given the spread in *IWC* results shown here, further investigation into the best methods to represent primary ice 712 production in such global and NWP models should be considered in future, with specific focus on employing prognostic ice 713 nucleating particles (similar to the CCN used here in UM_CASIM-100) to facilitate ice formation rather than simply using a 714 temperature-dependent function (e.g., Varma et al., 2021). The primary ice parameterisations used here do affect the clouds 715 modelled - for example, with a large spread in modelled IWC aloft during period 3 (Fig. 13c) - and a more realistic 716 representation of the ice phase would likely contribute to improved cloud liquid properties. In particular, it is likely that ice formation at warm supercooled temperatures (> -10 °C) will be of importance given the overestimated dominance of cloud 717 718 liquid at low altitude in our simulations.

719 Below 3 km, the mean modelled LWC often exceeds the observed value, with better agreement between 0.15 and 1 km than 720 between 1 and 3 km (Fig. 4, 13). This overestimation of cloud liquid is also evident from the LWP data, with each simulation 721 exhibiting a greater LWP than was measured (Fig. 5) when averaged over our meteorological periods (not shown). At first 722 glance, the simulations agree reasonably well with measurements (Fig. 5a), but this subtle overestimation is clear from the 723 PDFs (Fig. 5b). The exception to this is UM_RA2T; this is the only simulation which often underestimates LWP, due to its 724 increased cloud ice mass within the lower troposphere in comparison to the other simulations (Fig. 4d). For example, the mean measured LWP during period 3 is 122.8 g m⁻², yet UM_RA2T only produces 70.4 g m⁻². In contrast, UM_RA2T reproduces 725 the mean measured LWP well during period 6 (48.5 g m⁻² measured versus 43.2 g m⁻² modelled), with agreement improving 726 727 with time throughout the drift. This efficient ice-producing simulation suggests that the ice phase influences cloud properties 728 as time progresses more so in reality, while the other UM cases, with less dominant ice, retain too much liquid in comparison 729 to the measurements. To an extent, ECMWF_IFS also behaves in this way, retaining too much cloud liquid; however, it 730 performs much better than UM_RA2M and UM_CASIM-100 in reproducing the mean LWC and IWC during period 6 (Fig. 731 13g, h).

732 These simulations suggest that the model development community has effectively gone too far with the reduction of the ice 733 phase in central Arctic mixed-phase clouds. The surface LW balance is positively biased, and these excessive low-level clouds 734 are a contributing factor: by enabling too much liquid to form, and restricting the ice too efficiently, these clouds efficiently 735 absorb and re-emit upwelling LW radiation back towards the surface. Our results show that we have made great improvements 736 in the SW, driven by the improvements we have made to our cloud physics representation in these models (in addition to a 737 better estimation of the surface albedo). However, the too-consistent cloud cover coupled with too much cloud liquid is hampering our model capability, and further developments (such as the inclusion of representative CCN and INP inputs to 738 739 double-moment cloud schemes to facilitate cloud dissipation) will likely go some way to tackle this issue.

740 5 Conclusions

Model simulations with the Met Office UM and the ECMWF IFS were compared with observations made during the Arctic Ocean 2018 expedition to evaluate model performance in the high Arctic, with particular focus on modelled clouds and the surface radiative balance. Four key simulations were considered: a global configuration with the IFS and three nested configurations with the UM (each using different combinations of large-scale cloud and microphysics schemes yet driven by the same global model setup). These four simulations were compared with observations by using Cloudnet to build modelcomparable cloud fractions and water contents and thus identify consistent process weaknesses between the model configurations chosen.

