8
9 **Abstract.** Furans are emitted to the atmosphere during biomass burning from the pyrolysis of cellulose. They are one of the
10 major contributing VOC classes to OH and NO₃ reactivity in biomass burning plumes. The major removal process of furans
11 from the atmosphere at night is reaction with the nitrate radical, NO₃. Here we report a series of relative rate experiments in the
12 7300 L indoor simulation chamber at CNRS-ICARE, Orléans, using a number of different reference compounds to determine
13 NO₃ reaction rate coefficients for four furans, two furanones, and pyrrole. In the case of the two furanones, this is the first time
14 that NO₃ rate coefficients have been reported. The recommended values (cm³ molecule⁻¹ s⁻¹) are: furan (1.49±0.23)×10⁻¹², 2-
15 methylfuran (2.26±0.52)×10⁻¹¹, 2,5-dimethylfuran (1.02±0.31)×10⁻¹⁰, furfural (furan-2-aldehyde) (9.07±2.3)×10⁻¹⁴, α-
16 angelicalactone (5-methyl-2(3H)-furanone) (3.01±0.45)×10⁻¹², γ-crotonolactone (2(5H)-furanone) <1.4×10⁻¹⁶, and pyrrole
17 (6.94±1.9)×10⁻¹¹. The furfural + NO₃ reaction rate coefficient is found to be an order of magnitude smaller than previously
18 reported. These experiments show that for furan, alkyl substituted furans, α-angelicalactone, and pyrrole, reaction with NO₃ will
19 be the dominant removal process at night, and may also contribute during the day. For γ-crotonolactone, reaction with NO₃ is
20 not an important atmospheric sink.

21 **1 Introduction**

22 Furans are five membered aromatic cyclic ethers. Furans (and pyrroles – where N replaces O as the heteroatom) are generated
23 during the pyrolysis of cellulose and are a major component of emissions from wildfire burning (Hatch et al., 2015, 2017; Koss
24 et al., 2018; Coggon et al., 2019; Andreae et al., 2019). Such emissions are likely to increase in the future with the spatial extent,
25 number, and severity, of wildfires globally having increased markedly in recent decades (Jolly et al., 2015; Harvey, 2016) and
26 predicted to continue to do so as the climate warms (Krikken et al., 2019; Lohmander, 2020). Furans have also been measured
27 in emissions from residential logwood burning (Hartikainen et al., 2018), and burning of a wide variety of solid-fuels used for
28 domestic heating and cooking (Stewart et al., 2021a). Furans have been shown to account for a significant proportion of the total
29 NO₃ (Decker et al., 2019) and OH (Koss et al., 2018; Coggon et al., 2019; Stewart et al., 2021b) reactivity of emissions from
30 burning of typical wildfire and domestic fuels.

31 Alkyl substituted furans have also been suggested as promising biofuels as they can be derived from lignocellulosic biomass
32 (Roman-Leshkov et al., 2007; Binder et al., 2009; Wang et al., 2014). This would likely lead to fugitive emissions of these
33 compounds during distribution, as well as emissions of unburned and partially oxidised products from vehicle exhaust. The
34 oxidation of certain furan compounds has been shown to have large secondary organic aerosol yields (Hatch et al., 2017;
35 Hartikainen et al., 2018; Joo et al., 2019; Ahern et al., 2019; Akherati et al., 2020), which could adversely impact air quality.

36 Oxidation of furans in the atmosphere has been shown to produce 2-furanones (mono-unsaturated five-membered cyclic esters)
37 both via OH (notably hydroxy-furan-2-ones, Aschmann et al., 2014) and NO₃ (Berndt et al., 1997) reactions. 2-Furanones are

38 also produced from the OH oxidation of six-membered aromatic compounds (Smith et al., 1998, 1999; Hamilton et al., 2005;
39 Bloss et al., 2005; Wyche et al., 2009; Huang et al., 2015). In both cases, the initial product is thought to be an unsaturated
40 dicarbonyl, with production of the 2-furanone formed via photoisomerisation of the dicarbonyl to a ketene-enol (Newland et al.,
41 2019), followed by ring closure of this molecule. In the case of aromatics, the ketene-enol can also be formed directly via
42 decomposition of the bicyclic peroxy radical intermediate (Wang et al., 2020).

