17

18 **Abstract**

19 Aerosols can enhance ecosystem productivity by increasing diffuse radiation. Such
20 diffuse fertilization effects (DFEs) vary among different aerosol compositions and sky
21 conditions. Here, we apply a suite of chemical, radiation, and vegetation models in
22 combination with ground- and satellite-based measurements to assess the impacts of
23 natural and anthropogenic aerosol species on gross primary productivity (GPP) through
24 DFE during 2001-2014. Globally, aerosols enhance GPP by 8.9 Pg C yr⁻¹ under clear
25 sky conditions but only 0.95 Pg C yr⁻¹ under all sky conditions. Anthropogenic aerosols
26 account for 41% of the total GPP enhancement though they contribute only 25% to the
27 increment of diffuse radiation. Sulfate/nitrate aerosols from anthropogenic sources
28 make dominant contributions of 33% (36%) to aerosol DFE under all (clear) sky
29 conditions, followed by the fraction of 18% (22%) by organic carbon aerosols from
30 natural sources. In contrast to other species, black carbon aerosols reduce global GPP
31 by 0.28 (0.12) Pg C yr⁻¹ under all (clear) sky conditions. Long-term simulations show
32 that aerosol DFE is increasing 2.9% yr⁻¹ under all sky conditions mainly because of a
33 downward trend in cloud amount. This study suggests that the impacts of aerosols and
34 cloud should be considered in projecting future changes of ecosystem productivity
35 under varied emission scenarios.

39

40 **1 Introduction**

41 Diffuse light enhances plant photosynthesis more efficiently than direct light (Gu et
42 al., 2002;Alton et al., 2007;Mercado et al., 2009;Jing et al., 2010;Cirino et al.,
43 2014;Zhou et al., 2021a;Zhou et al., 2021c). The cause for such difference is that diffuse
44 light can penetrate into the deep canopy and enhance photosynthesis of more shaded
45 leaves with higher light use efficiency ($LUE=GPP/PAR$, gross primary productivity per
46 photosynthetically active radiation) (Roderick et al., 2001;Gu et al., 2003;Rap et al.,
47 2015). However, direct light is absorbed only by sunlit leaves and much of it is wasted
48 because these leaves are usually at the light saturated conditions (Gu et al., 2002;He et
49 al., 2013). As a result, increasing the diffuse radiation can help promote canopy
50 photosynthesis through the diffuse fertilization effect (DFE).

51 Atmospheric aerosols can alter the quality of sunlight reaching Earth's surface by
52 absorbing and scattering solar insolation (Zhou et al., 2021b). The aerosol-induced
53 radiative impacts on terrestrial ecosystem productivity have been investigated in both
54 observational and modeling studies (Table 1). Observations found unexpected decline
55 of atmospheric carbon dioxide in 1990s, which was attributed to the increase of
56 vegetation carbon uptake owing to the massive eruption of Mt. Pinatubo in 1991
57 (Roderick et al., 2001). Sulfate aerosols from volcanic eruption almost doubled diffuse
58 radiation at the clear sky, leading to the enhancement of plant productivity by 23% at
59 Harvard forests in 1992 (Gu et al., 2003). With the development of ground-based
60 instruments and satellite remote sensing, more observational data have been applied to
61 detect the aerosol DFE. Strada et al. (2015) estimated aerosol DFE on plant productivity

62 using aerosol optical depth (AOD) from satellite cloudless observations at 10 flux sites,
63 and found that aerosols enhance GPP by 13% in midday hours under high AOD
64 conditions (>0.4) for deciduous and mixed forests. Similarly, Ezhova et al. (2018) found
65 that aerosols increase clear-day diffuse fraction from 0.11 to 0.27 at five remote sites in
66 Eurasia, leading to the enhancement of site-level GPP by 6-14%.

67 In contrast to the large benefits at clear days, the aerosol DFE is limited at cloudy
68 days. Kanniah et al. (2013) explored cloud direct radiative effects on canopy
69 productivity using observed carbon fluxes and radiation in tropical savannas, and found
70 that thick cloud masked aerosol DFE and reduced GPP by 26%. Cirino et al. (2014)
71 also found that aerosol DFE cannot increase plant photosynthesis under cloudy
72 conditions. These studies indicated that aerosol DFE is subject to sky conditions and
73 aerosol loading, because the potential benefits from DFE can be offset or even reversed
74 by simultaneous reductions in direct radiation caused by thick cloud or high aerosol
75 loading (Alton, 2008; Cirino et al., 2014; Yue and Unger, 2017; Zhou et al., 2021b).

76 Although observational studies directly estimate site-level aerosol DFE, they are not
77 able to reveal regional or global aerosol DFE due to the limited spatiotemporal coverage.
78 On the global scale, studies using varied models showed that aerosol DFE enhances
79 global GPP by 4.9 Pg C yr^{-1} (Chen and Zhuang, 2014), 1-2% (Strada and Unger, 2016)
80 and $1.0 \pm 0.2 \text{ Pg C yr}^{-1}$ (Yue and Unger, 2018) at different periods. Rap et al. (2018)
81 specifically explored DFE from biogenic aerosols and found that biogenic aerosols
82 enhance global net primary productivity (NPP) by $1.23 \text{ Pg C yr}^{-1}$. Regionally, Matsui
83 et al. (2008) applied a land surface model and estimated that aerosol DFE decreased

84 NPP by 0.09% in 2000 but increased NPP by 0.5% in 2001 over eastern U.S., because
85 the cloud optical depth was about half in 2001 relative to 2000. At the same region,
86 Keppel-Aleks and Washenfelder (2016) estimated sulfate aerosol DFE using
87 Community Earth System Model and found that the reductions of sulfate aerosols by
88 $3.0 \pm 0.6\% \text{ yr}^{-1}$ led to reductions of $0.6\% \text{ yr}^{-1}$ in diffuse radiation and $0.07\% \text{ yr}^{-1}$ in
89 regional GPP during 1995-2013. In Amazon, fire aerosols are estimated to play varied
90 DFEs among different studies (Rap et al., 2015; Moreira et al., 2017; Yue and Unger,
91 2018; Malavelle et al., 2019). For example, Rap et al. (2015) found that fire aerosols
92 enhance NPP by 1.4-2.8% while Moreira et al. (2017) estimated that fire aerosols
93 enhance GPP by 27%. Such differences are mainly attributed to the high aerosol loading
94 in Moreira et al. (2017) for September 2010, but much lower loading in Rap et al. (2015)
95 for the 10-year (1998-2007) averages. Although these studies assessed the DFE of total
96 aerosols or the specific species (e.g., sulfate, fire, or biogenic), the individual DFEs of
97 natural and anthropogenic aerosols on global terrestrial productivity remain unclear.