748 We found that key issues identified in previous studies, such as positive near-surface temperature biases (Sotiropoulou et al., 749 2016), remain problems in recent releases of both the UM and IFS. Modelled BLs are often too deep (Fig. 9, 14), particularly 750 during the melt period, and thermodynamic biases, cloud occurrence, and cloud microphysics are consequently in poor 751 agreement with observations below 3 km. Excessive low-cloud occurrence is prevalent in both models (Fig. 3) and no 752 simulation adequately reproduces cloud-free periods and associated increases in longwave net emission (Fig. 2), consistent 753 with previous UM and IFS evaluations in the Arctic (Birch et al., 2012; Sotiropoulou et al., 2016). Strong negative 754 temperature biases (Figs. 8, 9, 13) coincide with too-frequent liquid-dominated cloud layers (Fig. 13a, b, f, g), likely associated 755 with over productive cloud-top radiative cooling in the models. Cloud liquid and ice water contents, especially below 1 km, 756 were within an order of magnitude of our observations (Fig. 4), but clouds occurred too frequently, contained too much liquid 757 between 1 and 3 km, and were often at too-high an altitude (Fig. 13a-c).

Radiative interactions are in better agreement with observations and all models capture the observed distribution of SW_{nor} and 758 759 LW_{net} better during the sea ice freeze period in comparison to the melt period (Fig. 9). Improved radiative interactions and 760 thermodynamic biases during the freeze can be linked with improved agreement of cloud occurrence and microphysics (Fig. 761 13, S7). We found that the surface albedo in each model configuration is underestimated with respect to observational estimates 762 (see **Supporting Information**), but this is unsurprising given the models are representing an average albedo over a 1.5 / 9 km 763 grid box while our observed estimates are from the area immediately surrounding the ship. Updating the surface albedo 764 parameterisation limits used within the UM Regional Atmosphere configurations (UM_RA2M/UM_RA2T) to those used in 765 the Global Atmosphere GA6.0/6.1 configuration (UM_CASIM-100) greatly improves our surface albedo comparison with 766 observational estimates (see Supporting Information) and thus contributes to the good comparison of UM CASIM-100 with 767 measured shortwave radiation data.

768 We propose that four factors are important to failings in our model simulations:

- 1. The choice and use of large-scale cloud schemes at high resolution:
- 770 \circ Both the UM and IFS poorly capture Cloudnet-calculated cloud fractions from observations over Aug—Sep7712018 in the central Arctic, particularly at altitudes between 2 km and 8 km (**Fig. 4a**). Building a comparable772mask based on *TWC* shows that the cloud modelled aloft is actually in good agreement with observations773(**Fig. 4b**), while highlighting that the over prediction of cloud occurrence below 3 km is in fact much worse774than suggested by the C_V comparison. As such, we suggest that cloud fractions should not be used in isolation