43 Furan type compounds are removed from the atmosphere by reaction with the major oxidants OH, NO₃ and O₃. There have been
44 a number of studies on the rates of reaction of furan type compounds with the dominant daytime oxidant, OH (Lee and Tang,
45 1982; Atkinson et al., 1983; Wine and Thompson, 1984; Bierbach et al., 1992, 1994, 1995; Aschmann et al., 2011; Ausmeel et
46 al., 2017; Whelan et al., 2020). However, there have been fewer studies on the rates of reaction of furan type compounds with
47 the major night-time oxidant, NO₃ (Atkinson et al., 1985; Kind et al., 1996; Cabañas et al., 2004; Colmenar et al., 2012).

48 The nitrate radical, NO₃, is produced in the atmosphere predominantly through the reaction of NO₂ with O₃, and exists in
49 equilibrium with N₂O₅. It has long been known to be an important night-time oxidant (Levy, 1972; Winer et al., 1984). While it
50 is also produced during the daytime, it is rapidly converted back to NO₂ by reaction with NO and by photolysis. However, in
51 environments with low NO, either due to low NO_x emissions, or suppression through high O₃ concentrations (e.g. Newland et
52 al., 2021), NO₃ oxidation has been observed to be significant during the day (Hamilton et al., 2021).

53 Here, we present results of a series of relative rate experiments for furan, 2-methylfuran, 2,5-dimethylfuran, furfural (furan-2-
54 aldehyde), α -angelicalactone (5-methyl-2(3H)-furanone), γ -crotonolactone (2(5H)-furanone), and pyrrole reaction with the NO₃
55 radical, performed in the 7300 L indoor simulation chamber at CNRS-ICARE, Orléans, France.

56 2 Experimental

57 2.1 CSA-Chamber

58

59 The CNRS-ICARE indoor chamber is a 7300 L indoor simulation chamber used for studying reaction kinetics and mechanisms
60 under atmospheric boundary layer conditions. Further details of the chamber setup and instrumentation are available elsewhere
61 (Zhou et al., 2017). Experiments were performed in the dark at atmospheric pressure (*ca.* 1000 mbar), with the chamber operated
62 at a slight overpressure to compensate for removal of air for sampling, and to prevent ingress of outside air to the chamber. The
63 chamber is in a climate controlled room and the temperature was maintained at 299±2 K.

64

65 2.2 Experimental Approach

66

67 Starting with the chamber filled with clean air, the VOCs of interest (*ca.* 3 ppmv) were added, followed by ~ 1 Torr of the inert
68 gas SF₆ to monitor the chamber dilution rate. A flow of 5 L/min of purified air was continuously added throughout the experiment,
69 and air is then removed from the chamber to maintain a constant pressure (this is a slight overpressure to prevent possible ingress
70 of air from outside the chamber). The chamber was left for at least thirty minutes prior to the start of the experiment to monitor
71 the dilution rate and losses of the VOCs to the chamber walls. These losses, $(1 - 8) \times 10^{-6} \text{ s}^{-1}$, were always smaller than dilution
72 ($\sim 1.2 \times 10^{-5} \text{ s}^{-1}$). The reaction was then initiated by continuously introducing an N₂O₅ sample, held in a trap at ~ 235 K with a part
73 of the purified air flow, (2.5 – 5) L/min directed through it, for the duration of the experiment. The chamber was monitored until

Deleted: of

75 most of the VOC of interest was consumed, with experiments generally taking 0.5 – 2 hours. The experiments were performed
76 under dry conditions (RH ≤ 1.5 %).

77 VOC abundance was determined by *in-situ* Fourier Transform Infrared (FTIR) Spectroscopy using a Nicolet 5700 coupled to a
78 White-type multipass cell with a pathlength of 143 m. Each scan was comprised of either 30 or 60 co-additions, taking a total of
79 2 or 4 minutes respectively, depending on the expected rate of loss of the VOCs, with a spectral resolution of 0.25 cm⁻¹.