98 In this study, we explore the impacts of natural and anthropogenic aerosol DFE on
99 global GPP during 2001-2014 using both multi-source observations and a series of well-
100 validated models. A chemical transport model (CTM) is used to predict changes of
101 natural and anthropogenic aerosol concentrations. A radiative transfer model is applied
102 to calculate the perturbations in direct and diffuse PAR caused by aerosols. A global
103 dynamic vegetation model is used to quantify changes of global GPP caused by aerosol
104 DFE. The main objectives are (1) to distinguish the DFEs of natural and anthropogenic
105 aerosols on global GPP and (2) to explore the different characteristics of aerosol DFEs

106 for varied species.

107

108 **2 Methods**

109 **2.1 Chemical transport model**

110 The Goddard Earth Observing System coupled with Chemistry (GEOS-Chem,
111 <http://geos-chem.org>) is a three-dimensional (3-D) CTM for simulating atmospheric
112 compositions and air quality (Bey et al., 2001). Global anthropogenic emissions during
113 2001-2014 are from the Community Emissions Data System (CEDS) inventory
114 (<http://www.globalchange.umd.edu/ceds/>). The CEDS inventory has been used as
115 anthropogenic emissions in the Coupled Model Intercomparison Project Phase 6
116 (CMIP6), and this emission database relies on existing energy consumption datasets
117 and regional or country-specific inventories to produce trends over recent decades
118 (Hoesly et al., 2018). The specific emission species include aerosols (black carbon,
119 organic carbon), aerosol precursors and reactive compounds (SO₂, NO_x, NH₃, CH₄, CO,
120 and non-methane volatile organic compounds (VOCs)) (Supplementary Table 1). To
121 estimate modeling uncertainties due to emission inventories, the Emissions Database
122 for Global Atmospheric Research (EDGAR) inventory vision 4.3.1
123 (<https://edgar.jrc.ec.europa.eu/>) during 2001-2010 is also used as alternative
124 anthropogenic emissions for GEOS-Chem model. For natural emissions, the Global
125 Fire Emission Database (GFED) version 4 inventory is used to represent emissions
126 from open fires (<http://www.globalfiredata.org/>). Biogenic VOC emissions are
127 calculated using the Model of Emissions of Gases and Aerosols from Nature (MEGAN

128 v2.1) (Guenther et al., 2012). Natural emissions of sea salt (Jaeglé et al., 2011), dimethyl
129 sulfate (Breider et al., 2017), volcanic SO₂ (Fisher et al., 2011) and NH₃ are from the
130 Global Emissions Initiative (GEIA, <http://www.geiacenter.org/>). In this study, GEOS-
131 Chem version 12.0.0 is used to simulate concentrations of natural and anthropogenic
132 aerosols at a horizontal resolution of 4°×5° and 47 vertical layers. The CTM is driven
133 with assimilated meteorology from the Modern-Era Retrospective analysis for
134 Research and Applications, version 2 (MERRA2).

135

136 **2.2 Radiative transfer model**

137 The Column Radiation Model (CRM) is the standalone version of the radiative
138 transfer module used by the NCAR Community Climate Model
139 (<http://www.cesm.ucar.edu/models/>). In this model, aerosol direct radiative effects
140 including absorbing and scattering processes are calculated at 20 vertical layers from
141 surface to 0.5 hPa at hourly intervals (Yue and Unger, 2017). The CRM utilizes aerosol
142 profiles of all species simulated by GEOS-Chem, including sulfate, nitrate, black
143 carbon (BC), organic carbon (OC), dust (clay and silt) and sea salt (coarse and
144 accumulation modes). Aerosol optical parameters (e.g. single scattering albedo,
145 extinction coefficients, and asymmetric parameters) are adopted from Yue and Liao
146 (2012) for sea salt, Yue et al. (2010) for mineral dust, and the RegCM4 model for other
147 species (Giorgi et al., 2012). In this study, the CRM is used to simulate aerosol-induced
148 perturbations in surface radiative fluxes including diffuse and direct PAR. The model
149 is driven with hourly 1°×1° meteorology from MERRA-2 reanalyses, and 3-hourly

150 cloud cover and liquid water path from CERES SYN1deg (<http://ceres.larc.nasa.gov>).

151

152 **2.3 Dynamic vegetation model**

153 The Yale Interactive terrestrial Biosphere (YIBs) model is a process-based vegetation
154 model that dynamically simulates tree growth and leaf area changes (Yue and Unger,
155 2015). The model uses the well-established leaf photosynthesis (Farquhar et al., 1980)
156 and stomatal conductance schemes (Ball et al., 1987). The canopy is divided into sunlit
157 and shaded portions to separate photosynthetic responses to diffuse and direct light
158 (Spitters et al., 1986). We distinguish light absorption between sunlit (receiving both
159 diffuse and direct light) and shaded leaves (receiving only diffuse light), and derive
160 canopy photosynthesis as the sum of that from sunlit and shaded leaves:

$$161 A_{total} = A_{sunlit} \times F_{sunlit} + A_{shaded} \times (1 - F_{sunlit}) \quad (1)$$

162 where A_{sunlit} and A_{shaded} are the photosynthesis of sunlit and shaded leaves,
163 respectively. The fraction of sunlit leaf area F_{sunlit} is calculated as:

$$164 F_{sunlit} = e^{-kL} \quad (2)$$

165 Here, L is leaf area index (LAI) at one canopy layer and k is extinction coefficient
166 defined as $0.5/\cos\alpha$ (solar zenith α). Compared with global *in situ* measurements,
167 this canopy radiative transfer scheme reasonably captures the different responses of
168 GPP to direct and diffuse radiation (Yue and Unger, 2018; Zhou et al., 2021a). For this
169 study, we use the original scheme without modifications.

170 Simulated GPP by YIBs model has been validated using ground-based observations
171 at 145 sites and yielded an average correlation coefficient of 0.76 for all sites (Yue and

172 Unger, 2015). The simulated global GPP also shows reasonable spatiotemporal
173 variations compared with satellite retrievals (Yue et al., 2015). Recently, the model
174 joined the multi-model ensemble project of TRENDY to provide the estimates of global
175 carbon budget (Friedlingstein et al., 2020). In this study, the YIBs is used to isolate
176 impacts of aerosol-induced PAR changes on GPP on the global scale. The model is
177 driven with $1^\circ \times 1^\circ$ meteorological forcing from MERRA-2 reanalyses and PAR (both
178 diffuse and direct) simulated by CRM model. Land cover product from MODIS is used
179 as vegetation coverage for YIBs model (Yue et al., 2021) and observed CO₂
180 concentrations from Mauna Loa are also used (Yue et al., 2015).

