**Abstract.** We present a method for estimating fossil fuel methane emissions using observations of methane and ethane, accounting for uncertainty in their emission ratio. The ethane : methane emission ratio is incorporated as a spatially and temporally variable parameter in a Bayesian model, with its own prior distribution and uncertainty. We find that using an emission ratio distribution mitigates bias from using a fixed, potentially incorrect emission ratio and that uncertainty in this ratio is propagated into posterior estimates of emissions. A synthetic data test is used to show the impact of assuming an incorrect ethane : methane emission ratio and demonstrate how our variable parameter model can better quantify overall uncertainty. We also use this method to estimate UK methane emissions from high-frequency observations of methane and ethane from the UK Deriving Emissions linked to Climate Change (DECC) network. Using the joint methane–ethane inverse model, we estimate annual mean UK methane emissions of approximately 0.27 (95 % uncertainty interval 0.26–0.29) Tg yr<sup>-1</sup> from fossil fuel sources and 2.06 (1.99–2.15) Tg yr<sup>-1</sup> from non-fossil fuel sources, during the period 2015–2019. Uncertainties in UK fossil fuel emissions estimates are reduced on average by 15 % and up to 35 % when incorporating ethane into the inverse model, in comparison to results from the methane-only inversion.

#### **1** Introduction

Atmospheric methane  $(CH_4)$  is a potent greenhouse gas with many natural and anthropogenic sources. These sources can be split into three main types: microbial methane, which

- <sup>5</sup> is emitted during the decomposition of organic matter; pyrogenic methane, which is formed during incomplete combustion of biomass; and thermogenic methane, which is released from fossil fuels during their extraction, refinement and use. Globally, anthropogenic sources account for approx-
- <sup>10</sup> imately 60 % of total methane emissions. The largest sources of methane are agriculture and waste management (approximately 35 % of total emissions) and fossil fuel production and use (approximately 20 % of total emissions) (Saunois et al., 2020).
- <sup>15</sup> Methane has contributed to approximately 25 % of the total anthropogenic radiative forcing caused by warming agents since pre-industrial times (Myhre et al., 2013). Due to its short atmospheric lifetime of around a decade and high impact on radiative forcing in the atmosphere, reduction in <sup>20</sup> methane emissions is a key target for many countries (Gane-
- san et al., 2019).

Despite its importance when considering climate change targets, concentrations of methane in the atmosphere are continuing to rise rapidly. Recent years have seen an accelera-

- <sup>25</sup> tion in this upward trend, with a global annual increase in atmospheric methane concentration of approximately 15 ppb (parts per billion) between 2019 and 2020 (Dlugokencky and NOAA/GML, 2021). There is no established consensus over the cause of the recent increase in atmospheric concentration,
- <sup>30</sup> with studies suggesting increases in tropical wetland emissions (Bousquet et al., 2011; Nisbet et al., 2019; Schaefer et al., 2016), potential changes to the hydroxyl radical concentration (Rigby et al., 2017; Turner et al., 2017; Thompson et al., 2018) and variation in fossil fuel emissions (McNorton
- <sup>35</sup> et al., 2018; Thompson et al., 2018; Hausmann et al., 2016) as possible contributors. The variety of proposed mechanisms for recent changes in atmospheric methane highlights why this is a key area for research.

In this work, we present a method to quantify <sup>40</sup> methane emissions with improved uncertainty characterisation through inverse modelling of atmospheric observations. Estimates of sector-level emissions are calculated using observations of a secondary trace gas and its emission ratio relative to methane. The key development in this work over pre-

<sup>45</sup> vious methods is the inclusion of an emission ratio as a variable parameter, which is inferred along with sectoral methane emissions using a Bayesian inversion framework.

A general discussion of methane emissions estimation and a review of previous work using ethane for fossil fuel emis-<sup>50</sup> sions estimation is provided in the rest of Sect. 1. We discuss our statistical method in Sect. 2. The methods used for a synthetic data experiment and for a case study on the UK's fossil fuel methane emissions are described in Sects. 2.1 and 2.2. Results from these two experiments are given in Sect. 3 and discussions of the results in Sect. 4, followed by our conclud- 55 ing remarks.

## 1.1 Estimating methane emissions

Methane emissions can be estimated using two main approaches: bottom-up and top-down modelling. Bottom-up methods model the physical and chemical processes of 60 methane emission to create estimates of sector-level emissions, which can be distributed in space and time at a range of resolutions. However, methane emissions inventories have been shown to be inaccurate in some cases when compared to observations, which could lead to an incorrect represen- 65 tation of methane sources. For example, the spatial distribution of methane emissions from oil and gas sources in the Emissions Database for Global Atmospheric Research v.4.2 (EDGAR) (Team EDGAR, 2021) was shown to be too heavily weighted towards locations where these fuels were dis-70 tributed and used, rather than areas of fossil fuel extraction and production (Chen et al., 2018). Recent updates to this inventory (v.5.0 and 6.0) now include more detailed temporal and spatial profiles.

Top-down estimation of emissions uses observations of <sup>75</sup> methane concentrations in the atmosphere and a chemical transport model to infer fluxes, often through Bayesian methods. These observations can be directly sampled from ambient air or remotely sensed. An estimate of emissions from a bottom-up model is typically used as prior information to inform the top-down inverse model during the inference of a posterior emissions distribution and to partition emissions to their source based on their location.

Measurements of additional trace gases can be used with a top-down approach to partition emissions, when these trace 85 gases are co-emitted with methane from a particular source at a characteristic ratio. For example, carbon monoxide (CO) is co-emitted with methane during incomplete combustion (Heald et al., 2004), so it could be used to quantify emissions from biomass burning. Ethane  $(C_2H_6)$  is emitted by  $_{90}$ fossil fuel production and use and has no significant emissions from biogenic sources (Peischl et al., 2013; Helmig et al., 2016), so it can be used to quantify fossil fuel methane emissions. Methane isotopologue observations (e.g. <sup>13</sup>CH<sub>4</sub>) can be utilised to apportion emissions in a similar method, 95 by considering the ratio of isotopologues emitted from each source type (Milkov et al., 2020; Lan et al., 2021). Studies have shown that when incorporating emission ratios or observations of additional gases into emissions quantification frameworks, the uncertainty in emission estimates of the pri-100 mary gas can be reduced significantly when compared to a single gas model (Palmer et al., 2006; Wang et al., 2009; Boschetti et al., 2018). However, these approaches always require a thorough understanding of the associated emission ratios, as inaccuracies in these values could introduce large 105 posterior errors (as discussed in Nathan et al., 2018) or lead

to emissions being incorrectly partitioned (Schwietzke et al., 2016; Sherwood et al., 2017).