80

81 2.3 Materials

82

83 The VOCs of interest: furan (>99%, Sigma-Aldrich), 2-methylfuran (>98%, TCI), 2,5-dimethylfuran (>98%, TCI), pyrrole
84 (>99%, TCI), α -angelicalactone (>98%, TCI), furfural (>98%, TCI), and γ -crotonolactone (>93%, TCI); and reference
85 compounds: 2,3-dimethyl-but-2-ene (98%, Sigma-Aldrich), 2-carene (97%, Sigma-Aldrich), camphene (95%, Sigma-Aldrich),
86 α -pinene (98%, Sigma-Aldrich), cyclohexene (\geq 99%, Sigma-Aldrich), 3-methyl-3-buten-1-ol (97%, Sigma-Aldrich), and
87 cyclohexane (99.5%, Sigma-Aldrich), were used as supplied without further purification.

88 N₂O₅ was synthesised by reacting NO₂ with excess O₃. First, NO and O₃ were mixed to generate NO₂ (Reaction R1). This NO₂ /
89 O₃ mixture was then flushed into a bulb in which NO₃ and subsequently N₂O₅ were generated through Reactions R2-R3.

90

94

95 N₂O₅ crystals were then collected in a cold trap at 190K. The N₂O₅ sample was purified by trap to trap distillation under a flow
96 of O₂ / O₃. The final sample was stored at 190 K and used within a week.

97

98 2.4 Analysis

99

100 VOC concentrations were monitored by FTIR. The furans generally have a number of major absorption bands in the infrared.
101 The main bands used for analysis are shown in Table 1 (bold), as well as other characteristic bands for each compound. Reference
102 spectra of the major bands for each compound taken in the chamber at a resolution of 0.25 cm⁻¹ are provided in the Supplement
103 (Figures S8-S14). The ANIR curve fitting software (Ródenas, 2018), which implements a least squares fitting algorithm was
104 used to generate time profiles for each compound based on their reference spectra. Profiles were checked by doing a number of
105 manual subtractions. Example time profiles from an experiment with α -angelicalactone and furan, with cyclohexene as the
106 reference compound, are shown in Figure 1. Further example plots are provided in the supplement (Figures S1-S7). All of the
107 concentration-time profiles are provided in .txt format at [10.5281/zenodo.5721518](https://zenodo.org/record/5721518) and all the raw FTIR output is provided in
108 .csv format at [10.5281/zenodo.5721518](https://zenodo.org/record/5721518). Relative rate plots for all of the experiments are shown in Figure 2.

115

116

117 **Table 1** Maxima of major absorption bands (of Q branches if present) for the compounds used in this study. Bands used
 118 predominantly for analysis are shown in bold.

Compound	Main absorption bands / cm ⁻¹
Furan	995 , 744
2-Methylfuran	792 , 726, 1151, 2965
2,5-Dimethylfuran	777 , 2938, 2961
Furfural	756 , 1720
Pyrrrole	724 , 1017, 3531, 718-722
α-angelicalactone	731, 939 , 1100, 1834
γ-crotonolactone	1098 , 805, 866, 1045, 1812, 2885, 2945
2,3-Dimethyl-2-butene	2878, 2930, 3005
2-Carene	2874, 2928, 3009
α-pinene	2971, 2998, 3035 , 789, 2847, 2893, 2925, 2931
Camphene	2967, 2972, 2986 , 882, 2881, 3075
Cyclohexene	2934 , 744, 919, 1140, 2892, 2943, 3033, 3036
3-Methyl-3-buten-1-ol	1065 , 896, 903, 2886, 2948, 2981, 3084
Cyclohexane	2862, 2933

119

120 Relative rate experiments were performed, whereby a compound (or two) with an unknown reaction rate coefficient (k_{VOC}) with
 121 NO₃ was added to the chamber with a reference compound with a known NO₃ reaction rate coefficient (k_{ref}). A plot of the relative
 122 loss of the compound against the reference compound following addition of NO₃ (via N₂O₅ decomposition), accounting for both
 123 chamber dilution and wall losses (k_d), gives a gradient of k_{VOC}/k_{ref} (Equation E1).