181

182 **2.4 Model simulations**

183 We perform 2 GEOS-Chem runs, as well as 22 CRM and YIBs runs to isolate aerosol
184 direct radiative impacts on GPP at different sky conditions (Supplementary Table 2).
185 The GEOS-Chem runs GC_ALL and GC_NAT are driven with the same meteorology
186 and emissions except that the former includes all sources of emissions while the latter
187 excludes only anthropogenic emissions. Following the methods in Nascimento et al.
188 (2021) and Ryu et al. (2013), we use the differences between GC_ALL and GC_NAT
189 to represent aerosol concentrations contributed by anthropogenic sources. In this
190 practice, the sums of natural and anthropogenic aerosol concentrations are equal to the
191 total aerosol concentrations without non-linear effects. Both GC_ALL and GC_NAT
192 runs provide 3-D concentrations of different aerosol types including sulfate, nitrate, OC,
193 BC, dust and sea salt. The CRM runs aim to calculate aerosol-induced PAR changes

194 using aerosol profiles simulated by GEOS-Chem. These runs can be divided into two
195 groups, with CLD runs (all-sky conditions) forced with observed cloud profiles while
196 CLR runs (clear-sky conditions) forced without any cloud coverage. CRM_ALL and
197 CRM_NAT are driven with aerosol profiles of all species from GC_ALL and GC_NAT,
198 respectively. The impacts of individual aerosol species on PAR are isolated with
199 individual aerosol profiles from either GC_ALL or GC_NAT. For example, OC from
200 GC_ALL and cloud amounts from CERES SYN1deg are used to drive CRM
201 (CRM_ALL_OCCLD) so as to isolate the impacts of OC aerosols on PAR under all
202 sky conditions. It should be noted that such setup cannot resolve the interactive
203 responses among aerosol species, because the sum of individual aerosol effects are not
204 necessarily equal to the net impact of all aerosols. The magnitude of these non-linear
205 effects will be evaluated accordingly. For each of CRM runs, the predicted diffuse and
206 direct PAR are used as input for YIBs model to simulate GPP changes caused by aerosol
207 DFEs. For YIBs runs, other forcings (e.g., CO₂ concentrations and climate meteorology)
208 except diffuse and direct PAR are kept the same in all runs, so as to exclude their
209 impacts on global GPP.

210

211 **2.5 Observations for model evaluations**

212 We use site-level measurements of carbon fluxes from the FLUXNET2015 product
213 (<http://fluxnet.fluxdata.org/>) to validate model GPP and its responses to diffuse/direct
214 radiation. We select 10 sites providing simultaneous observations of diffuse radiation
215 and GPP at half-hourly time interval for at least 8 years. On the global scale, observed

216 AOD is retrieved from the Moderate Resolution Imaging Spectroradiometer (MODIS,
 217 <https://modis.gsfc.nasa.gov>) and GPP is derived using global OCO-2-based SIF product
 218 (Li and Xiao, 2019). The all-sky and clear-sky shortwave radiation are adopted from
 219 CERES SYN1deg (<http://ceres.larc.nasa.gov>) to validate the CRM radiative transfer
 220 model. To evaluate the performance of models, we use statistical metrics including
 221 correlation coefficients (R) and normalized mean biases (NMB) defined as follows:

$$222 \quad R = \frac{\sum_{i=1}^{i=n} (M_i - \bar{M})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^{i=n} (M_i - \bar{M})^2 \times \sum_{i=1}^{i=n} (O_i - \bar{O})^2}} \quad (1)$$

$$223 \quad NMB = \frac{\sum_{i=1}^{i=n} (M_i - O_i)}{\sum_{i=1}^{i=n} O_i} \quad (2)$$

224 where O_i and M_i are observed and modeled values, respectively. \bar{O} and \bar{M} are the
 225 averages of the observed and modeled values. In this study, R and NMB are used to
 226 evaluate the performance of models on the spatial scale, and Student t-test test is used
 227 to examine the significance of correlation coefficients and long-term trends.

228

229 **3 Results**

230 **3.1 Model evaluations**

231 The YIBs model simulates reasonable spatial pattern of GPP compared to
 232 observations (Figure S1) with a high correlation coefficient (R) of 0.88 ($p < 0.01$) and a
 233 low normalized mean bias (NMB) of -2.3%. Similarly, modeled AOD from GEOS-
 234 Chem model reproduces the observed spatial pattern from MODIS product with high
 235 R of 0.78 ($p < 0.01$), though overestimates the mean AOD by 21.7% in eastern China
 236 and 37.9% in southern Africa while underestimates AOD by 35.7% in Amazon, 25.2%
 237 in Central Africa and 53.4% in southeast Asia, leading to a global NMB of -25.8%.

238 The CRM model driven with aerosol concentrations from GEOS-Chem shows
239 similar patterns of shortwave radiation to the satellite observations (Figure S2). The
240 simulations match observations well with high R of 0.98 and low NMB of 4.1% under
241 all sky conditions, and show even better performance with R of 1 and NMB of 3.7%
242 under clear sky conditions. Although the CRM model presents high R and low NMB
243 under both sky conditions, evaluations still show that modeled shortwave radiation is
244 higher than observations. Such overestimation may be related to the underestimation of
245 simulated AOD (Figure S1), which leads to more shortwave radiation reaching the
246 surface. We further evaluate the simulated diffuse fraction (DF) with satellite
247 observations (Figure S3). Simulations reproduce observed spatial pattern with high R
248 of 0.82 and low NMB of -0.1% on the global scale, but overestimate regional DF over
249 high latitudes and underestimate DF over Asia. Moreover, the CRM model simulates
250 reasonable aerosol direct radiative effects compared to multiple radiative transfer
251 models as shown in Yue and Unger (2018).

252 We then compared the simulated and observed GPP responses to direct (diffuse
253 fraction <0.2) and diffuse radiation (diffuse fraction >0.8) (Figure 1). Observations and
254 simulations show that diffuse light can increase GPP more efficiently than direct
255 radiation as shown by the higher GPP-PAR slopes at diffuse conditions. Similar results
256 were achieved by Mercado et al. (2009) and Yue and Unger (2018) using the same
257 methods. The diffuse fertilization efficiency, percentage changes in GPP per unit diffuse
258 PAR, is estimated to be 0.45-0.7% $W^{-1} m^2$ for observations and 0.3-0.69% $W^{-1} m^2$ for
259 simulations. As a result, the YIBs model can reasonably reproduce varied light-response

260 curves so as to isolate GPP responses to direct and diffuse radiation.