# 1.2 Previous work using ethane observations to infer fossil fuel methane emissions

- <sup>5</sup> Previous studies have used ethane observations and emission ratios in a range of methods for the source partitioning of methane emissions. Typically, the enhancement in aircraft mole fraction observations of methane and ethane is compared to a bottom-up estimate of an ethane : methane ratio
- <sup>10</sup> to assign a proportion of total regional methane emissions to a fossil fuel source (e.g. Baier et al., 2020; Mielke-Maday et al., 2019). Similar methods have also been used more locally over cities or individual gas fields, where comparisons between literature and observed emission ratios have
- <sup>15</sup> been used for source attribution of methane enhancements seen in individual plumes observed by ground-based vehiclemounted instruments (Yacovitch et al., 2017; Lowry et al., 2020).
- Ethane observations have also been incorporated more di-<sup>20</sup> rectly into joint inverse models, where emissions are optimised simultaneously to create emission profiles characteristic of each source type (Peischl et al., 2013; Kuwayama et al., 2019). Ethane and methane aircraft observations have also been optimised in a joint model to estimate surface methane
- <sup>25</sup> fluxes, by comparing the observed ethane : methane emission ratios to a bottom-up estimate of the ratio (Barkley et al., 2019).

Most of these previous works using observations of methane and ethane have used a fixed estimate of the ethane :

<sup>30</sup> methane emission ratio as a basis for the apportionment of methane emissions. Whilst some have considered trends in the ratio (Wunch et al., 2016), most studies assume that this ratio is constant, which is unlikely to be true in most situations (Hausmann et al., 2016; Lan et al., 2019; Nisbet et al., 25 2019) as the ratio can vary with location and over time, de-

<sup>35</sup> 2017) as the ratio can vary with location and over time, depending on the type of fossil fuel source and the type of extraction or processing techniques being used. Incorrectly assuming that this ratio is fixed could introduce errors into any sector-level emissions estimates and could alter the inference <sup>40</sup> of emission trends.

## 2 Methods

In this work, a top-down hierarchical Bayesian inverse model uses observations of a secondary trace gas and its emission ratio with respect to a primary gas to solve for emissions of <sup>45</sup> the primary gas at a sectoral level. Uncertainties in the emission ratio between the primary and secondary gases are statistically propagated into the emissions distributions through the hierarchical framework. The principle of this method is described below.

A forward model (Eq. 1) links observed mole fractions of a gas  $\mathbf{y}$  to its emissions  $\mathbf{x}$  via a linear atmospheric chemistry and transport model **H** and model–measurement error  $\epsilon$ **IISI**. **x** is inferred through an inversion of the forward model using Bayesian statistics.

$$\mathbf{y} = \mathbf{H}\mathbf{x} + \boldsymbol{\epsilon} \tag{1}$$

TS2

Prior probability density functions (PDFs) must first be assigned to the parameters. To reduce the subjectivity involved when choosing these PDFs, additional hyper-parameters can be included in a hierarchical Bayesian framework, which <sup>60</sup> places distributions on these uncertain parameters rather than imposing them as fixed values. Ganesan et al. (2014) found that by including uncertainty in parameters (such as model– measurement error) as hyper-parameters, one could better propagate uncertainties into the posterior estimate of emissions. To use these hyper-parameters in the inverse model, Bayes' theorem is extended to include the joint distributions between primary and secondary parameters  $\theta$  (Ganesan et al., 2014),

$$\rho(\mathbf{x}|\mathbf{y}) \propto \rho(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}) \cdot \rho(\mathbf{x}|\boldsymbol{\theta}) \cdot \rho(\boldsymbol{\theta}).$$
(2) 70

There is no analytical solution to maximise Eq. (2), so a Markov chain Monte Carlo (MCMC) method is used to produce a posterior distribution containing possible solutions for each of the parameters. This is an iterative method, based on the Metropolis-Hastings algorithm, that randomly sam-75 ples the PDFs of the parameters involved and then accepts or rejects these new parameter values based on their probability density, relative to the prior and observation distributions (Ganesan et al., 2014). The step sizes used to dictate the size of the sampling distribution for each parameter are 80 optimised through an adaptive MCMC process to produce an acceptance ratio of approximately 0.35, using an adapted version of Algorithm 4 from Andrieu and Thoms (2008). The first 50 % of these samples are discarded as a burn-in period to remove memory of the initial state, and every 100th value 85 of the remaining samples is retained to form posterior distributions for the optimised parameters. With MCMC methods, non-Gaussian distributions can be used to represent the input parameters; for example, a less-well-understood parameter may be better represented by a uniform distribution, where 90 upper and lower bounds of the distribution can be set to cement the solution in physical terms.

To solve for emissions from separate sources, the forward model is expanded to include emissions of the primary gas from two sectors A and B:

$$\mathbf{y}_{\text{Gas1}} = \mathbf{H}_{\text{Gas1},A} \cdot \mathbf{x}_{\text{Gas1},A} + \mathbf{H}_{\text{Gas1},B} \cdot \mathbf{x}_{\text{Gas1},B} + \epsilon_{\text{Gas1}}.$$
 (3)

Observations of the secondary gas and its emission ratio are incorporated into this model as follows. Assuming that Gas 2 is only co-emitted from sector A, with emission ratios **R** relative to Gas 1, the forward model for Gas 2 is ex- <sup>100</sup> pressed as

$$\mathbf{y}_{\text{Gas2}} = \mathbf{H}_{\text{Gas2},A} \cdot \mathbf{R} \cdot \mathbf{x}_{\text{Gas1},A} + \epsilon_{\text{Gas2}}.$$
 (4)

In an application where a particle dispersion model is used to provide transport model footprints (as is the case for the remainder of this work) and when analysing observations of

<sup>5</sup> gases with long atmospheric lifetimes, atmospheric transport of both gases can be assumed to be equivalent. Therefore, the linear transport model is the same for both gases and is represented from this point onward as **H**.