124

$$125 \quad \ln \frac{([VOC]_0)}{([VOC]_t)} - k_d t = \frac{k_{VOC}}{k_{ref}} \ln \frac{[ref]_0}{[ref]_t} - k_d t \quad (E1)$$

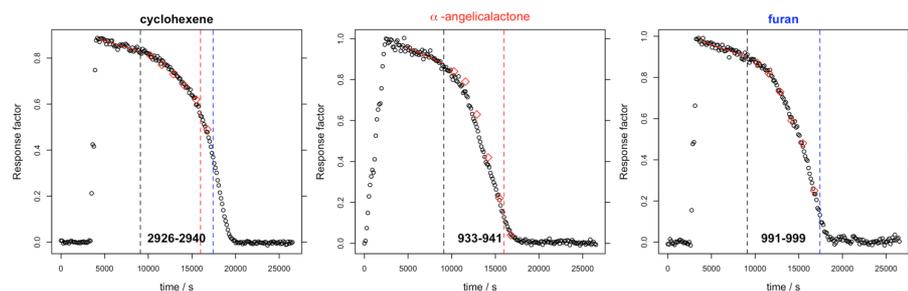

126

127 A number of reference compounds were used for each VOC, chosen so that the reference rate coefficient was roughly within a
 128 factor of five of the expected unknown rate coefficient, and with an attempt to use different references that had both larger and
 129 smaller NO₃ reaction rate coefficients than the VOC. Rate coefficients of the reference compounds (Table 2) are taken from the
 130 Database for the Kinetics of the Gas-Phase Atmospheric Reactions of Organic Compounds v2.1.0 (McGillen et al., 2020),
 131 available at data.eurochamp.org/data-access/kin/#/home.

132 N₂O₅ was not present at detectable levels (by FTIR) during most of the experiments. The only experiments in which N₂O₅
 133 concentrations built up in the chamber, were those with the slowest reacting VOCs, i.e. furfural and γ-crotonolactone. NO₂
 134 concentrations increased throughout all experiments, typically up to 2 – 3 ppmv. The NO₂ is initially produced from the
 135 decomposition of N₂O₅, and later potentially by the loss of NO₂ from nitrated VOCs / nitrated radicals. HNO₃ concentrations

136 increased throughout the experiments, typically up to 3 – 4 ppmv. This could be either due to impurities in the N₂O₃ sample, or
 137 from H abstraction reactions of NO₃. It is not thought that this level of HNO₃ will cause any interference in the rate coefficient
 138 determinations.

139

140

141 **Figure 1** Concentration-time profiles from experiment with cyclohexene, α -angelicalactone and furan. Black circles are response
 142 factors generated by the ANIR curve fitting program relative to the reference spectra. Red diamonds are obtained from manual
 143 subtractions. Left black dashed vertical line is the beginning of the region used for the relative rate calculation, the red dashed
 144 line is the end of the region used for the calculation of the α -angelicalactone relative rate, the blue line is the end of the region
 145 used for the calculation of the furan relative rate. Bold values at the bottom are the absorption bands used for analysis.

146 **Table 2.** Reference compounds used. Recommended rate coefficients and uncertainties from McGillen et al. (2020).

Compound	$k / \text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$
2,3-dimethyl-2-butene	$(5.70 \pm 1.71) \times 10^{-11}$
2-carene	$(2.0 \pm 0.3) \times 10^{-11}$
α -pinene	$(6.20 \pm 1.55) \times 10^{-12}$
camphene	$(6.60 \pm 1.65) \times 10^{-13}$
cyclohexene	$(5.60 \pm 0.84) \times 10^{-13}$
3-methyl-3-buten-1-ol	$(2.60 \pm 0.78) \times 10^{-13}$
cyclohexane	$(1.35 \pm 0.20) \times 10^{-16}$

147

148 It is noted that no OH scavenger was used in these experiments (as is the case for most, if not all, NO₃ previous relative rate
 149 studies to the authors' knowledge). NO₃ reaction with alkenes tends to proceed by electrophilic addition to the double bond
 150 followed by addition of O₂ to the resulting radical, leading to a nitrooxy peroxy radical (β -ONO₂-RO₂) (Barnes et al., 1989;
 151 Hjorth et al., 1990). It has recently been shown (Novelli et al., 2021) that there is the possibility of OH formation through the
 152 reactions of β -ONO₂-RO₂ with HO₂. HO₂ could be generated in these experiments from the abstraction of an H atom by O₂ from
 153 a β -ONO₂-RO radical with available H atoms. The initial NO₃ reaction with furans is not thought to form β -ONO₂-RO₂ radicals,
 154 with NO₃ addition to the C₂ carbon followed by O₂ addition to the C₅ carbon (Berndt et al., 1997), analogous to the OH addition
 155 reaction (Bierbach et al., 1995; Mousavipour et al., 2009; Yuan et al., 2017; Whelan et al., 2020). However, some of the reference
 156 compounds used in the experiments will form such radicals. For example, the reaction of HO₂ with the β -ONO₂-RO₂ radicals

