Abstract

A large fraction of annual precipitation over the western United States comes from wintertime orographic clouds associated with atmospheric rivers (ARs). Transported African and Asian dust and marine aerosols from the Pacific Ocean may act as ice-nucleating particles (INPs) to affect cloud and precipitation properties over the region. Here we explored the effects of INPs from marine aerosols on orographic mixed-phase clouds and precipitation at different AR stages for an AR event observed during the 2015 ACAPEX field campaign under low dust (< 0.02 cm^{-3}) conditions. Simulations were conducted using the chemistry version of the Weather Research and Forecasting model coupled with the spectral-bin microphysics at 1-km grid spacing, with ice nucleation connected with dust and marine aerosols. By comparing against airborne and ground-based observations, accounting for marine INP effects improves the simulation of cloud phase state and precipitation. The marine INPs enhance the formation of ice and snow, leading to less shallow warm clouds but more mixed-phase and deep clouds, and increased ice water path (over 5 times) and snow precipitation (over 40 times). The responses of cloud and precipitation to marine INPs vary with the AR stages with more significant effects before AR landfall and post-AR than after AR landfall, mainly because the moisture and temperature conditions change with the AR evolution. This work suggests weather and climate models need to consider the impacts of marine INPs since their contribution is notable under low dust conditions despite the much lower relative ice nucleation efficiency of marine INPs.

1 Introduction

Atmospheric river (AR) events have great impacts on atmospheric and hydrological processes in the western United States during winter. On a long-term average, AR storms contribute to 20–50% of California's precipitation totals (Dettinger et al., 2011). Understanding the factors influencing different types of precipitation (rain vs. snow) associated with ARs is crucial for planning and managing regional water resources and hydrologic hazards and improving atmospheric and hydrologic forecasting in the western United States. Rain and snow precipitation produced by orographic clouds over the Sierra Nevada Mountains is closely related to the partitioning between cloud liquid and ice phases, which can be largely modified by aerosol particles (Rosenfeld et al., 2013; Fan et al., 2014, 2017b). However, aerosol-orography-precipitation relationships are complicated, depending on aerosol properties, mountain geometry, cloud phase, temperature, humidity, and flow patterns as reviewed in Chouldhury et al. (2019).

Over the western United States, understanding the roles of aerosols, particularly those capable of initiating ice crystal formation in altering clouds and precipitation is still limited, which has motivated recent observational and modeling studies (Ault et al., 2011; Creamean et al., 2013, 2015; Rosenfeld et al., 2013; Fan et al., 2014, 2017b; Martin et al., 2019; Levin et al., 2019). While it has been found that long-range transported aerosols particularly dust particles as ice nucleating particles (INPs) influence clouds and precipitation in the mountainous western United States (Uno et al., 2009; Ault et al., 2011; Creamean et al., 2013), it is also clear from measurements that clouds occurring in and around ARs can also be influenced by INPs with apparent sources from the ocean (Levin et al., 2019).

Previous studies showed that INPs can increase total precipitation through the "seeder feeder" mechanism (Choularton and Perry, 1986; Creamean et al., 2013), in which ice crystals

that form in the upper portions of orographic clouds can collect droplets and grow to a larger size as they fall through a supercooled liquid layer before reaching the ground. Fan et al. (2014, 2017b) found that INPs like dust particles can increase precipitation by enhancing riming and deposition processes in mixed-phase orographic clouds, consistent with other studies (e.g., Muhlbauer and Lohmann, 2009; Xiao et al., 2015; Hazra et al., 2016; Yang et al., 2020). Fan et al. (2017a) also noted that the relative importance of riming to deposition depends on the mixed-phase cloud temperatures. Despite the importance of INPs in cloud formation and precipitation, they typically have a low abundance and large variations in their nucleating characteristics, especially in terms of the temperatures over which they initiate ice crystal formation (Kanji et al., 2017; Levin et al., 2019). Hence, there is large uncertainty in evaluating INPs impacts on mixed-phase and ice clouds as well as precipitation.

Dust and biological particles are known INPs. Biological particles can cause freezing at temperatures as warm as −5 °C (Murray et al., 2012). During ARs, the long-range transport of dust or biological particles is highly episodic (Creamean et al., 2013). Sea spray or marine aerosols consisting of sea salt and marine organic carbon resulting from wave breaking and bubble bursting at the ocean surface may also be a source of INPs (Burrows et al., 2013; Vergara-Temprado et al., 2017; McCluskey et al., 2018b; Levin et al., 2019). Recently, McCluskey et al. (2018a) derived an ice nucleation parameterization for INPs from sea spray aerosols based on observations collected at a North Atlantic coastal site and its relation to the marine aerosol surface area. Given the distinct physio-chemical characteristics and the different ice-nucleating efficiency (magnitudes lower than mineral dust; McCluskey et al. 2018a), the impact of marine INPs on cloud and precipitation could be very different from dust or biological particles (DeMott et al., 2016; Kanji et al., 2017). However, studies of marine-sourced INP

effects on clouds and associated precipitation are limited (Kanji et al., 2017; Levin et al., 2019). A few previous studies investigated the impacts of marine INPs on precipitation and radiation with global climate models (Hoose et al., 2010; Burrows et al., 2013; Yun and Penner, 2013), albeit without the advantage of direct data on their ice nucleation efficiencies. Further, a detailed, process-level understanding of how marine INPs affect mixed-phase cloud processes and precipitation is lacking.