Combining the two forward models, Eqs. (3) and (4), pro-<sup>10</sup> duces a joint model where both gases inform the estimate of emissions:

$$\begin{bmatrix} \mathbf{y}_{\text{Gas1}} \\ \mathbf{y}_{\text{Gas2}} \end{bmatrix} = \begin{bmatrix} \mathbf{H}_A & \mathbf{H}_B \\ \mathbf{R} \cdot \mathbf{H}_A & 0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_{\text{Gas1},A} \\ \mathbf{x}_{\text{Gas1},B} \end{bmatrix} + \begin{bmatrix} \epsilon_{\text{Gas1}} \\ \epsilon_{\text{Gas2}} \end{bmatrix}.$$
(5)

Without a framework that can consider the uncertainty in the emission ratios, **R** would be imposed as a fixed parameter <sup>15</sup> into the sensitivity matrix at this point. In our work, the emission ratio **R** is treated as a variable parameter, requiring the expansion of Bayes' theorem as discussed above and shown in Eq. (6). Model–measurement uncertainty ( $\sigma_y$ ) is also included as a hyper-parameter, again with its own prior PDF <sup>20</sup> and uncertainty,

$$\rho(\mathbf{x}, \mathbf{R}, \boldsymbol{\sigma}_{y} | \mathbf{y}) \propto \rho(\mathbf{y} | \mathbf{x}, \mathbf{R}, \boldsymbol{\sigma}_{y}) \cdot \rho(\mathbf{x}) \cdot \rho(\mathbf{R}) \cdot \rho(\boldsymbol{\sigma}_{y}).$$
(6)

A MCMC process is used to produce posterior distributions for both the emissions and emission ratio parameters. In this study, we used this model to estimate methane emissions <sup>25</sup> from fossil fuel (FF) and non-fossil fuel (non-FF) sources, using ethane as the secondary gas. However, this model framework is highly adaptable and could be used with other tracers, for example, methane isotopologues.

### 2.1 Synthetic data experiment

<sup>30</sup> To investigate the influence of the ethane : methane emission ratio on posterior estimates of methane emissions, we carried out model runs as described above, using synthetic data generated from a known emission field and a known emission ratio. These tests used a two-sector model of identi-<sup>35</sup> cal UK fossil fuel (FF) and non-fossil fuel (non-FF) fluxes, with the same magnitude and spatial distribution of emissions. Total UK methane emissions from the UK National Atmospheric Emissions Inventory (NAEI) (https://naei.beis.gov.uk/, last access: 9 February 2022) were used to represent

<sup>40</sup> emissions from both sectors. This test simulates a scenario when fluxes from both sectors are inseparable by spatial differences alone. For these synthetic data tests we did not consider background levels of methane (i.e. the contribution to the total mole fraction from emissions outside the UK) and <sup>45</sup> only tested the ability of the inversion to return the regional (UK) emissions field.

The a priori ethane : methane emission ratio,  $\mathbf{R}$ , was assumed to be uniform across the whole domain, with a value of 0.075. This is the approximate mean ethane : methane

emission ratio from natural gas sources in Europe (Table 1). 50 We assumed no ethane emissions from the non-FF sector.

We created 4-hourly synthetic methane observations at four UK tall-tower sites and one coastal site in the UK Deriving Emissions linked to Climate Change (DECC) network (Stanley et al., 2018; Stavert et al., 2019) at Mace 55 Head (MHD), Tacolneston (TAC), Bilsdale (BSD), Ridge Hill (RGL) and Heathfield (HFD) (see Fig. A1 for locations) by combining the synthetic emissions fields with atmospheric transport footprints made using the Met Office's Lagrangian Numerical Atmospheric-dispersion Modelling En- 60 vironment (NAME) (Jones et al., 2007). See Appendix A for details on how NAME was run and for an example transport footprint. Synthetic ethane observations were created by combining FF ethane emissions (generated as FF methane emissions times the known uniform emission ratio of 0.075) 65 with the transport model footprints. To mirror the DECC network, methane observations were created for all five sites, but ethane observations were only created for two sites, MHD and TAC. For both gases, Gaussian noise with a standard deviation equal to 10 % of each measurement was added to sim- 70 ulate instrument noise and model error.

Three sets of inversions were run.

- 1. Joint methane–ethane inversions where the emission ratio was fixed at values ranging from 0.5–1.5 times the true value. This test simulates studies that hardwire <sup>75</sup> emission ratios at potentially incorrect values, without considering their uncertainty.
- 2. Joint methane–ethane inversions where the emission ratio is a variable parameter with its own PDF representing the range of uncertainty in the emission ratio. The emission ratio prior PDF was given a uniform distribution of 0.5–1.5 times the true value<sup>[1]</sup>. This simulates the situation where uncertainty in the emission ratio is built into the framework.
- 3. A methane observation only (i.e. one gas) inversion <sup>85</sup> where no ethane observations or emission ratio are included and the attribution of emissions is only informed by the spatial distinction of sources in the prior (which in this case, does not exist).

In all tests, the inversion solved for emissions as a scaling <sup>90</sup> of the a priori emission field, on a coarser grid than the native resolution of the transport model. The inversion estimated parameters for 49 regions over the UK, with the rest of the European domain split into four larger regions (see Fig. C1 for a representation of the inversion domain). The ethane : <sup>95</sup> methane emission ratios were solved for at the same resolution as methane emissions. Gaussian distributions were used for emissions parameters in these synthetic data tests. As the true emission field is known here and to represent a real-world situation where the prior mean may not necessarily be <sup>100</sup> the true value, we used emission PDFs with a priori means

#### A. E. Ramsden et al.: Quantifying fossil fuel methane emissions

Molar ratio (median and range)	Source type	Reference
0.045 (0–2.76)	Global conventional oil and gas composition	(Sherwood et al., 2017)
0.038 (0.001–1.0)	European raw gas composition	(Visschedijk et al., 2018)
0.03	UK gas and oil distribution	(Xiao et al., 2008)
(0.049–0.09)	UK gas leaks	(Lowry et al., 2020)

Table 1. Estimates of ethane : methane molar emission ratios from a range of fossil fuel methane sources.

equal to 125 % and 75 % of their true values for the FF and non-FF sectors, respectively, to simulate slightly incorrect a priori emission fields (i.e. correct total emissions but incorrect partitioning). Both sectors were given a standard devi-5 ation of 50 % of their true values. Model–measurement uncertainty was fixed at 10 % of the mean pseudo-observation value for both methane and ethane.