157 formed from α -pinene + NO_3 has been reported to have an OH yield of up to 70 % (Kurtén et al., 2017). An additional minor
158 source of HO_2 during the experiments will be H abstraction reactions by NO_3 . These will produce RO_2 that can react to form RO
159 radicals which may yield HO_2 following abstraction of an H atom by O_2 . However, the rate coefficient of H abstraction by NO_3
160 is generally expected to be negligible relative to that of the NO_3 addition pathway. A box model run was performed to test the
161 impact of this chemistry in this study. The α -pinene scheme from the MCMv3.3.1 (Jenkin et al., 1997; mcm.york.ac.uk) was
162 incorporated into the box model AtChem (Sommariva et al., 2020), and an OH yield of 0.5 was assigned to the reaction of HO_2
163 with the initial β - ONO_2 - RO_2 radicals formed from the α -pinene+ NO_3 reaction. The model was initiated with 2-methylfuran and
164 α -pinene concentrations of 3 ppmv, representative of the experiments performed here. NO_3 concentrations were constrained to
165 give a lifetime of ~ 1 hour for the VOCs, typical of the experiments. OH reaction was found to account for less than 1 % of the
166 removal of 2-methylfuran or α -pinene through the model run. Consequently, it can be assumed that OH chemistry is a negligible
167 interference in these experiments.