775		as a model comparison metric over the Arctic as models represent this parameter differently at the present		
776		time (as detailed in the Supporting Information).		
777	2.	The cloud microphysics scheme chosen to represent resolved clouds:		
778		• UM_CASIM-100 performs best in terms of SW_{net} (Fig. 2, Table 4), but it struggles to capture cloud-free		
779		episodes, thus producing a LW_{net} PDF which is too narrow in comparison to our measurements.		
780		• ECMWF_IFS shares the too-narrow LW _{net} PDF of UM_CASIM-100; however, it often produces a IWC in		
781		reasonable agreement with observations, and its mean LWC profile does agree particularly well with the		
782		observations at times (e.g., period 6; Fig. 13g).		
783		o Of the UM simulations considered, UM_CASIM-100 is in best agreement with both ECMWF_IFS and		
784		observations in terms of net radiation, SW_{net} and SW_{\downarrow} . This improved radiative agreement can be linked to		
785		its better cloud microphysical agreement with our Cloudnet-derived cloud liquid water content over the		
786		standard Regional Atmosphere configurations (Figs. 4, 5, 13); however, UM_CASIM-100 produces even		
787		poorer cloud fractions aloft than either UM_RA2M or UM_RA2T.		
788	3.	Representative CCN concentrations, and thus droplet number concentrations, as a function of altitude:		
789		\circ Representative CCN concentrations in UM_CASIM-AeroProf somewhat improves the overestimation of q_{liq}		
790		within low level clouds in UM_CASIM-100. However, the q_{liq} decrease is not sufficient to trigger an		
791		increase in liquid precipitation, which would thus decrease cloud lifetime, so the modelled C_V is essentially		
792		unchanged (Fig. 7). Crucially, thermodynamic biases with respect to observations are not improved through		
793		this enhanced complexity (Fig. 10), highlighting that these biases may not be fixed by a more comprehensive		
794		representation of cloud physics. Further work is required, with the inclusion of wet scavenging of aerosols		
795		and prognostic INP, to rule out whether such processes could improve the model biases over and above the		
796		inclusion of representative aerosol concentrations alone.		
797	4.	The global model analyses used to produce boundary conditions for high resolution nests:		
798		• The thermodynamic biases identified in our models differ only a little between the UM simulations despite		
799		differences in their cloud configurations. Comparisons with the global model show that the biases within the		
800		LAM are largely inherited from the global model and associated DA system (Fig. 9, 11); therefore, for LAM		
801		configurations such as that tested here, we will not obtain the true benefit of more sophisticated cloud		
802		microphysics schemes in NWP simulations until we address the large-scale biases in their driving models/DA		
803		system.		
804	While	representative CCN concentrations are indeed important for properly reproducing Arctic cloud structure and its		
805	conseq	uential impact on the net surface radiation, our findings indicate that such representative cloud nuclei inputs still have		
806	little in	npact on thermodynamic biases in the lower troposphere. For our given LAM configuration, we speculate that these		
807	biases will always be inherited from the driving model/DA and will continually bias cloud formation processes and BL depth;			

808 however, using an increased domain size, with the science area of interest as far from the lateral boundaries as possible, may

- 809 help to reduce the influence of the driving model/DA. The issue of inherited thermodynamic biases is concerning as both the
- 810 UM global model and IFS are both used within the community to drive NWP configurations of the same model (UM) or others

- 811 (IFS). For example, the IFS configuration tested here is similar to that used by ERA5; therefore, these biases could influence
- future high Arctic NWP simulations if these reanalyses are used for initialisation.
- 813 Our recommendations are thus twofold. To improve our Arctic cloud modelling capability, we must continue to improve the
- 814 cloud physics description striving for an optimum complexity, such as the introduction of representative CCN concentrations
- and double-moment cloud liquid illustrated here, in addition to the inclusion of prognostic INP and associated aerosol
- 816 processing mechanisms. However, we must concurrently address the overabundant occurrence of a too-well-mixed and too-
- 817 cloudy lower troposphere, and tackle the resultant thermodynamic biases, in our global driving models and their respective DA
- 818 systems.
- 819

820 Appendix A Cloudnet mishandling of fog data

LWP measurements from the HATPRO microwave radiometer were used in this study; this instrument provides measurements
of microwave brightness temperatures, from which *LWP* is derived for the full atmospheric column above the instrument (here
located approximately 13 m above the surface). This includes measurement of liquid clouds at altitudes below the radar's first
range gate at 156 m. Fog periods occurred frequently throughout the expedition (Vüllers et al., 2021); therefore, we had several
instances where liquid fog was measured with the HATPRO with small quantities of liquid, or none, detected in the clouds
above (from lidar/radar).

827 Cloudnet calculates an offset to be deducted from the LWP time series dependent upon its categorisations of cloud to ensure

828 that liquid is partitioned throughout the cloud column only if liquid clouds were present. This offset is non-uniform, calculated

829 as a given fraction of the LWP signal on a daily basis, and is deducted from the LWP data to ensure liquid partitioning is

830 conducted correctly within the Cloudnet algorithm. Given the frequency of fog occurrence, this offset was often overestimated

and too much liquid data were removed, thus negatively impacting the *LWP* and *LWC* comparisons with our model simulations.