261

262 **3.2 Changes of PAR by aerosols**

263 Aerosols reduce total PAR but enhance diffuse PAR at surface. Relative to PAR
264 changes without aerosols, appearance of aerosols on average reduces total surface PAR
265 by 1.52 W m^{-2} under all sky conditions and 2.73 W m^{-2} under clear sky conditions on
266 the global scale. Under all-sky conditions, aerosols enhance diffuse PAR by 1.26 W m^{-2}
267 (Figure 2a) but reduces direct PAR by 2.78 W m^{-2} (Figure S4a). These changes are
268 larger in clear-sky conditions with enhancement of diffuse PAR by 4.98 W m^{-2} (Figure
269 2d) and reduction of direct PAR by 7.71 W m^{-2} (Figure S4d). Regionally, aerosols cause
270 large enhancement of diffuse PAR ($>3 \text{ W m}^{-2}$) over southern U.S., Australia, Europe,
271 and northern Asia under clear sky conditions (Figure 2d). However, these
272 enhancements of diffuse PAR are largely dampened under all sky conditions (Figure
273 2a). Similar changes in diffuse radiation by aerosols are predicted by Chen and Zhuang
274 (2014) and Rap et al. (2018), though the former study yielded much larger changes in
275 radiation and the latter examined only biogenic aerosols. The cause of smaller PAR
276 changes under all sky conditions is that cloud tends to weaken aerosol radiative forcing
277 by amplifying absorption and diminishing scattering (Paulot et al., 2018).

278 Relative to diffuse PAR changes without aerosols, natural aerosols dominate aerosol-
279 induced PAR changes by enhancing diffuse PAR of 0.93 W m^{-2} (Figure 2b) and
280 reducing direct PAR of 2.05 W m^{-2} (Figure S4b) under all sky conditions. As a
281 comparison, anthropogenic aerosols induce much smaller changes of diffuse radiation

282 by 0.33 W m^{-2} and direct radiation of -0.72 W m^{-2} (Figures 2c and S4c). Natural aerosols
283 mainly influence PAR fluxes in northern Africa owing to large amount of dust aerosols,
284 while anthropogenic aerosols dominate PAR changes in eastern China, India, and
285 eastern U.S due to the large anthropogenic emissions. Under clear sky conditions,
286 natural aerosols enhance diffuse PAR by 3.79 W m^{-2} (Figure 2e) and reduce direct PAR
287 by 5.84 W m^{-2} (Figure S4e), and anthropogenic aerosols on average enhance diffuse
288 PAR by 1.19 W m^{-2} and reduce direct PAR by 1.88 W m^{-2} .

289 We further explore the contributions of individual aerosol species to the changes of
290 diffuse and direct PAR under all sky conditions (Figures S5 and S6). On the global scale,
291 sulfate and nitrate aerosols enhance diffuse PAR by 0.57 W m^{-2} , accounting for 51% of
292 aerosol-induced diffuse PAR changes. Meanwhile, diffuse PAR is enhanced 0.05 W m^{-2} ,
293 0.37 W m^{-2} and 0.25 W m^{-2} by the scattering effects of OC, dust, and sea salt aerosols.
294 However, BC aerosols reduce diffuse PAR by 0.06 W m^{-2} due to the strong absorption.
295 The changes of direct PAR caused by all aerosol species are negative, especially that
296 by sulfate and nitrate (-0.97 W m^{-2}), dust (-0.86 W m^{-2}), and sea salt (-0.5 W m^{-2}).
297 Generally, natural aerosols dominate changes of diffuse and direct PAR owing to the
298 large contributions from dust and sea salt aerosols. However, sulfate, nitrate, and BC
299 aerosols from anthropogenic sources dominate the changes of diffuse and direct PAR
300 over eastern China, Indian and eastern U.S.

301

302 **3.3 DFE by natural and anthropogenic aerosols**

303 We quantify the percentage changes of global GPP caused by aerosol DFE. Relative

304 to GPP changes without aerosols, aerosol DFE enhances global GPP by 0.65 % ($0.95 \pm$
305 $0.13 \text{ Pg C yr}^{-1}$) under all sky conditions (Figure 3a). Relatively high enhancements
306 ($>2\%$) in GPP are found over middle latitudes ($20\text{-}50^\circ\text{N}$) following the changes of
307 diffuse PAR (Figure 2a). The DFE of natural aerosols enhance global GPP by 0.38%
308 ($0.56 \pm 0.1 \text{ Pg C yr}^{-1}$), mainly over Middle East and northern Africa due to dust aerosols
309 (Figure 4a and 5g). The DFE of anthropogenic aerosols enhance global GPP up to 0.27 %
310 ($0.39 \pm 0.04 \text{ Pg C yr}^{-1}$), especially over populous regions including northeast China,
311 Middle East and contiguous U.S (Figure 4b).

312 Under clear sky conditions, aerosol DFE enhances global GPP up to 7.8% ($8.91 \pm$
313 $0.26 \text{ Pg C yr}^{-1}$) (Figure 3c), which is around 9.5 times of that under all sky conditions
314 (Figure 3a). In most regions, aerosol DFE increases GPP by more than 4%, with the
315 maximum enhancement of 22.7% in East Asia. The DFE of natural aerosols enhances
316 global GPP by 4.6%, with large changes over Amazon, center Africa, boreal Asia, and
317 North America (Figure 4c). Meanwhile, anthropogenic aerosols enhance global GPP by
318 3.2%, mainly located at eastern U.S, Europe, boreal Asia, India and East Asia (Figure
319 4d).

320 We further quantify the contributions of anthropogenic aerosols to the total aerosol
321 DFE. Although cloud masks aerosol DFE and significantly reduces GPP enhancement,
322 the contributions of anthropogenic aerosols remain similar between all-sky (Figure 3b)
323 and clear-sky (Figure 3d) conditions. Relatively high contributions ($>50\%$) are located
324 at low-mid latitudes including North America, Europe, and eastern China. Low
325 contributions ($<50\%$) are found at other regions such as Africa, South America, and

326 Australia. On the global scale, anthropogenic aerosols on average contribute to 41% of
327 the total aerosol DFE under all sky conditions (Figure 4a and 4b). Anthropogenic
328 aerosols dominate DFE over 30.5% of land grids under all sky conditions, but only 19.5%
329 under clear sky conditions (Figure 3b and 3d). The most significant differences are
330 located at boreal Europe where the anthropogenic aerosols make dominant
331 contributions to DFE under clear sky conditions while the natural species dominate
332 under all sky conditions.

333

334 **3.4 DFE by individual aerosol species**

335 We isolate the DFE of individual aerosol species on global GPP (Figures 5 and
336 S7), and found that sulfate and nitrate aerosols make dominated role of aerosol DFE on
337 the global scale. Under all sky conditions, sulfate and nitrate aerosols averagely
338 enhance GPP by $0.79 \text{ Pg C yr}^{-1}$, to which anthropogenic sources contribute 0.58 Pg C
339 yr^{-1} (Figure 5f). OC aerosols increase global GPP by $0.47 \text{ Pg C yr}^{-1}$, to which natural
340 sources contribute $0.32 \text{ Pg C yr}^{-1}$ (Figure 5c). As the dominant natural species, dust and
341 sea salt are generated from non-vegetated areas. They can increase GPP of downwind
342 land regions by $0.17 \text{ Pg C yr}^{-1}$ (Figure 5g) and $0.06 \text{ Pg C yr}^{-1}$ (Figure 5h), respectively.
343 Different from the above species, BC aerosols lead to negative impacts on GPP up to -
344 $0.28 \text{ Pg C yr}^{-1}$ globally due to the strong absorbing radiative effects. Regionally, such
345 negative effects are prominent over center Africa from biomass burning (Figure 5a) and
346 eastern China from anthropogenic emissions (Figure 5b).