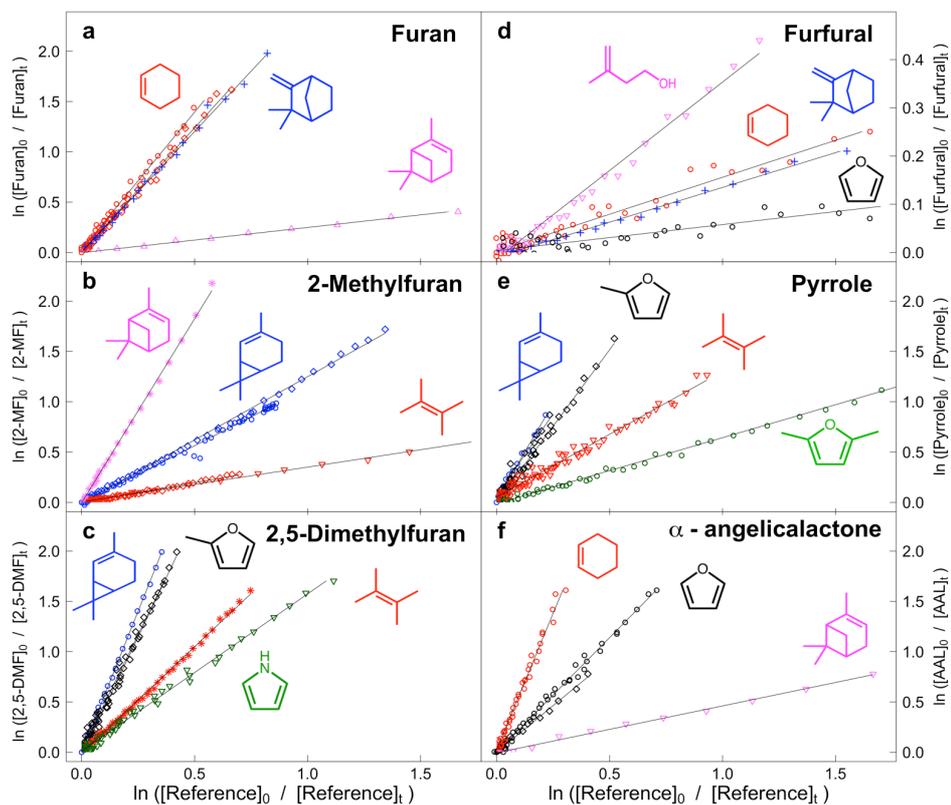

168 A further potential interference with the current experimental setup, is the reaction of NO_2 with the compounds used. Rate
169 coefficients have been measured for reaction of NO_2 with a number of unsaturated compounds (Atkinson et al., 1984; Bernard
170 et al., 2013). For conjugated dienes, these values can be large enough ($\sim 10^{-18}$ cm^3 molecule $^{-1}$ s $^{-1}$) to provide a significant loss
171 under the experimental conditions employed here. NO_2 is formed during these experiments from the decomposition of N_2O_5
172 with the NO_2 mixing ratio typically increasing up to roughly 3 ppmv through the experiment. Separate experiments were
173 performed to look at the potential reaction of NO_2 with furan, 2,5-dimethylfuran and pyrrole. The experiments were performed
174 with initial VOC mixing ratios of 3 ppmv, and initial NO_2 mixing ratios of roughly 5 ppmv, similar to the maximum amount of
175 NO_2 observed during the NO_3 experiments. For all three compounds, their loss in the presence of NO_2 (allowing for dilution)
176 was indistinguishable from zero, allowing an upper limit of $< 2 \times 10^{-20}$ cm^3 molecule $^{-1}$ s $^{-1}$ to be placed on their $k(\text{NO}_2)$ rate
177 coefficients. Based on these experiments, it was assumed that the $k(\text{NO}_2)$ rate coefficients for 2-methylfuran, furfural, and a-
178 angelicalactone are likely to be of a similar magnitude, and hence provide negligible interference under the experimental
179 conditions employed.

190 3 Results and Discussion

191 The $k(\text{NO}_3)$ rate coefficients determined with each reference compound are given in Table 3 and Figure 3. Overall recommended
 192 values for the rate coefficient for each compound are calculated by taking the mean (weighted by the reported uncertainty of the
 193 reference) of the rate coefficient derived from each experiment with each reference compound, including using the recommended
 194 values for the other furans presented in Table 3. Uncertainties for the relative rates in Table S1 are assumed to be < 10 % and to

Deleted: A recommendation of an updated rate coefficient for α -terpinene+NO₃ is also given in Table 3.

197 be dominated by statistical errors in fitting to the absorption bands. Uncertainties for the rate coefficients reported in Table 3 are
198 dominated by the assumed uncertainties in $k(\text{NO}_3)$ of the reference compounds. For most of the references, the uncertainties are
199 20 – 30 %, taken from the recommendations of McGillen et al. (2020). For 2,3-dimethyl-2-butene, the recommended uncertainty
200 in McGillen et al. (2020) is 150 %, but based on the fact that the rate coefficients derived using 2,3-dimethyl-2-butene for 2-
201 methylfuran, 2,5-dimethylfuran and pyrrole agree very well with those using other references with much smaller uncertainties,
202 a conservative estimate of 30 % is used here. It is noted that for all compounds, the rate coefficients derived with different
203 references agree very well, to within 10%. The experimentally determined $k(\text{NO}_3)$ rate coefficients of the furans relative to each
204 other are in good agreement (to within 6%) with those calculated using the weighted means shown in Table 3 (Table S2). This
205 gives further confidence in the $k(\text{NO}_3)$ values used for the reference compounds.

206

207 The rate coefficient derived for furan, agrees well with the value previously reported by Atkinson et al. (1985) from a chamber
208 relative rate experiment. However, there is significant differences between the values reported here for furan, 2-methylfuran and
209 2,5-dimethylfuran, and those reported by Kind et al. (1996) from relative rate experiments in a flow reactor. While the value
210 reported for 2-methylfuran agrees within the uncertainties between the two studies, the values for furan and 2,5-dimethylfuran
211 ~~reported here~~ are ~ 50 % and 100 % greater respectively. It is unclear what is behind this observed disparity; the good agreement
212 between the two studies for the 2-methylfuran rate coefficient suggests that there is not a systematic difference between the
213 experimental setups. For pyrrole, the rate coefficient determined here is about 50% faster than the value reported by Atkinson et
214 al. (1985) from a chamber relative rate experiment using N_2O_5 thermal decomposition. Cabañas et al. (2004) reported an upper
215 limit of $<1.8 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (298K) using an absolute technique of fast flow discharge.