#### 2.2 UK methane emissions case study

We used the methane-only and joint methane–ethane inverse <sup>10</sup> models to estimate monthly UK methane emissions from 2015 to 2019. We also tested the impacts of a fixed emission ratio on posterior flux estimates and investigated the propagation of uncertainties through the model when applying an uncertainty to this emission ratio.

## 15 2.2.1 Observations and transport footprints

Methane observations were used from the five current UK DECC network sites, as discussed in Sect. 2.1. Mole fraction observations of methane were made using cavity ring-down spectroscopy (CRDS) instruments Picarro 20 G2301 and G2401, calibrated using daily standard measurements, and are reported on the WMO-X2004A scale (Stanley et al., 2018; Stavert et al., 2019). Ethane observations were made at two DECC sites, MHD and TAC, using

a Medusa gas-chromatography-mass-spectrometry (GCMS) <sup>25</sup> instrument (Prinn et al., 2018). Calibration of ethane observations is currently based on the provisional SIO-p (Scripps Institution of Oceanography) scale. Frequent comparisons between Advanced Global Atmospheric Gases Experiment (AGAGE) ethane measurements (for example those made at

- <sup>30</sup> the MHD site) and those reported by the National Oceanic and Atmospheric Administration (NOAA) at the same site, but using an independent calibration scale, show no significant long-term bias. A complete description of the ethane calibration employed here is given in Mühle et al. (2007).
- <sup>35</sup> Observations from the highest inlet at each tall-tower site were used to reduce the impact of local fluxes and to increase the size of the footprint, with the exception of 2015–2016 for ethane, when the instrument measured from the middle inlet (100 m a.g.l.) at TAC. A complete discussion of instrumen-
- <sup>40</sup> tation, inlet heights and uncertainty characterisation is presented in Stanley et al. (2018) for the MHD, TAC and RGL sites, as well as in Stavert et al. (2019) for HFD and BSD.

Observations of both gases were filtered to remove points when local emissions are likely to bias results, using similar methods to those described in Lunt et al. (2021). Measurements made at times when the tower inlet was sampling air from above the planetary boundary layer were removed. Measurements were also removed when more than 10 % of the area-integrated sensitivity at the site was from the 25 grid cells surrounding the site (i.e. local sources). Remaining observations were averaged into 4-hourly periods. On average 40 % (range 18 %–69 %) of observations were filtered each month.

The NAME model was used to produce transport footprints for all observation sites. See Appendix A for more 55 detail on how NAME was run and for an example footprint for the network of sites. As methane's lifetime of around a decade is long compared to the timescale of transport within the regional domain (on the order of days), we assumed that atmospheric loss is negligible and that only transport 60 influences the relationship between surface emissions and atmospheric concentrations. Ethane has a shorter lifetime than methane (from approximately 2 months in summer to 6 months in winter (Helmig et al., 2016)). However, we found atmospheric loss of ethane on a 2-month timescale to have 65 a negligible effect on the footprints over the UK, and therefore we used the same transport footprints for both gases (see Fig. B1 for a comparison of a footprint for an inert gas and for a gas with a 2-month lifetime).

## 2.2.2 Model parameters and a priori PDFs

The a priori estimate of UK methane emissions from each sector was taken from the UK Greenhouse Gas (UKGHG, Levy, 2020) model of spatially and temporally disaggregated emissions, which is based on national, annual totals from the UK National Atmospheric Emissions Inventory <sup>75</sup> (NAEI). Emissions from the sectors "energy production", "offshore", "industrial and domestic combustion", "industrial processes", "road transport" and "other transport" were summed to form an a priori field for FF emissions. Emissions from "agriculture", "waste" and "natural" sectors formed the <sup>80</sup> a priori field for the non-FF sector. Emissions from areas outside the UK but within the modelling domain, including for example western Europe, were taken from the Emissions Database for Global Atmospheric Research (EDGAR) v5.0 (Crippa et al., 2020; Team EDGAR, 2021). The spatial distri- <sup>85</sup>

bution and percentage contribution from each source to total emissions from each grid cell are given in Fig. E1.

Boundary condition curtains representing the methane mole fractions at the edges of the study domain, were derived

- <sup>5</sup> from the global methane model CAMS v19r1 (available via https://ads.atmosphere.copernicus.eu/, last access: 9 February 2022). Spatially uniform boundary condition curtains were used for ethane, based on the monthly mean ethane concentration observed at MHD.
- Scaling factors to the a priori emissions and emission ratios were solved for at a coarser resolution than the resolution of the transport model. The study domain was split into 49 regions using a quadtree algorithm (see e.g. Western et al., 2021) which placed a higher density of smaller grid cells in
- <sup>15</sup> areas with greater sensitivity to emissions and a lower density of larger cells in areas with less sensitivity to emissions. The inverse model then solved for a scaling factor of the a priori emissions from each sector and an emission ratio for each of the 49 regions, for each calendar month (see Fig. C1 for
- <sup>20</sup> an example of the inversion grid). Four boundary condition scaling parameters representing adjustments to the curtains at each horizontal boundary were also estimated for each gas, also at monthly resolution.
- Prior distributions for emission scaling factors were as-<sup>25</sup> sumed to be Gaussian, truncated at zero to prevent the model from converging at negative emissions. Prior emission scaling factor PDFs were given a mean of 1 and standard deviation of 0.5 (before truncation). Boundary condition scaling factors for the four horizontal boundaries for each gas were
- <sup>30</sup> also given Gaussian PDFs, truncated at zero, with a mean of 1 and an uncertainty of 0.05 and 0.5 (before truncation) for methane and ethane, respectively. Ethane boundary condition uncertainties are assumed to be large due to their large seasonal and latitudinal variations.
- <sup>35</sup> Observational uncertainty includes both measurement and model uncertainty. Measurement uncertainty of 4-hourly data was calculated as the variability within the averaging period. Model uncertainty was included as a hyper-parameter, with one value per site per month solved for, during the in-
- <sup>40</sup> version. This model uncertainty was given a uniform PDF between 10 and 50 ppb for methane and between 20 and 50 ppb for ethane (these values were chosen based on results from similar work using these datasets (Ganesan et al., 2014)). Total uncertainty for each observation is calculated as the
- <sup>45</sup> quadratic sum of the measurement uncertainty at each time point and the model uncertainty at each site. A full description of a similar use of model uncertainty in a hierarchical framework can be found in Ganesan et al. (2014).