347 Under clear sky conditions, scattering aerosols show larger DFE compared to the

348 all-sky conditions. Relative to GPP changes without aerosols, sulfate and nitrate
349 aerosols increase global GPP by $5.18 \text{ Pg C yr}^{-1}$, which is 6.6 times of that under all sky
350 conditions. The DFE of OC aerosols also largely increase to $2.89 \text{ Pg C yr}^{-1}$, in which
351 $2.21 \text{ Pg C yr}^{-1}$ is from natural sources. Dust and sea salt aerosols lead to positive impacts
352 on global GPP by $1.32 \text{ Pg C yr}^{-1}$ and $0.48 \text{ Pg C yr}^{-1}$, respectively. In contrast, BC
353 aerosols reduce global GPP by $0.12 \text{ Pg C yr}^{-1}$, much weaker than the magnitude of 0.28
354 Pg C yr^{-1} under all sky conditions. Such change mainly follows the larger diffuse
355 absorption by BC aerosols under all sky conditions (0.06 W m^{-2}) than that under clear
356 sky conditions (0.02 W m^{-2}).

357 We then identify the aerosol species making the dominant contributions to the total
358 aerosol DFE (Figure 6). Under all sky conditions, sulfate and nitrate aerosols lead the
359 DFE at 65% of the grid cells (Figure 6a) and account for 44.7% of the total absolute
360 GPP changes (Figure 6c). The secondary contribution is from OC aerosols, which
361 account for 26.7% of the total DFE. Dust and sea salt aerosols contribute to the total
362 DFE by 9.5% and 3.4%, respectively (Figure 6c). BC aerosols exert negative DFE, the
363 absolute value of which is equivalent to 15.8% of the total DFE. Regionally, sulfate and
364 nitrate aerosols lead DFE in eastern China, India, eastern U.S., and Europe, while dust
365 aerosols dominate DFE at Middle East (Figures 6e and 6f). Under clear sky conditions,
366 the percentage contributions of sulfate and nitrate aerosols to the total DFE further
367 increase to 51.8% on the global scale (Figure 6d). OC, dust, and sea salt aerosols show
368 comparable contributions to DFE as that under all sky conditions. However, the
369 absolute ratios by BC aerosols significantly reduce to 1.2%, because BC-induced DFE

370 is limited while DFE of other species is significantly strengthened under clear sky
371 conditions (Figure S7).

372 We further explore the interannual variations of GPP changes caused by aerosol
373 DFE from natural and anthropogenic sources (Figure 7). Under all sky conditions,
374 aerosol DFE significantly ($p < 0.05$) increases by $2.89\% \text{ yr}^{-1}$ ($24.6 \text{ Tg C yr}^{-2}$) on the
375 global scale (Figure S8a). Such enhancement is mainly located in northeastern China,
376 India, central Africa, and Europe (Figure S9a). Natural aerosols lead to a positive trend
377 of $4.7\% \text{ yr}^{-1}$ in the global GPP (22 Tg C yr^{-2}), which is six times of the trend of $0.67\% \text{ yr}^{-1}$
378 (2.6 Tg C yr^{-2}) from anthropogenic aerosols (Figure 7a). Under clear sky conditions,
379 aerosol DFE increases by only $0.4\% \text{ yr}^{-1}$ (Figure S8b), much lower than that under all
380 sky conditions (Figure S8a). Both the DFE trends from natural and anthropogenic
381 aerosols are limited (Figure 7b). The contrast of DFE trends between different sky
382 conditions is related to the changes of cloud amount, which shows a significant
383 reduction trend of $0.38\% \text{ yr}^{-1}$ in 2001-2014 (Figure S8c), especially over Amazon and
384 eastern U.S. (Figure S9d). The reduction of cloud helps increase or maintain aerosol
385 DFE under all sky conditions (Figure S9c). The trend of all-sky aerosol DFE is mainly
386 contributed by dust aerosols from natural sources, which increases by $4.75\% \text{ yr}^{-1}$ during
387 2001-2014 (Figure 7c). The trend of clear-sky aerosol DFE is mainly attributed to
388 sulfate and nitrate aerosols, which increase by $0.44\% \text{ yr}^{-1}$ during 2001-2014 (Figure 7d).

389 The differences between natural and anthropogenic aerosol DFE are inconsistent
390 at varied sky conditions (Figure 7). For the year 2003, ΔGPP by natural aerosols is very
391 close to that by anthropogenic aerosols under all-sky conditions (Figure 7a). However,

392 the same year sees large differences of Δ GPP between different sources of aerosols at
393 clear-sky conditions (Figure 7b). Analyses show that increased cloud amount weakens
394 aerosol DFE especially over central Africa and boreal Asia with high loading of natural
395 aerosols before 2003 (Figure S11a), but decreased cloud amount enhances natural
396 aerosol DFE over Amazon, central Africa, and boreal Asia after 2003 (Figure S11b).
397 These opposite trends of cloud over regions with high loading of natural aerosols lead
398 to a turning point for natural aerosol DFE in 2003 under all-sky conditions.

399

400 **4 Discussion**

401 4.1 Factors influencing aerosol DFE

402 We quantified the impacts of sky conditions, emission sources, and aerosol species
403 on terrestrial ecosystem productivity through aerosol DFE. In our simulations, aerosols
404 increase global GPP by 8.91 Pg C yr⁻¹ under clear sky conditions but only 0.95 Pg C yr⁻¹
405 under all sky conditions. Similarly, Cohan et al. (2002) and Yue and Unger (2017)
406 found aerosol DFE was limited at cloudy skies. Cloud can mask aerosol DFE by
407 modifying both the quantity and quality of aerosol radiative perturbations (Yu et al.,
408 2006). First, cloud weakens the impacts of aerosols on both direct and diffuse radiation
409 (Figure 2 and S4) by reducing the total sunlight available for the extinction by aerosols
410 (Kinne, 2019). Therefore, the smaller changes in diffuse PAR by aerosols under all sky
411 conditions (Figure 2) result in lower DFE than that under clear sky conditions. Second,
412 cloud significantly reduces direct radiation and limits the potential of increasing GPP
413 by diffuse radiation. Observations have shown an optimal diffuse fraction of 0.4-0.6 to

414 enhance GPP for most plant types (Zhou et al., 2021c). A further increase of diffuse
415 fraction above the optimal range will dampen GPP due to the reduced photosynthesis
416 of sunlit leaves. Appearance of cloud has provided an environment with high diffuse
417 fraction that aerosols may have limited benefits or even negative effects for GPP (Yue
418 and Unger, 2017). Such relationship also explains why the decreasing trend of global
419 cloud amount contributes to an increased aerosol DFE (Figure 7a).