216 For 2-furaldehyde (furfural) + NO_3 , the rate coefficient recommended here is an order of magnitude slower than the only
217 previously reported values (Colmenar et al., 2012), derived from small chamber relative rate experiments with 2-methyl-2-butene
218 and α -pinene as references. The rate coefficient from Colmenar et al. (2012) is very similar to the reported rate coefficient for
219 furan+ NO_3 . This is surprising, since the presence of a formyl group attached to a double bond is expected to be strongly
220 deactivating with respect to addition to that bond, due to the electron withdrawing mesomeric effect of the $-\text{C}(\text{O})\text{H}$ group
221 (Kerdouci et al., 2014). This has also been observed for other electrophilic addition reactions, such as those with OH and O_3
222 (Kwok and Atkinson, 1995; McGillen et al., 2011; Jenkin et al., 2020). And while there is the possibility of H abstraction from
223 the formyl group, which would increase the overall rate coefficient, such reactions are typically of the order of $10^{-14} \text{ cm}^3 \text{ s}^{-1}$
224 (Kerdouci et al., 2014), and hence would not be expected to compensate for the reduction in the contribution to the overall rate
225 coefficient of the addition reaction.

226 For 5-methyl-(3H)-furan-2-one (α -angelica lactone) + NO_3 this is the first reported rate coefficient. For (5H)-furan-2-one (γ -
227 crotonolactone), relative rate experiments with several reference compounds were attempted, with the slowest reacting of these
228 being cyclohexane ($k_{\text{NO}_3} = 1.4 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$). ~~In this experiment, roughly 10 % of the cyclohexane was removed by~~
229 ~~reaction with NO_3 (accounting for loss by dilution), whereas there was no appreciable chemical loss of γ -crotonolactone.~~ We can
230 therefore deduce that $k(\gamma\text{-crotonolactone}+\text{NO}_3) \ll 1.4 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. Again, this is the first time a NO_3 reaction rate
231 coefficient has been measured for this compound. A comparison of the two furanones shows that 5-methyl-(3H)-furan-2-one
232 reacts more than four orders of magnitude faster than (5H)-furan-2-one. This can be explained in part by the presence of a methyl
233 group, which is seen to increase the rate coefficient by roughly an order of magnitude from e.g. furan to 2-methylfuran to 2,5-
234 dimethylfuran. Berndt et al. (1997) derived an NO_3 reaction rate coefficient of $1.76 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for (3H)-furan-2-

239 one. However, the majority of the difference must be explained by the structure of the two compounds, namely the conjugated
 240 nature of the C=C and C=O bonds in (5H)-furan-2-one. The carbonyl group removes electron density from the C=C bond greatly
 241 reducing the rate coefficient. A similar relationship is seen for analogous acyclic compounds e.g. the NO₃ rate coefficient of the
 242 conjugated ester methyl acrylate is almost two orders of magnitude greater than that of the non-conjugated isomer vinyl acetate.

264

265 4 Atmospheric implications

266 The atmospheric lifetimes of the compounds, based on the rate coefficients reported herein, are given in Table 5. These assume
 267 concentrations of OH = 5×10^6 molecules cm^{-3} (typical daily peak summertime concentrations $1.5 \times 10^6 - 1.5 \times 10^7$ molecules cm^{-3}
 268 ³ (Stone et al., 2012)), night-time $\text{NO}_3 = 2 \times 10^8$ molecules cm^{-3} (typical night-time concentrations $1 \times 10^8 - > 1 \times 10^9$ cm^{-3} (Brown
 269 and Stutz (2012)) daytime $\text{NO}_3 = 1 \times 10^7$ molecules cm^{-3} (limited daytime measurements suggest concentrations $\sim 0.5 - > 1$ pptv
 270 (2.5×10^7 molecules cm^{-3}) (Brown and Stutz (2012)), and $\text{O}_3 = 40$ ppbv (background O_3 concentration ~ 40 ppb (Parrish et al.,

271 2014)). It is noted that oxidant concentrations have a high spatial and temporal variability due to variability in their sources and
 272 sinks, and that oxidant levels within biomass burning plumes in particular are poorly understood. Hence the relative importance
 273 of the oxidants shown in Table 5 is likely to vary dependent on conditions. From the values given in Table 5, it is clear that the