A uniform a priori emission ratio PDF was used for each of <sup>50</sup> the 49 regions with bounds of 0.0075 and 0.2. These values were chosen to include the most common ratios found by bottom-up estimates of European fossil fuel ethane : methane ratios from a range of studies and databases (Table 1).

### **3 Results**

#### 3.1 Synthetic data experiment results

Results from synthetic data tests, showing the impacts of a fixed and variable emission ratio, are summarised in Fig. 1. Because there is no spatial distinction between sources in the prior and because the total posterior emissions are the true total, the methane-only (one gas) model returns the prior mean <sup>60</sup> emissions for each sector. This lack of sectoral information from the prior is also expressed in the relatively large posterior uncertainties for both sectors.

In the joint methane-ethane inversion, there is more information available for the model to constrain emissions from 65 each source. However, when the emission ratio  $\mathbf{R}$  is fixed in the inversion at an incorrect value, the sectoral partitioning of emissions is also incorrect but is derived with high confidence. If the emission ratio is fixed at a value which is 50%lower than its true value, posterior mean FF fluxes are esti-70 mated to be over 80 % larger than their true value. As total emissions are constrained by the methane observations, the estimate for non-FF fluxes is therefore skewed in the opposite direction, with posterior mean fluxes smaller than their true value. The 95 % confidence intervals on FF emissions in 75 this test are too small to be visible on this scale, due to the high level of constraint from the fixed emission ratio. This synthetic data test highlights how errors could be introduced when using a fixed ethane : methane ratio that does not reflect the true uncertainty in the parameter. 80

Results from the joint methane–ethane model that considers the uncertainty in the emission ratio (Fig. 1 rightmost points in both Fig. 1a and b) show that the potential errors introduced by assuming an incorrect ratio can be mitigated by including **R** as a variable parameter. In this case, posterior fluxes from both sectors converge closer to the true sector-level emissions, with a reduced posterior uncertainty compared to the methane-only model output but with larger uncertainty than if fixing the emission ratio. True emissions are not replicated exactly as there is some small dependence on the emissions prior. FF emissions are constrained by both methane and ethane observations, so most of the uncertainty in **R** is therefore carried forward into the estimates of non-FF fluxes.

### 3.2 UK monthly methane emissions 2015–2019

We used the joint methane–ethane inverse model to create posterior estimates of the UK's monthly FF and non-FF methane emissions for 2015 to 2019. The methane-only model was run for the same period for comparison. Figure 2 gives the monthly posterior flux from the UK for the FF and 100 non-FF sectors. Because total methane emissions are constrained by the methane observations, posterior total emissions from the methane-only and joint methane–ethane in-

55

**Figure 1.** Posterior methane emissions expressed as means and 95 % confidence intervals from the synthetic data tests. Methane-only model (solid line and shading) and joint methane-ethane model (dots and error bars) with a range of fixed emission ratios and a variable emission ratio (rightmost point in both panels **a** and **b**). FF fluxes on the left (**a**) in purple and non-FF fluxes on the right (**b**) in green. The true and a priori mean fluxes are given as dashed and dotted grey lines, respectively.

**Figure 2.** Posterior monthly UK methane emissions in teragrams per year  $(Tgyr^{-1})$ . Total (**a**, blue), FF (**b**, purple) and non-FF (**c**, green), expressed as posterior means and 95 % uncertainty intervals of these PDFs. Methane-only model output (lighter shade line and shading) and joint methane–ethane model output (darker shade line and shading) both shown for comparison. A priori mean fluxes from the UKGHG model are given as a grey dashed line.

versions are equal. The differences in results are shown in the partitioning of emissions from the two sectors.

The joint methane–ethane inversion finds that emissions from FF sources contribute on average 15 % less to total 5 methane emissions than in the methane-only inversion. This is balanced by a proportional increase in non-FF emissions. The impact on posterior uncertainty varies across the period, with an average 15% reduction in the size of the posterior FF flux's 95% uncertainty interval, which increases up to 35% for some months. Our results show declining emissions 10

Year	$FF CH_4 (Tg yr^{-1})$	Non-FF CH <sub>4</sub> (Tg yr <sup><math>-1</math></sup> )	Total $CH_4$ (Tg yr <sup>-1</sup> )
2015	0.28 (0.26-0.31)	2.16 (2.00-2.30)	2.44 (2.32-2.56)
2016	0.28 (0.24-0.30)	2.18 (1.98-2.37)	2.46 (2.28-2.64)
2017	0.26 (0.24-0.28)	2.05 (1.88-2.21)	2.31 (2.16-2.47)
2018	0.29 (0.26-0.32)	2.01 (1.82-2.21)	2.29 (2.11-2.48)
2019	0.25 (0.23-0.28)	1.90 (1.78-2.04)	2.15 (2.03-2.28)

Table 2. Results from the joint methane–ethane inversion. Annual posterior UK methane emissions from FF and non-FF sectors, given as posterior means and 95 % uncertainty intervals.

over the time period, which is largely driven by emissions from non-FF sources. Annual mean posterior flux estimates are given in Table 2. These results are consistent with total emissions derived in previous inverse modelling studies us-5 ing the same data (Western et al., 2020; Lunt et al., 2021).