420 Anthropogenic aerosols account for ~25% of the total aerosol-induced
421 enhancement of diffuse radiation (Figure 2), while they contribute 41% to the total
422 aerosol DFE at both all and clear sky conditions (Figure 3). The higher efficiency of
423 anthropogenic aerosols in increasing GPP is partly associated with their geographic
424 distribution. Regionally, anthropogenic aerosols take a leading role in DFE over North
425 America, Europe, India, and eastern China, consistent with the estimations by Strada
426 and Unger (2016). On the other hand, natural aerosols dominate DFE at the tropical
427 regions. Observations have revealed higher optimal diffuse fraction at higher latitudes,
428 where the higher solar zenith angle induces larger fraction of shading leaves (Zhou et
429 al., 2021c). As a result, the same amount of diffuse radiation increased by anthropogenic
430 aerosols results in higher GPP enhancement at the middle latitudes than natural aerosols
431 at low latitudes. Furthermore, a dominant fraction of natural aerosols is contributed by
432 dust and sea salt, which increase diffuse radiation over the barren land or open ocean
433 with little forest coverage (Figure 2). In contrast, most anthropogenic aerosols locate at
434 populous regions covered with dense vegetation. Consequently, the diffuse radiation by
435 anthropogenic aerosols has more interactions with ecosystems than that from natural

436 sources.

437 Different aerosol species induce varied DFEs to global GPP. Sulfate and nitrate
438 dominate the aerosols-induced GPP changes (Figure 6) because their strong scattering
439 effects (Gu et al., 2003) largely increase diffuse radiation (Figure 5 and S7). Keppel-
440 Aleks and Washenfelder (2016) estimated that the regional reductions of sulfate
441 aerosols decreased diffuse radiation by $0.6\% \text{ yr}^{-1}$ and GPP by $0.07\% \text{ yr}^{-1}$ in eastern U.S.
442 during 1995-2013. Such negative trends of GPP can also be found over the same region
443 in our clear-sky simulations (Figure S9b). However, the global ΔGPP shows limited
444 trends under clear sky conditions (Figure 7b) because the enhanced SO_2 emissions in
445 China at the same period (Hoesly et al., 2018) increased sulfate loading, promoted local
446 GPP (Figure S9b), and offset the negative ΔGPP in eastern U.S. In our simulations, OC
447 aerosols promote global GPP by $0.47 \text{ Pg C yr}^{-1}$. Such magnitude is much lower than the
448 estimates of $0.76\text{-}1.61 \text{ Pg C yr}^{-1}$ for the same aerosol species by Rap et al. (2018). The
449 main cause of such discrepancy is related to the predicted aerosol concentrations and
450 radiative effects in two studies (Zhou et al., 2021b). Dust and sea salt aerosols increase
451 regional GPP over arid and coastal regions due to the large local emissions (Yue et al.,
452 2010; Yue and Liao, 2012). Under all sky conditions, dust exerts a large DFE over North
453 Africa and Middle East (Figure 3a) because of the low cloud coverage (Figure S10).
454 However, such high GPP ratio shows limited contributions (Figure 4) to global total
455 ΔGPP because of the extremely low baseline GPP in arid regions. Different from above
456 species, BC exerts negative impacts on direct and diffuse PAR owing to strong
457 absorbing properties (Kvalevåg and Myhre, 2007). As a result, BC aerosols always

458 decrease GPP with stronger dampening effects under all sky conditions (Figures 6c and
459 6d) when the light availability is much smaller than that under clear sky conditions.

460

461 4.2 Uncertainties

462 Our simulations are subject to limitations and uncertainties. First, biases in aerosol
463 profiles may influence the derived aerosol DFE. We used the chemical transport model
464 GEOS-Chem to predict aerosol concentrations and identify contributions from natural
465 and anthropogenic sources. Evaluations showed that GEOS-Chem underestimated
466 global AOD by 25.8%, especially over Amazon, central Africa, and boreal Asia (Figure
467 S1) where natural aerosols dominate. In contrast, simulated AOD is overestimated in
468 eastern China where anthropogenic sources dominate. To explore the effects of such
469 underestimation on global aerosol DFE, we performed three additional simulations with
470 1.5, 2 and 3 times of original aerosol concentrations. Predicted aerosol DFE in these
471 three simulations are respectively, 1.13 Pg C yr⁻¹, 1.18 Pg C yr⁻¹ and 0.97 Pg C yr⁻¹
472 (Figure S12), similar to the estimate of 0.95 Pg C yr⁻¹ (Figure 3a) with original aerosol
473 concentrations. Regionally, aerosols reduce GPP up to -3% over Amazon, Center
474 Africa, India, eastern China and Indonesia under double or tripled aerosols conditions,
475 which are related to negative effects from high cloud amount (Figure S11) or aerosol
476 loading (Figure S1).

477 Second, the uncertainties of emission inventory may influence the conclusions. In
478 this study, CEDS emission inventory is used for anthropogenic emissions. Here, we
479 used another emission database (EDGAR) to assess the uncertainties of DFE from

480 anthropogenic aerosols. The new simulations showed that anthropogenic aerosols
481 increased global GPP by $0.31 \text{ Pg C yr}^{-1}$ (Figures S13-S14), lower than the value of 0.39
482 Pg C yr^{-1} predicted with CEDS inventory (Figure 3). The spatial pattern of the
483 percentage contributions remains similar for the two inventories, both of which show
484 dominant impacts by anthropogenic aerosols over Eastern China, India, Europe and
485 North America. For DFE of aerosol species, anthropogenic sulfate and nitrate aerosols
486 still dominate global aerosol DFE up to 28.2 % and natural OC aerosols contribute 18.2%
487 to aerosol DFE (Figure S15), which is similar to that from CEDS.

488 Third, uncertainties in the radiative transfer may cause biases to aerosol DFE.
489 Although the CRM was fully validated with observations (Figure S2 and S3), simulated
490 aerosol radiative effects showed large differences compared to other studies. For
491 example, Chen and Zhuang (2014) found that aerosols increased surface diffuse PAR
492 by 5.2 W m^{-2} using another radiative transfer model. In our simulations, we estimated
493 that aerosols increased diffuse PAR by only 1.26 W m^{-2} . As a result, the GPP
494 enhancement by aerosol DFE is $0.95 \pm 0.13 \text{ Pg C yr}^{-1}$ in our study, much lower than the
495 value of 4.9 Pg C yr^{-1} in Chen and Zhuang (2014) though the latter study also considered
496 aerosol-induced changes in temperature and soil moisture. However, the aerosol
497 radiative effects are likely overestimated in Chen and Zhuang (2014), which predicted
498 total (direct + diffuse) reductions of 21.9 W m^{-2} in surface solar radiation by aerosols;
499 such magnitude is much higher than the multi-model ensemble estimate of -6.3 W m^{-2}
500 under clear sky conditions (Yu et al., 2006). As a comparison, our simulations showed
501 a reduction of 5.8 W m^{-2} in surface shortwave radiation, much closer to the ensemble

502 estimates by Yu et al. (2006).