Following the CalWater campaigns in 2009, 2011, 2014, an interagency sponsored study, CalWater 2015, utilized a larger suite of instruments and measurement platforms to study ARs and aerosol-cloud interactions in AR environments (Ralph et al., 2016). As part of CalWater 2015, the U.S. Department of Energy sponsored Atmospheric Radiation Measurement (ARM) Cloud Aerosol Precipitation Experiment (ACAPEX) field campaign aimed specifically at improving understanding and modeling of aerosol impacts on winter storms associated with landfalling ARs (Leung et al., 2016). The ACAPEX campaign conducted intensive sampling of clouds and aerosols using instruments on board the ARM Aerial Facility Gulfstream (G-1) aircraft and ARM Mobile Facility on board the research vessel Ron Brown. These measurements were made in conjunction with clouds and aerosols, meteorological, hydrological, and oceanic measurements collected by instruments on three other aircraft and Ron Brown and at a coastal surface station. Collectively, these data provide a unique opportunity to examine the complex interactions among aerosols, orographic clouds, and ARs.

A major AR event spanning over 5 - 9 February 2015 occurred during the ACAPEX campaign, producing heavy rainfall with some regions receiving up to 400 mm of total precipitation during the event (Ralph et al., 2016; Cordeira et al., 2017). This AR event was extensively sampled by the G-1 aircraft (Schmid et al., 2014) for characterizing aerosol and

111 cloud properties. During this event, marine aerosols were the main aerosol type and marine INPs
112 were dominant at cloud activation temperatures. Aerosol sampled by G-1 indicated that dust and
113 biological particles were rather scarce in and around ARs, which is in stark contrast to the
114 dominance of dust INPs during the AR events in the CalWater 2011 campaign (Levin et al.,
115 2019). Therefore, the AR event during the ACAPEX campaign provides a rather unique
116 opportunity to explore the role of marine aerosols in the orographic clouds and precipitation
117 associated with landfalling ARs in the western United States.

118 In our previous modeling studies (Fan et al., 2014, 2017b), we implemented an
119 immersion freezing parameterization for dust particles (DeMott et al. 2015) in a spectral-bin
120 microphysics (SBM) scheme to examine the long-range dust effects on AR-associated
121 orographic mixed-phase clouds and precipitation during CalWater 2011. With marine INPs
122 dominating in CalWater 2015/ACAPEX, in this study we implemented the recently developed
123 ice immersion nucleation parameterization for sea spray aerosols by McCluskey et al. (2018b) in
124 the SBM scheme. To explicitly simulate various aerosol types, different from Fan et al. (2014,
125 2017a) who prescribed aerosols based on observations, a chemistry version of the Weather
126 Research and Forecasting model (WRF-Chem) coupled with the SBM (Gao et al., 2016) was
127 employed to predict aerosol properties and their interactions with clouds and radiation for the AR
128 event on 6 - 9 February 2015. We focused on exploring the effects of INPs from sea spray
129 aerosols, in competition with mineral dust INPs, on the orographic mixed-phase clouds and
130 precipitation at different stages of the AR event as thermodynamic conditions evolved with the
131 different AR stages.

2 Model configuration and experiment design

The WRF-Chem version 3.6 coupled with SBM as described in Gao et al. (2016) is employed for model simulations of this study, in which SBM is coupled with the Model for Simulating Aerosol Interactions and Chemistry (MOSAIC; Fast et al., 2006; Zaveri et al., 2008). The SBM scheme is a fast version in which ice crystal and snow (aggregates) are represented with a single size distribution (low-density ice) with a separation at 150 μm in radius, and graupel or hail is for high-density ice represented with an additional size distribution (Khain et al., 2009, 2010; Fan et al., 2012, 2017a). Here we choose the graupel version since hail is not one of the major cloud hydrometeors in the case we simulate. The fall speed power law relationships for ice/snow and graupel are depicted in Xue et al. (2017). The WRF-Chem-SBM model is particularly designed to improve simulations of aerosol effects on clouds for complicated aerosol compositions and heterogeneous spatial distribution of aerosols. It has been applied in several studies including warm stratocumulus clouds (Gao et al., 2016), thunderstorms (Fan et al. 2020; Zhang et al., 2020), and supercell storms (Lin et al., 2020). Here WRF-Chem-SBM is employed, different from our previous studies in Fan et al. (2014, 2017a) which used WRF-SBM with prescribed aerosols, in order to explicitly simulate various aerosol types including marine aerosols and dust particles.