A comparison between observed methane and ethane mole fractions and posterior modelled mole fractions from the joint methane–ethane model for two example months (April-May 2019) is given in Fig. 3. Percentage differences between <sup>10</sup> observed and modelled mole fractions across the time series are given as histograms for each site. Baseline mole fractions from all methane sites (dashed lines in Fig. 3) are consistent with those from the background site (MHD). Figure F1 shows a scatter plot comparing observed and modelled pos-

<sup>15</sup> terior mole fractions from the joint methane–ethane model for the full time series from 2015–2019. There is generally a good fit to observations, but the model does not always fit to the largest methane peaks from TAC, RGL and HFD, the three sites closest to areas of high emissions. Comparisons

<sup>20</sup> between observations and an a priori estimate of mole fractions made by combining the a priori map of fluxes with the transport model are also given in Fig. F1. Overall, there is an improved fit to both methane and ethane observations in the posterior estimate of mole fractions produced by the inverse <sup>25</sup> model.

Model uncertainty for methane mole fractions converged at similar values for all sites across the time period, with a mean value of 7.75 ppb overall (with 75 % of all mean model error values between 5 and 10 ppb). Due to the high peaks 30 and troughs in ethane observations, the model consistently

attempted to converge the ethane total model uncertainty at the upper bound of its prior uncertainty range.

The a priori emissions and average spatial distribution of posterior emission scaling factors for 2019 are shown in

- <sup>35</sup> Fig. 4. The ethane observations only indirectly constrain the much larger non-FF emissions, so there is little difference in the spatial distribution of non-FF emissions between the methane-only and joint methane-ethane inversions. However, the joint methane-ethane inversion suggests a differ-
- <sup>40</sup> ent distribution of FF emissions, where emissions are scaled down in most locations, apart from a few regions with large positive scaling which often correlate with heavily populated

areas (e.g. the West Midlands, London and south coast of England).

Across the whole period of study, posterior mean ethane : 45 methane emission ratios varied across the domain between 0.009 and 0.2 (we discuss the implications of these posterior ratio values in Sect. 3.4). For example, in July 2019, approximately 20% of R values converged with clear Gaussian posterior distributions, suggesting a strongly correlated rela- 50 tionship between the two gases that the model was able to use to inform the posterior distribution of both the methane flux and ethane : methane ratio in that area. Posterior emission ratio PDFs in the remaining areas of the domain were more uniform, indicating a weak constraint from the observations 55 in those areas. Mean posterior emission ratios for two different periods are shown in Fig. 5. Some regions, for example, central south England, London and the West Midlands, often converge with high emission ratios close to the upper bound of the a priori PDF. Grid cells where the posterior un-60 certainty in R (defined as posterior 95th percentile divided by posterior mean) is less than 50 % of the prior uncertainty (prior 95th percentile divided by prior mean) are highlighted in Fig. 5, showing areas where the observations were most able to constrain **R**. 65

## 3.3 Comparison of posterior emission ratios with independent measurements

We compare posterior ethane : methane emission ratios from the hierarchical inverse model to independent calculations of this ratio, made during a range of mobile observation studies. These independent datasets are sparse, and thus only a limited validation can be performed.

Ethane and methane airborne observations were made during flight C191 of the Facility for Airborne Atmospheric Measurements (FAAM) campaign over North Sea oil and gas fields on 29 July 2019, as part of the Methane Observations and Yearly Assessments (MOYA) project. A mean average ethane : methane emission ratio of 0.088 (range 0.04–0.18) was calculated from four different plume observations using two different methods, Gaussian plume fitting and linear regression. See Appendix D for information on how these ratios were calculated. In addition, the Royal Holloway mobile laboratory sampled air around potential shale gas production sites for baseline monitoring (Lowry et al., 2020). They ob-

**Figure 3.** Left: observations (dots) and modelled observations (solid lines) of methane (red) and ethane (blue) from the UK DECC network for April–May 2019. Modelled boundary condition (baseline) emissions are also given (dashed line) along with the a priori modelled concentrations (grey). Note the different scales for each site and for each gas. Right: histograms showing the percentage differences between observed and modelled mole fractions are provided for each gas and site.

served ethane : methane ratios of approximately 0.06 from local gas leaks, on 27 February 2018. Comparisons between these individual plume estimates and our monthly posterior mean emission ratios are shown in Fig. 5a and b. Both inde-5 pendently measured ratios are approximately consistent with

the emission ratios estimated in this work. However, observations from flight C191 are located far from the DECC observation network, so our estimates of emission ratios over the North Sea are likely to have larger uncertainties than those 10 closer to the towers.

As most independent observations of ethane : methane ratios over the UK have only been taken over short time periods, this limits the scope of comparison available with our monthly model estimates of these ratios. Partitioning of the

<sup>15</sup> domain into coarse grid cells could also impact the comparison, as ratios are likely to be heterogeneous within each of these regions. As we are focused on average emissions over the month, this should not significantly affect our results but could limit the ability for further validation of our posterior emission ratios.

## 3.4 Impact of a fixed ethane : methane emission ratio on UK methane fluxes

As in the synthetic data test, we tested the impact of using a fixed ethane : methane ratio on 1 month of posterior UK sectoral methane fluxes (Fig. 6). We ran the model for <sup>25</sup> 1 month (April 2019) but used a range of spatially uniform emission ratios (**R**). As in the synthetic data test results, posterior fluxes are strongly influenced by a fixed emission ratio. For example, by assuming a fixed ratio scaling factor of 0.5 (which equates to an emission ratio of approximately 0.04, <sup>30</sup> similar to literature values for natural gas fossil fuel methane sources), the estimate of mean posterior FF flux is approximately 60 % higher than when using a fixed ratio of 0.075 (approximately the mean emission ratio from a range of studies, e.g. Table 1). As the rightmost points in both Fig. 6a and b show, the joint methane–ethane inversion with a vari-

**Figure 4.** A priori emissions and 2019 annual mean posterior emission scaling factors for UK FF (left, **a**, **c**, **e**) and non-FF (right, **b**, **d**, **f**) methane fluxes. A priori fluxes from the UKGHG model, as described in the text, are given at the resolution of the transport model (**a**, **b**). Posterior mean flux scaling factors from the methaneonly (**c**, **d**) and joint ethane–methane (**e**, **f**) inverse models are given at the coarser resolution of the transport model. Red and blue indicate a scaling up or down, respectively, of the a priori estimate.

able emission ratio samples the uncertainty in the emission ratio and propagates this into the posterior flux estimates. Uncertainties in the posterior flux estimates are therefore higher for both sectors than when using a fixed emission ratio but 5 capture the overall uncertainty in the system more accurately.