503 Fourth, we ignored the interactive effects among different aerosol species.
504 Although we isolated the impacts of individual aerosol species on global GPP, their
505 non-linear influences still exist in our simulations. For the radiative responses to aerosol
506 species, we found that total aerosols enhance diffuse PAR by 1.26 W m^{-2} (Figure 2) and
507 reduce direct PAR by 2.78 W m^{-2} (Figure S4). However, the sum of individual aerosol
508 effects causes a net enhancement of 1.35 W m^{-2} in diffuse PAR (Figure S5) and a
509 reduction of 2.9 W m^{-2} in direct PAR (Figure S6), both of which are slightly higher than
510 the effects of all aerosols. Similarly, aerosols enhance global GPP by $0.95 \text{ Pg C yr}^{-1}$
511 (Figure 3) but the sum of individual aerosol species enhance global GPP by 1.21 Pg C
512 yr^{-1} (Figure 5). Such non-linearity is caused by the complicated responses of individual
513 aerosol species, which can offset each other when they are put together. To facilitate
514 the comparisons, we explore both the absolute (Figures 6c and 6d) and actual (Figures
515 6e and 6f) contributions of individual aerosol species to global GPP.

516 Finally, we neglected the climatic responses to aerosol radiative effects. Surface
517 temperature and relative humidity is altered in response to radiative changes caused by
518 aerosols (Jing et al., 2010; Cirino et al., 2014). The increase of relative humidity can
519 increase plant photosynthesis owing to the enhancement of water use efficiency (Lu et
520 al., 2017; Wang et al., 2021), but the impacts of cooling on photosynthesis are dependent
521 on whether local background temperature is over the optimal temperature (Farquhar et
522 al., 1980). In our previous studies, we explored the direct aerosol radiative effects on
523 NPP in China through changes in radiation, temperature and soil moisture, and found

524 that aerosol DFE enhances regional NPP by $0.09 \text{ Pg C yr}^{-1}$ which accounts for $\sim 50\%$ of
525 the total aerosol effects (Yue et al., 2017b). Similarly, Zhang et al. (2021) explored the
526 impacts of anthropogenic aerosols on global carbon sink during 1850-2014, and found
527 that aerosol DFE accounts for 78% of the total aerosol effects on carbon uptake, which
528 is much higher than the effects caused by temperature and precipitation changes.
529 Moreover, the changes in clouds from aerosol indirect effects were not considered in
530 this study. Clouds can significantly influence aerosol DFE because of its strong
531 scattering effects (Figure 3). The perturbations in clouds can further influence surface
532 temperature, precipitation, and radiation (Zhu et al., 2019), leading to more complex
533 impacts on terrestrial ecosystem productivity. However, these interactive effects by
534 aerosols need to be resolved using earth system models that implement fully coupled
535 atmospheric chemistry, radiation, land biosphere, and climate feedbacks.

536

537 4.3 Implications

538 Our study reveals that aerosol DFE can enhance global GPP by $0.95 \text{ Pg C yr}^{-1}$
539 under all sky conditions and as high as $8.91 \text{ Pg C yr}^{-1}$ under clear sky conditions. The
540 natural and anthropogenic aerosols make comparable contributions globally but with
541 distinct spatial patterns. The DFE, as well as the climatic effects, suggests that aerosols
542 play important roles in mitigating global warming through direct (cooling) and indirect
543 (more carbon assimilation) processes. Although the reductions of aerosols may weaken
544 the DFE, the associated reductions of cloud amount due to reduced aerosol-cloud
545 interactions may induce more benefits to ecosystems. Furthermore, reductions of black

546 carbon aerosols help relieve both climate warming and GPP inhibitions. Our results
547 suggest that aerosol DFE should be considered in projecting future changes in terrestrial
548 ecosystem productivity especially for different emission scenarios.

768

Period	Region	Method	Species	Results ^a	References
2000-2001	Eastern United States	Model	Aerosols	Aerosol DFE decreases NPP by 0.71 g C m ⁻² (-0.09%) in 2000 but increases NPP by 5 g C m ⁻² (0.5%) in 2001	Matsui et al. (2008)
1960-1999	Global	Model	Cloud and aerosols	DFE enhances the land carbon sink by approximately one quarter during 1960-1999	Mercado et al. (2009)
2002-2003	Amazon	Flux.obs	Smoke aerosols	The increase of CO ₂ uptake under high AOD is due to DFE (80%) and decreased temperature (20%)	Doughty et al. (2010)
2007 July–August	Northwest China	Flux.obs	Cloud and aerosols	Cloud dominates DFE, but aerosols lead to negative carbon uptake	Jing et al. (2010)
2003-2010	Global	Model	Aerosols	Aerosol DFE enhances GPP by 4.9 Pg C yr ⁻² , NPP by 3.8 Pg C yr ⁻² , and NEP by 3.9 Pg C yr ⁻²	Chen and Zhuang (2014)
1999-2009	Amazon	Flux.obs	Cloud and fire aerosols	Low AOD and cloud cover lead to relatively larger photosynthetic efficiency than high aerosol loading and thick cloud	Cirino et al. (2014)
1998-2007	Amazon	Model	Fire aerosols	Fire aerosols enhance diffuse radiation by 3.4-6.8% and NPP by 1.4-2.8%	Rap et al. (2015)
2003-2012	Eastern United States	Flux.obs	Aerosols	High AOD (>0.6) enhances plant productivity for forests, but causes negative effects for croplands and grasslands.	Strada et al. (2015)
2000	Global	Model	Aerosols	Aerosol DFE increases global GPP by 1-2%	Strada and Unger (2016)
1995-2013	United States	Model	Sulfate aerosols	The reductions of sulfate aerosols lead to decreased diffuse light by 0.6% yr ⁻¹ and GPP by 0.07% yr ⁻¹	Keppel-Aleks and Washenfelder (2016)
2010	Amazon	Model	Fire aerosols	Fire aerosols increase GPP by 27%, plant respiration by 10% and decrease soil respiration by 3%	Moreira et al. (2017)
2010-2050	Boreal North America	Model	Fire aerosols	Fire aerosols increase NPP by 8 Tg C yr ⁻¹ at 2010s and 14 Tg C yr ⁻¹ at 2050s due to increased diffuse radiation of 2.6 W m ⁻² (1.7%) and 4.0 W m ⁻² (2.3%)	Yue et al. (2017a)
2009-2011	China	Model	Aerosols	Aerosols increase NPP by 1.6±0.5% under all sky conditions and 35±0.9%	Yue and Unger (2017)