832 To rectify this problem, we removed the *LWP* offset calculation from the Cloudnet procedure, enabling all ingested data to be833 used by Cloudnet. We then compared these adapted Cloudnet *LWC* data to a *LWC* calculated under an adiabatic assumption to

test whether the latter could be used as an approximation of the true *LWC* if there was not as much fog present during the

expedition. Figure A1 shows this comparison using all data from the drift period and indicates that, by keeping all fog liquid
data in the time series, Cloudnet artificially partitions these data to liquid cloud layers identified by the lidar, leading to too

837 much liquid in clouds within the lowest 1 km of the atmosphere (with comparison to the adiabatic profile). These data also

838 indicate that we can safely use the adiabatic *LWC* as this artificial liquid enhancement is confined to the lowest 1 km and does

839 not significantly affect the comparison for higher altitudes. Following these comparisons, we chose to include the adiabatic

- 840 *LWC* in our comparisons with model simulations to exclude the artificial enhancement of cloud liquid at low altitudes in our
- 841 measurement data.

849 Figures

Figure 1: LHS: Map of cruise track and sea ice cover during AO2018 expedition from **Vüllers et al. (2021)**, with drift period (red) in inset. RHS: Ship position during the drift period (red), with grid outline for UM_CASIM-100, UM_RA2T, and UM_RA2M shown in blue and mid-points of ECMWF_IFS grid indicated by yellow crosses. Note grid size difference for illustrative purposes and not to scale: UM grid boxes are 1.5×1.5 km, IFS grid boxes are 9×9 km in size.

Figure 2: SW_{net} , LW_{net} , and R_{net} simulated by UM_RA2M (dark blue), UM_RA2T (light blue), UM_CASIM-100 (green), and ECMWF_IFS (yellow). Hourly-averaged measurements on board the ship (black) shown for comparison. LHS: timeseries; RHS: PDFs. PDFs are split between melting and freezing sea ice conditions using a threshold of 28 Aug as indicated by the grey vertical dashed line in panels (a), (d), and (g). Radiation terms are defined as positive downwards. Sub-periods used in subsequent sections are marked (red) in panel (g).

Figure 3: Total water content (*left, TWC*) and cloud fraction (*right, C_V*). (**a**—**b**) calculated from observations using Cloudnet and diagnosed by (**c**—**d**) ECMWF_IFS, (**e**—**f**) UM_CASIM-100, (**g**—**h**) UM_RA2T, and (**i**—**j**) UM_RA2M. Missing measurement data are indicated by hatched areas; times where data are missing from the observations are removed from the model data to provide a fair comparison. Missing data periods differ between the *TWC* and *C_V* products due to the different instrumentation requirements within Cloudnet for each.

Figure 4: Comparison between (**a**) mean C_V observed (black, calculated using Cloudnet) and modelled (UM_RA2M = dark blue; ECMWF_IFS = yellow; UM_CASIM-100 = green; UM_RA2T = light blue) over the AO2018 drift period. (**b**) *TWC* cloud mask comparison, where masks are calculated using only in-cloud data as described in **Sect. 2.4**. (**c**—**d**) Same comparison for liquid and ice cloud water contents respectively, using in-cloud data only. *LWC* data from the observations are calculated using Cloudnet by assuming an adiabatic profile (see **Appendix A**). Lines indicate the mean profiles of each dataset, shaded areas depict \pm one standard deviation from the mean. Uncertainties associated with the retrieval process are not shown.

Figure 5: Timeseries of $(\mathbf{a}-\mathbf{b})$ liquid water path (LWP) and $(\mathbf{c}-\mathbf{d})$ total precipitation flux at the surface over the full drift period. $(\mathbf{a}-\mathbf{b})$ HATPRO measurements (grey) are included for comparison with the model data (coloured markers). *LWP* data averaged on to the UM grid by Cloudnet are shown in black (*Obs_UMgrid*). $(\mathbf{c}-\mathbf{d})$ Weather sensor (PWS) measurements of total precipitation from the 7th deck (grey) are included for comparison with model rain and snow fields. (\mathbf{a}, \mathbf{c}) model data shown every 3 hours for clarity; (\mathbf{b}, \mathbf{d}) all model data included for comparison.