274 alkyl substituted furans and pyrrole have very short lifetimes both during the day, when the dominant daytime sink is likely to
 275 be reaction with OH, and at night, when the dominant sink will be reaction with NO_3 . O_3 may contribute somewhat to the removal
 276 of these compounds both during the day and night, particularly for 2,5-dimethylfuran. As $k(\text{NO}_3)$ approaches the same order of
 277 magnitude as $k(\text{OH})$, e.g. for 2-methylfuran, 2,5-dimethylfuran and pyrrole, the NO_3 reaction is likely to be competitive with the
 278 OH reaction even during the day in low NO_x environments, with daytime NO_3 concentrations reported to be ~ 1 ppt (2.5×10^7
 279 molecules cm^{-3}) (Brown and Stutz, 2012). The relatively large rate coefficient reported here for α -angelicalactone, suggests that
 280 NO_3 reaction will be an important sink for unsaturated non-conjugated cyclic esters. On the other hand, the very small rate
 281 coefficient for the γ -crotonolactone + NO_3 reaction suggests that this will not be an important atmospheric sink. γ -crotonolactone
 282 has also been shown to have a very slow reaction with O_3 (lifetime > 100 years, Ausmeel et al., 2017), whereas for reaction with
 283 OH, the lifetime is much shorter, and this will be the predominant gas-phase sink for γ -crotonolactone. Such a slow NO_3 reaction
 284 might be expected to extend to all 2-furanones with a conjugated structure, e.g. hydroxyfuranones – major products of OH
 285 oxidation of methyl substituted furans (Aschmann et al., 2014), such that the nitrate reaction may be unimportant in the
 286 atmosphere for these structures. Although substitution at the double bond is likely to increase the rate coefficient somewhat, as
 287 observed for OH and O_3 reactions with the methyl-substituted form of γ -crotonolactone (Ausmeel et al., 2017).

288 One of the major sources of furan type compounds to the atmosphere is wildfires. Wildfire plumes can be regions of high NO_3
 289 even during the day due to suppressed photolysis rates in optically thick plumes (Decker et al., 2021). NO_3 oxidation of furans
 290 may be even more important in such plumes than in the background atmosphere. Such plumes can extend over hundreds of
 291 kilometres and hence affect air quality on a local and regional scale (e.g. Andreae et al., 1988; Brocchi et al., 2018; Johnson et
 292 al., 2021). Domestic wood burning is an increasing trend in northern European cities (Chafe et al., 2015). Burning will generally
 293 be in the winter during which, with short daylight hours and peak daytime OH often an order of magnitude lower than during
 294 the summer, the reaction with NO_3 is likely to be the dominant fate of furan type compounds in such emissions, contributing
 295 significantly to organic aerosol in urban areas (Kodros et al., 2020).

Deleted: these

297 Berndt et al. (1997) identified the major first generation products of furan+NO₃ to be the unsaturated dicarbonyl, butenedial, and
 298 2(3H)-furanone, with the NO₃ recycled back to NO₂. However, Tapia et al. (2011), and Joo et al. (2019) found that the major
 299 products of the 3-methylfuran+NO₃ reaction predominantly retain the NO₃ functionality. In this case, furan+NO₃ oxidation
 300 chemistry may be a significant sink for NO_x, sequestering it in nitrate species, which might release it far from source on further
 301 gas-phase oxidation, or, due to their low volatility, be taken up into aerosol (Joo et al. 2019).

319 5 Conclusions

320 Rate coefficients are recommended for reaction of seven furan type VOCs with NO₃ at 298 K and 760 Torr, based on a series of
 321 relative rate experiments. These new recommendations highlight the importance of NO₃ chemistry to the removal of furans, and
 322 other similar VOCs, under atmospheric conditions. The measured rate coefficients suggest that for the three furans reported here,
 323 as well as for pyrrole and α -angelicalactone, reaction with NO₃ is likely to be their dominant night-time sink. For the alkyl furans

324 and pyrrole, reaction with NO₃ may also be a significant sink during the daytime. This work also extends the existing database
325 of VOC+NO₃ reactions, providing valuable reference values for future work.

326

327

328 *Data availability.* Further example plots and experiment information are provided in the supplement. All of the response-time
329 profiles from the FTIR are provided in .txt format at 10.5281/zenodo.5724967, and all of the raw FTIR output is provided in .csv
330 format at 10.5281/zenodo.5721518.

331

332 *Author contributions.* MJN performed the experiments with the technical support of YR and MRM and performed the data
333 treatment and interpretation. MJN wrote the paper. All co-authors revised the content of the original manuscript and approved
334 the final version of the paper.