				under clear sky conditions	
2008-2017	Eurasia	Flux.obs	Aerosols	High aerosol loading increases GPP by 6-14% at all sites.	Ezhova et al. (2018)
2000	Global	Model	Biogenic aerosols	Biogenic aerosols enhance global NPP by 1.23 Pg C yr ⁻¹ due to DFE	Rap et al. (2018)
2001-2011	Global	Model	All and fire aerosols	All (fire) aerosols increase global GPP by 1.0±0.2 (0.05±0.3) Pg C yr ⁻¹ due to DFE	Yue and Unger (2018)
2014-2015	China	Flux.obs	Aerosols	Photosynthesis of sunlit and shaded leaves increases by 0.56% and 10.71% due to the increase AOD of 0.1	Wang et al. (2018)
2000	Amazon	Model	Fire aerosols	Fire aerosols increase NPP by 5-13 Tg C yr ⁻¹ due to radiative effects	Malavelle et al. (2019)
2018	Western North America	Flux.obs	Wildfire-smoke aerosols	Aerosols lead to GPP enhancement of 1.2-4.1% compared to the previous growing season	Hemes et al. (2020)
2006-2015	China	Model	Aerosols	Aerosols enhance GPP by 0.36 Pg C yr ⁻¹ (5%), and DFE makes the dominant contribution (59-62%)	Xie et al. (2020)

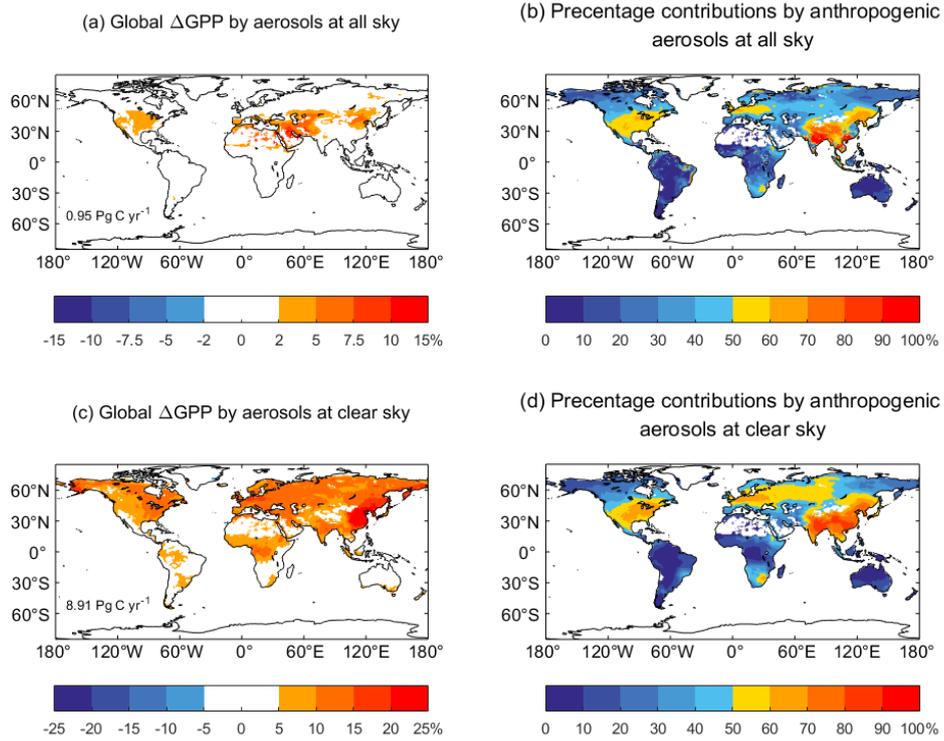

Figure 1 Simulated and observed GPP responses to direct and diffuse radiation. The comparisons are performed at 10 FLUXNET sites where more than 8 years of observations are available. For each site, hourly observations are divided into direct and diffuse conditions if diffuse fraction is <0.2 (blue squares) and >0.8 (red diamonds), respectively. The classified observations are averaged over PAR bins of 40 W m^{-2} with errorbars indicating one standard deviation of GPP for each bin. Similarly, simulations are also divided into direct (green) and diffuse (yellow) bins of PAR with gray shading indicating one standard deviation. The plant function types include evergreen broadleaf forest (EBF), evergreen needleleaf forest (ENF), deciduous broadleaf forest (DBF), grassland (Grass), and cropland (Crop). The site name and vegetation type are listed on the title of each panel.

789

790 **Figure 2** Global annual changes of diffuse PAR at surface by all, natural, and anthropogenic aerosols
 791 under all sky conditions (a, b, c) and clear skies (d, e, f). The aerosol species include natural (BC,
 792 OC, dust, sea salt, sulfate, and nitrate) and anthropogenic (BC, OC, sulfate, and nitrate) aerosols.
 793 The total changes in PAR caused by different aerosol sources are shown on corresponding panels.
 794 Changes of diffuse PAR caused by individual aerosol species are shown in Fig. S4. The units are W
 795 m⁻².

Figure 6 (a, b) Dominant aerosol species contributing to the simulated changes in annual GPP, (c, d) percentage contributions of aerosol species to global GPP, and (e, f) actual DFE of aerosol species in specific regions at (a, c, e) all skies and (b, d, f) clear skies. The contributions in (c) and (d) are calculated as the ratios of absolute DFE, as BC aerosols induce negative DFE. The normal (bold) fonts in (c) and (d) represent aerosol species from natural (anthropogenic) sources. Regions with relatively high percentage changes in GPP (>1% for all-sky and >5% for clear-sky) by aerosols are shown in (a) and (b). The regions include eastern China (ECH), India (INA), Middle East (ME), eastern U.S. (EUS), and Europe (EUR), which are marked as black boxes in (a) and (b). The black, green, red, yellow, and blue represent the effects of BC, OC, sulfate and nitrate, dust, and sea salt aerosols, respectively.

830

831 **Figure 7** Interannual variations of GPP changes induced by the DFE of natural and anthropogenic
 832 aerosols at (a, c) all skies and (b, d) clear skies during 2001-2014. The left and right bars at each
 833 year in (c) and (d) represent the effects of natural and anthropogenic aerosol species, respectively.
 834 The hollow circles and shadings in (a) and (b) represent annual mean and standard deviation of
 835 aerosol-induced GPP changes from all months in each year. The black, green, red, yellow, and blue
 836 bars indicate the effects of BC, OC, sulfate and nitrate, dust, and sea salt aerosols, respectively.