854

Figure 6: Model biases in radiation terms (SW_{\downarrow} (*left*), LW_{\downarrow} (*middle*), and R_{net} (*right*)), LWP, and C_V . Model-observation biases are calculated hourly for the radiation and LWP terms using measurements from the ship-based radiometers and HATPRO microwave radiometer, respectively. Shading: model-observation difference between mean C_V below 3 km, where model data below the height of the lowest radar range gate (156 m) is excluded from the comparison with observations. Correlation coefficients for the radiation-LWP (*top*) and radiation- C_V regressions (*bottom*) are noted in the top right of each panel.

856

Figure 7: Comparison of UM_CASIM-100 and UM_CASIM-AeroProf, demonstrating the influence of representative aerosol concentrations on the modelled cloud structure. (**a**—**b**) downwelling shortwave radiation (SW_1) at the surface, with observations (black) shown for comparison; (**c**—**e**) C_V ; (**f**—**h**) cloud droplet number concentration (N_d); and (**i**—**k**) liquid water mixing ratio (q_{liq}). (**c**, **f**, **i**): UM_CASIM-100; (**d**, **g**, **j**): UM_CASIM-AeroProf; (**e**, **h**, **k**): mean profiles with \pm one standard deviation shown in shading. Radiative differences are only notable between 22 Aug and 27 Aug. Slight differences in q_{liq} and cloud fraction can also be identified during this period; for example, UM_CASIM-100 produces a larger cloud fraction below 2 km at 23 Aug

Figure 8: *T* (left) and *q* (right) measured by the radiosondes over the AO2018 drift period. (\mathbf{a} — \mathbf{b}): radiosonde data regridded to the UM vertical grid for model comparisons. (\mathbf{c} — \mathbf{d}): biases of IFS data, re-gridded to the UM vertical grid, with respect to observations. (\mathbf{e} — \mathbf{j}) UM_CASIM-100, UM_RA2T, and UM_RA2M biases, with no vertical re-gridding. The common vertical grid (from the UM) provides 50 vertical levels below 10 km, with 21 of these below 2 km. The black line in all panels depicts the altitude of the main inversion base as identified using the radiosonde measurements, and meteorological time periods with common characteristics are indicated in white (see Vüllers et al., 2021 for details).

Figure 9: Median profiles of modelled (**a**, **c**) *T* and (**b**, **d**) *q* biases with respect to the radiosonde measurements over the sea ice melt (*top*) and freeze (*bottom*) periods (using 28 Aug as a threshold). Model data are coloured as previous (ECMWF_IFS: yellow; UM_CASIM-100: green; UM_RA2T: light blue; and UM_RA2M: dark blue) and \pm one standard deviation shown to illustrate variability. Median anomalies from the UM global model (UM_GLM; grey) are also included for reference; variability is not shown for these data.

861

Figure 10: Temperature (*left*) and moisture (*right*) biases exhibited by the UM_CASIM-100 (green) and UM_CASIM-AeroProf (purple) simulations with respect to radiosonde measurements made over the entire drift period. \pm one standard deviation shown in shading to illustrate variability.

863

Figure 11: Median *T* and *q* biases from a subset of the drift (31 Aug to 5 Sep) for ECMWF_IFS (yellow), UM_RA2M-ERAI-GLM (red), UM_RA2M (dark blue), and UM_GLM (grey). UM_RA2M-ERAI-GLM biases follow ECMWF_IFS biases up to approximately 1 km, above which they largely behave more like the other UM cases. \pm one standard deviation shown in shading to illustrate variability.

