

1 Comment on “Isotopic evidence for dominant secondary production of HONO in
2 near-ground wildfire plumes.”

5

6 **Abstract**

7 Chai et al. (2021a) recently published measurements of wild fire (WF) derived oxides of nitrogen
8 (NO_x) and nitrous acid (HONO) and their isotopic composition. The method used to sample
9 NO_x, collection in alkaline solution, has a known 1:1 interference from another reactive nitrogen
10 compound, acetyl peroxyxynitrate (PAN). Although PAN is thermally unstable, subsequent
11 reactions with nitrogen dioxide (NO₂) in effect extend the lifetime of PAN many times longer
12 than the initial decomposition reaction would indicate. This, coupled with the rapid and efficient
13 formation of PAN in WF plumes, means the NO_x measurements reported by Chai et al. were
14 severely impacted by PAN. In addition, the model reactions in the original paper did not include
15 the reactions of NO₂ with hydroxyl radical (OH) to form nitric acid, nor the efficient reaction of
16 larger organic radicals with nitric oxide to form organic nitrates (RONO₂).

17

18 **Main Text**

19 Chai et al., present ground-based measurements of nitrous acid (HONO) and the oxides
20 of nitrogen (NO_x) and their ¹⁵N and ¹⁸O isotopic abundances in airmasses in the immediate
21 vicinity of wildfire (WF) (Chai, et al., 2021a). Although the paper was openly reviewed by me
22 (Roberts, 2021) and somewhat modified as a result, there are several aspects of the methodology
23 and interpretation of the results that bear further commenting on.

24 The main problem with the methodology, sample collection of NO_x in alkaline solution,
25 is a 1:1 interference (as N) from acetyl peroxyxynitrate (CH₃C(O)OONO₂, PAN) a ubiquitous
26 product of volatile organic compound (VOC)-NO_x photochemistry. We have known this for
27 decades as alkaline collection and hydrolysis has been used in a number of studies as a means to
28 calibrate PAN sources (see for example Stephens, 1969, Grosjean et al., 1984, Grosjean and
29 Harrison, 1985, and references in Roberts 1990). The basis of PAN interference with NO_x
30 collection is really not in dispute since PAN is at least 2-orders of magnitude more soluble in
31 water than NO and NO₂ (Sander, 2015) and its alkaline hydrolysis is extremely rapid and forms

32 nitrite (see for example Steer et al., 1969). Nitrite of course is one main product of the aqueous
33 reactions of NO_x and is converted to nitrate by permanganate in the method of Chai et al.,
34 (2021a). Thus, any conditions that will completely collect and convert NO_x to nitrate will
35 convert PAN to nitrate quantitatively.

36 Regrettably, there are no PAN measurements in this study with which to constrain this
37 interference. However, Chai et al., argue in their reply and in their paper (Chai et al., 2021a&b),
38 that very little PAN would be present in the air masses they sampled due to the relative freshness
39 of the WF emissions not having made much PAN yet and/or due to the thermal instability of
40 PAN. The gist of this Comment is that the arguments underlying two assumptions are simply not
41 correct.

42 The kinetics of the thermal decomposition of PAN and related compounds are well
43 studied, (see for example the review by Kirchner et al., (1999), and the more recent work of
44 Kabir (2014)). It is true that the initial reaction:

46
47
48 is relatively rapid at 298K, $4 \times 10^{-4} \text{ s}^{-1}$. However, net loss of PAN only occurs if the peroxy
49 radical is lost due to reaction with nitric oxide;

51
52
53 The other main fate of the peroxyacetyl (PA) radical is recombination with NO₂ to reform PAN

55
56
57 As a result, the loss of PAN due to thermal decomposition should be expressed as an effective
58 net loss rate;

$$59 \text{Net Loss Rate} = k_1 \{ 1 - (k_3[\text{NO}_2] / (k_3[\text{NO}_2] + k_3[\text{NO}])) \} \quad (4)$$