## 4 Discussion

This work demonstrates the potential advancements that can be made in sector-level emissions estimation when incorporating observations of a secondary co-emitted tracer into an 10 inverse model, but only when considering the uncertain na-

- ture of emission ratios. Both our synthetic data and UK tests show that overconfidence in knowledge of emission ratios can bias the model toward incorrect source partitioning. We also show that in the UK, the joint methane–ethane model
- <sup>15</sup> suggests a different spatial distribution of FF and non-FF emissions than reflected in the a priori estimate, which would be the sole constraint on sector partitioning in a methaneonly inversion.

One limitation of this study is that we assume that there <sup>20</sup> are no ethane emissions from sources other than those coemitted with methane from the FF sector. Small amounts of ethane are emitted naturally from geological seeps and during biomass burning (Nicewonger et al., 2016), but this should have negligible contribution to ethane emissions over

Figure 5. Comparison of posterior emission ratios  $\mathbf{R}$  from the joint methane–ethane inverse model with independently observed ethane : methane ratios labelled in white boxes. Average emission ratio for July 2019 and comparison with ratios derived from plumes observed during FAAM flight C191 (a). Average emission ratio for February 2018 and comparison to observations from the Royal Holloway mobile laboratory sampling (b). Grid cells where the posterior uncertainty (defined as posterior 95th percentile divided by posterior mean) is less than 50 % of the prior uncertainty (prior 95th percentile divided by prior mean) are filled with a hatching of black dots.

our study domain. We also assume one possible range of <sup>25</sup> emission ratios for all fuel types, rather than applying different ranges to, for example, coal or natural gas sources. A more detailed partitioning of methane sources into subsectors of fossil fuel emissions may also be possible with the model if more specific emission ratios are considered and <sup>30</sup> with a higher density of ethane observations. Our emission ratios are estimated monthly, which does not account for any short-term changes in ratios seen from, for example, flaring or gas leaks.

This study has highlighted the effectiveness of the highdensity observational network in and around the UK for estimating regional methane emissions. The methane-only model was able to produce total methane emissions estimates consistent with previous top-down estimates of UK emissions from similar years (Ganesan et al., 2015; Western et al., 40 2020). The difference between methane-only and methaneethane inversions in constraining FF sector is small, likely because of the strong spatial separation between FF and non-FF sources in the UK. Therefore, this two-gas inverse model may be even more important for quantifying sectoral emissions estimates in areas of the world where inventories are more uncertain and where there is greater spatial and temporal overlap between sources.

#### Case study sensitivity test

**Figure 6.** Posterior UK methane fluxes for May 2015, expressed as means and 95 % uncertainty intervals. Methane-only model (solid line and shading) and joint methane–ethane model (dots and error bars) with either a fixed emission ratio or a variable emission ratio (rightmost value in both **a** and **b**). FF fluxes on the left in purple (**a**) and non-FF fluxes on the right in green (**b**). The a priori mean fluxes are given as dashed grey lines.

## **5** Conclusions

We have presented a method of estimating sector-level emissions of a trace gas using a Bayesian atmospheric inverse model, observations of a secondary co-emitted tracer and its

- <sup>5</sup> emission ratio relative to the primary gas. We use methane and ethane, co-emitted from fossil fuel emissions sources, as an example to highlight the utility of this method. A critical advancement of this work is in the inclusion of ethane : methane emission ratios as a variable parameter, with its own
- <sup>10</sup> prior PDF and uncertainty. We show how this uncertainty is carried forward into posterior flux estimates to improve overall uncertainty characterisation. Through a synthetic data experiment and the UK case study, we show how errors can potentially be introduced into posterior methane estimates if
- <sup>15</sup> the ethane : methane emission ratio is assumed to be fixed but incorrect. Using a variable emission ratio and considering the uncertainty in this ratio mitigates these potential errors.

Using this model, we find average 2015–2019 UK methane emissions from fossil fuel sources of 0.27 (95%)

<sup>20</sup> uncertainty interval 0.26–0.29) Tg yr<sup>-1</sup> and from non-fossil fuel sources of 2.06 (1.99–2.15) Tg yr<sup>-1</sup>. The 95 % uncertainty intervals of the UK total methane emission estimates made here are within the bounds of most previous estimates (Ganesan et al., 2015; Zammit-Mangion et al., 2015; Lunt <sup>25</sup> et al., 2016; Western et al., 2020), but fossil fuel emissions are 15 % lower than when estimated using only methane ob-

servations and the spatial separation of emissions in the prior. This inverse model is highly adaptable and could be used

with other trace gases to constrain methane emissions from <sup>30</sup> other target sources. For example, methane isotopologue observations could be used in place of ethane to estimate methane fluxes from a range of key sources. Recent developments in instrumentation, allowing for high-frequency isotopologue observations, are a promising target for future in-

35 vestigations of methane emissions with this method.

## Appendix A: Numerical Atmospheric-dispersion Modelling Environment (NAME)

NAME is a Lagrangian particle model (Jones et al., 2007) used to estimate the relationship between surface emissions and atmospheric observations. The model simulated the 40 transport of 20 000 inert gas particles from the measurement location each hour, back in time for up to 30 d, and quantified their interaction with the surface and their exit locations/times from the study domain. These hourly footprints were then averaged into 4-hourly footprints to match the av- 45 eraging of the observations. Meteorological data from the UK Met Office's Unified Model (Walters et al., 2014) and a nested UK-specific 1.5 km horizontal resolution meteorological product were used to drive NAME at a 1-hourly temporal resolution over the UK and at 3-hourly resolution over the 50 rest of the domain. The output was stored at  $0.23^{\circ} \times 0.35^{\circ}$ spatial resolution over a domain spanning 10.7° to 79.3° N, -97.9° to 39.7° E. This process was carried out for each observation made at each site to build up a field of emissions sensitivity for the whole domain. 55

**Figure A1.** Monthly NAME sensitivities for May 2019 for the full NAME domain (**a**). Close-up of the UK (**b**) showing locations of the four tall-tower observation sites and the coastal observation site used in this study: Mace Head (MHD) at  $53.33^{\circ}$  N,  $9.90^{\circ}$  W; Tacolneston (TAC) at  $53.52^{\circ}$  N,  $1.14^{\circ}$  E; Bilsdale (BSD) at  $54.36^{\circ}$  N,  $1.15^{\circ}$  W; Ridge Hill (RGL) at  $52.00^{\circ}$  N,  $2.54^{\circ}$  W; and Heathfield (HFD) at  $50.98^{\circ}$  N,  $0.23^{\circ}$  E. Areas with higher values have greater sensitivity to emissions from the surface. Sites with a diamond marker have both methane and ethane observations. Site with a circular marker only have methane observations.