865

867

Figure 12: Mean profiles of (a) equivalent potential temperature (θ_e) and (b) *q* measured by radiosondes launched during periods 3—6 of the expedition, with ± one standard deviation shown in shading.

Figure 13: Comparison of mean cloud mask, *LWC*, and *IWC* profiles with median biases in *T* and *q* with respect to radiosondes for period 3 (**a**—**e**, *top row*) and period 6 (**f**—**j**, *bottom row*). Again, observed *LWC* calculated assuming adiabatic conditions using Cloudnet. \pm one standard deviation shown in shading to illustrate variability.

871

Figure 14: Model temperature inversion base as a function of the identified inversion base from radiosonde (RS) measurements. *org. inv*: strongest inversion below 3 km, identified following Vüllers et al. (2021). *adj. inv*: where models exhibit a secondary weaker inversion at lower altitude in better agreement with identified radiosonde inversions, these identified inversions are adjusted accordingly. *unadj.inv*: unadjusted primary inversions, not used for further analysis and shown for reference only. Correlation coefficients are quoted in red in at the top of each panel.

872

873

Figure 15: Scaled median model-observation *T* bias profiles for the full drift (*left*), melt (*middle*), and freeze (*right*) periods. Profiles are scaled such that -1 is the surface, 0 is the main inversion base, and 1 is 3 km.

Figure A1: Comparison of mean *LWC* profiles calculated using an adiabatic assumption (black, \pm one standard deviation shown in dark grey shading) and from HATPRO *LWP* measurements (grey, \pm one standard deviation shown in light grey) without the Cloudnet offsetting procedure.

876 Data availability

877 UK contributions, as well as selected other data, are available within the MOCCHA (Microbiology-Ocean-Cloud Coupling in

- 878 the High Arctic) data collection in the Centre for Environmental Data Analysis (CEDA) archives (http://archive.ceda.ac.uk/).
- 879 Other cruise data are available from the Bolin Centre for Climate Research MOCCHA/AO2018 holdings
- 880 (http://bolin.su.se/data).

881 Author Contributions

- 882 GY led the model data analysis, aided by PF, RP, JD, and RF. JV led the measurement and Cloudnet data analysis, with
- contributions from PA, IMB, MT, and EO. IMB, PA, MT, and JP performed the measurements during AO2018. IMB, MT, JD,
- 884 PF, RN, GY and JV all contributed to the study design. All authors contributed to the discussion of results and writing of the
- 885 manuscript.

886 Competing Interests

887 The authors declare that they have no conflict of interest.

888 Acknowledgements

- 889 This work was supported by the UK Natural Environment Research Council (NERC; grant no. NE/R009686/1) and the Knut
- 890 and Alice Wallenberg Foundation (grant no. 2016-0024). The Swedish Polar Research Secretariat (SPRS) provided access to
- the icebreaker Oden and logistical support. We are grateful to the Chief Scientists Caroline Leck and Patricia Matrai for
- 892 planning and coordination of AO2018, to the SPRS logistical staff and to I/B Oden's Captain Mattias Peterson and his crew.
- 893 The Atmospheric Measurements and Observations Facility (AMOF) of the UK National Centre for Atmospheric Science
- 894 (NCAS) provided the cloud radar, HALO lidar, RPG HATPRO radiometer, Campbell ceilometer, Kipp & Zonen radiometers,
- 895 and Vaisala radiosounding station. The soundings were supported by Environment and Climate Change Canada in collaboration
- 896 with the Year of Polar Prediction, Polar Prediction Project.
- 897 We acknowledge use of the Monsoon2 system, a collaborative facility supplied under the Joint Weather and Climate Research
- 898 Programme, a strategic partnership between the Met Office and the Natural Environment Research Council. This work also
- 899 used JASMIN, the UK collaborative data analysis facility, and was achieved in part with help from the Centre for
- 900 Environmental Modelling and Computation (CEMAC), University of Leeds.