60
61

62 This introduces a dependence of the loss rate on the ratio $[\text{NO}_2]/[\text{NO}]$ shown in Fig. 1. NO_x
63 measurements from the Chai study itself correspond to lifetimes as long as 8 hours, clearly long
64 enough for PAN to persist at ground level, and to be mixed throughout the daytime planetary
65 boundary layer (PBL). This aspect of PANs chemistry has considerable experimental support,
66 (see for example Roberts et al., 2007), and is one of the reasons why PANs are universally
67 observed at ground level. In fact, the only instances in which ground level PAN concentrations
68 over the continent reach very low levels, essentially zero, are nighttime periods under very stable
69 nocturnal boundary layers with local sources of nitric oxide (see for example Roberts et al.,
70 2002). Daytime PAN levels are more characteristic of the entire daytime PBL because of the
71 relatively long lifetime and PBL mixing times on the order of a few hours. The other major gas
72 phase losses of PA radical involve reaction with HO_2 or RO_2 radicals and have similar rate
73 constants to Reactions (2&3), $1-2 \times 10^{-11} \text{ cm}^3\text{molec}^{-1}\text{s}^{-1}$, so will only be important when NO_x
74 levels are below 100 pptv or so. It should also be noted that other photochemical loss processes
75 for PAN (photolysis, reaction with OH) are quite slow compared to thermal decomposition
76 (Talukdar et al., 1995) and will not impact PAN in this environment. So, it is possible that that
77 the Chai et al., (2021a) results from young nighttime plumes could have been had very low to no
78 PAN contributions, but all the other sampling instances will have had substantial contributions
79 due to PAN.

80 The magnitude of this contribution could be quite large due to rapid a formation of PANs
81 in WF plumes and the fact that long PAN lifetimes mean that formation of PANs aloft will
82 impact the ground due to mixing. As indicated by the references quoted by Chai et al, (2021a)
83 and other relatively recent papers, PANs formation is often rapid in WF plumes, so PAN/ NO_x
84 can reach or exceed 1 within $\frac{1}{2}$ -to-several hours. For example: Alvarado et al., (2010) observed
85 40% conversion of WF NO_x to PAN within a few hours, Juncosa Callahorrano (2020) found
86 PAN/ NO_x averaged more than 1 after 1 hr of processing during one of the same projects as Chai
87 et al. So, we can conclude with considerable confidence that production of PAN from WF NO_x
88 likely impacted airmasses that authors have termed as “young daytime”, and certainly impacted
89 the airmasses that have been categorized as “mixed” and “aged”. **There are ground-level**
90 **measurements of PAN and oxides of nitrogen in the Boise, Idaho urban area during the 2017 WF**
91 **season (McClure, and Jaffe, 2018), and they show that PAN levels are a substantial fraction of**
92 **odd-nitrogen, and are certainly significant relative to NO_x .**

93 Chai et al. (2021a&b) use the results of their ^{15}N -NO_x measurements, particularly those
94 of the aged categories, to argue against a significant contribution from PAN. However, their
95 conceptual model does not take into account the other NO_x chemistry that we know to be taking
96 place in this environment: reaction of NO₂ to form HNO₃ from OH +NO₂, the formation of
97 organic nitrate species RONO₂ from reaction of RO₂ radicals with NO, and nighttime reactions
98 of NO₃ and N₂O₅. So, PAN formation is not the only reactive nitrogen chemistry that will shift
99 $\delta^{15}\text{N}$ -NO_x (which is actually $\delta^{15}\text{-(NO}_x + \text{PAN)}$) to lower values relative to the WF signature. This
100 other NO_x chemistry needs to be considered.

101 The community engaged in ^{15}N isotopic analysis appears to be left with a conundrum:
102 why don't ^{15}N signatures, from NO_x + PAN and other reactions of NO_x, match their current
103 understanding of the effects of photochemistry? As with many such situations, this is an
104 opportunity to learn and refine our understanding of ^{15}N cycling in atmospheric photochemistry.