**Figure B1.** Monthly NAME sensitivities for May 2019 using ethane with a 2-month atmospheric lifetime, from sites MHD and TAC. The sensitivity to emissions (**a**) where areas with higher values have greater sensitivity to emissions from the surface. The percentage difference (**b**) between a sensitivity footprint for an inert gas (such as methane over the study time period) and a footprint for a gas with a shorter lifetime (such as ethane's summer lifetime of 2 months). The percentage difference is very low over the UK, where sensitivity is high, so we were able to assume equivalent transport for this work.

## Appendix C: Study domain grid cells

**Figure C1. (a)** Division of the study domain into grid cells used for the synthetic data tests (as discussed in Sect. 2.1). A spatially uniform grid of 49 grid cells covers UK latitude and longitudes and the remainder of the domain is split into four surrounding cells. (b) An example spacing of grid cells used in the UK case study (as described in Sect. 2.2). A quadtree function was used to split the domain into 49 grid cells, with a higher density of smaller cells in areas with higher sensitivity to emissions. In both cases, scaling factors of the a priori emissions or emission ratios are found for each coloured area in the plot.

## Appendix D: FAAM ethane : methane emission ratios

Measurements of methane and ethane were made using an <sup>5</sup> Aerodyne interband cascade laser (ICL), at a resolution of 1 Hz (France et al., 2021). These data were used to identify time periods during flight C191 with concurrent enhancements in methane and ethane. Two methods were used to derive ethane–methane ratios. (1) Regression analyses of <sup>10</sup> ethane and methane mixing ratios were performed for each enhancement. The slopes of these regressions were used to

- derive the ethane : methane ratio, using a similar approach to Wilde et al. (2021). (2) A Gaussian curve was fit to each enhancement of methane and concurrent ethane enhancement. <sup>15</sup> The integral of each of these curves was then used to calculate the athane methane ratio of each methane anhancement
- late the ethane–methane ratio of each methane enhancement. Previous work in France et al. (2021) showed that consistency is expected between these two methodologies.

## Appendix E: A priori flux estimates

**Figure E1.** Monthly FF (**a**) and non-FF (**b**) methane emissions estimates from the UKGHG model for 2015. The percentage contribution of each source to the total emissions from each grid cell is given in panel (**c**) to illustrate the strong spatial separation of methane sources in the UK and the dominance of emissions from the non-FF (primarily biogenic) sector.

#### Appendix F: Posterior mole fraction comparisons

**Figure F1.** Scatter plot comparing mole fraction observations of methane (left,  $\mathbf{a}, \mathbf{c}$ ) and ethane (right,  $\mathbf{b}, \mathbf{d}$ ) as used in this study (2015–2019) to posterior mean modelled estimates of these values, made using the joint methane–ethane inversion ( $\mathbf{a}, \mathbf{b}$ ). Comparison with a priori estimates of mole fraction concentrations made by combining the a priori flux maps with the transport model are also given ( $\mathbf{c}, \mathbf{d}$ ) to show how the joint model improves the fit to observations. Points are colour-coded by site, with the locations of these sites given in Fig. A1.

**Code and data availability.** Measurements of methane from the UK DECC network sites Tacolneston, Bilsdale, Ridge Hill and Heathfield are available from https:

- 5 //data.ceda.ac.uk/badc/uk-decc-network/data/Tacolneston[TS3], https://data.ceda.ac.uk/badc/uk-decc-network/data/Bilsdale, https://data.ceda.ac.uk/badc/uk-decc-network/data/Ridge\_Hill/, https://data.ceda.ac.uk/badc/uk-decc-network/data/Heathfield/ (last access: 9 February 2022). Measurements of methane from
- <sup>10</sup> the Mace Head site are available from https://agage2.eas.gatech. edu/data\_archive/agage/gc-md/complete/macehead/ (AGAGE Team, 2021). Ethane observations from the Mace Head and Tacolneston sites are included in the Supplement. The NAME III v7.2 transport model is available from the UK Met Office
- <sup>15</sup> under licence by contacting https://enquiries@metoffice.gov.uk (Jones et al., 2007). The meteorological data used to drive the transport model from the UK Met Office operational numerical weather prediction (NWP) Unified Model (UM) are available from https://data.ceda.ac.uk/badc/ukmo-nwp (Met Of-
- fice NAME Team, 2021). The UK Greenhouse Gas (UKGHG) 20 model is available from https://github.com/NERC-CEH/ukghg (Levy, 2020). The EDGAR v5.0 methane inventory is available https://edgar.jrc.ec.europa.eu/dataset\_ghg60 from (Team EDGAR. 2021). Data from the MOYA FAAM 25 aircraft campaign are available from the Centre for Environmental Data Analysis (CEDA) archive, at https: //catalogue.ceda.ac.uk/uuid/dd2b03d085c5494a8cbfc6b4b99ca702 (MOYA Team, 2022). The code used to infer methane emissions using these data products, with an example month of data for 30 testing, is available from https://doi.org/10.17605/OSF.IO/VH8ND (Ramsden, 2022). Any other data or code can be made available by the corresponding author on request.

**Supplement.** The supplement related to this article is available online at: https://doi.org/10.5194/acp-22-1-2022-supplement.

**Author contributions.** AR and AG led the method and code <sup>35</sup> development, investigation, and manuscript preparation. LW contributed to code development, methodology and manuscript editing. MR advised on the study. AM provided NAME footprints. PL provided the UKGHG methane flux model. AF, JF and PB collected and analysed the ethane : methane ratio validation data. DS, AW, <sup>40</sup> TA, CR, KS, SO and DY made the measurements from the UK DECC network.