The four-sector MOSAIC aerosol module is chosen for the simulations of aerosols and the CBMZ (Carbon Bond Mechanism version Z) is used for gas-phase chemistry. The MOSAIC module treats nine major aerosol species (sulfate, nitrate, chloride, ammonium, sodium, black carbon, primary organics, other inorganics (OIN), and water). OIN is used as a surrogate of dust and the production of dust is parameterized with the dust transport model DUSTRAN (Shaw et al., 2008). Sea salt aerosol (a combination of sodium and chloride), as a surrogate for all SSA, is

parameterized as a function of sea-surface wind speed (Gong et al., 1997b, a). The dry diameters of the particles over the four bins have a range of 0.039–0.156, 0.156–0.624, 0.624–2.5, and 2.5–10.0 μm, respectively. For the total aerosol, aerosol size distribution over each section is represented with a 2-moment approach that predicts aerosol mass and number following a log-normal distribution (Simmel and Wurzler, 2006). For each composition such as dust and sea salt, only the mass mixing ratio in each section is predicted and outputted. The aerosol number mixing ratio in each bin is only predicted for the total aerosol. Therefore, in this study, the dust and sea salt number mixing ratios used for ice nucleation parameterizations were derived based on their respective mass mixing ratios by assuming the same size and density of all particles over each bin, that is,

$$N_{i,j} = \frac{m_j}{6\pi(D_j)^3\rho_i}$$

where i denotes the aerosol composition (sea salt or dust here), j denotes the j^{th} aerosol bin, m_j is the total mass mixing ratio of the j^{th} bin, ρ_i is the assumed density (i.e., 2.6 g cm^{-3} for dust and 2.2 g cm^{-3} for sea salt), and D_j is the geometric mean diameter of j^{th} bin. The approach for deriving the number mixing ratio for each aerosol component has been used in the literature (i.e., Zhao et al., 2013). We understand that the assumption that all particles have the same size over each bin may introduce some uncertainty. However, the size distribution of each aerosol component is unknown in the model and any assumption on the size distribution might introduce uncertainty.

2.1 Implementing immersion freezing parameterization for marine INPs

In the original SBM model, the ice nucleation accounting for both deposition ice nucleation and condensation-freezing is parameterized based on Meyers et al. (1992) and Bigg

178 (1953) is employed for immersion and homogeneous drop freezing. Neither of the ice nucleation
179 parameterizations is connected with aerosols. Bigg (1953) was formulated based on the
180 stochastic hypothesis where the freezing probability is assumed proportional to drop mass and
181 the freezing rate is as a function of temperature without involving INPs. Fan et al. (2014, 2017a)
182 implemented DeMott et al. (2015) as an immersion freezing parameterization to investigate the
183 effects of dust INPs on orographic mixed-phase clouds and precipitation during CalWater 2011.
184 We adapted this implementation to WRF-Chem-SBM for this study to connect ice nucleation
185 with dust particles. Developed based on both laboratory data and field measurements, DeMott et
186 al. (2015) is an empirical parameterization for immersion freezing of natural mineral dust
187 particles. INP concentrations are quantified as functions of temperature and the total number
188 concentration of particles larger than 0.5 μm diameter. In our implementation, the dust number
189 mixing ratio for each aerosol bin is derived from its mass as detailed in the section above. The
190 total dust number mixing ratio inputted to DeMott et al. (2015) is the integration over 0.5 -10
191 μm.

192 To connect ice nucleation with sea spray aerosols, we implemented McCluskey et al.
193 (2018a, thereafter MC2018), which was developed for quantifying ice nucleating activity by
194 marine organics over the North Atlantic Ocean, in SBM following a similar approach as the
195 implementation of DeMott et al. (2015). The nucleation site density in MC2018 is described as

196 $$n_s = exp(-0.545(T - 273.15) + 1.012)$$

197 where n_s is the nucleation site density (m^{-2}) and T is the temperature (K). With n_s determined by
198 MC2018, the nucleated ice particle concentration is obtained following Niemand et al. (2012) as

199 $$\sum_{j=1}^{n} N_j = \sum_{j=1}^{n} N_{\mathrm{tot},j}\{1 - \exp[-S_{\mathrm{ae},j} n_s(T)]\}$$

where $S_{ae,j}$ is the surface area of individual sea spray aerosol particles in the j^{th} bin which is calculated from $\pi D_j^2/4$ (D_j is the geometric-mean diameter), $N_{tot,j}$ is the total sea spray aerosol number in each bin which is derived from its mass as detailed in the section above, and N_j is the ice particle number in each bin. Sea salt particles are used as the surrogate of sea spray aerosols given that most marine organic aerosols exist with coating on the surface of sea salt particles in the size range that dominates surface area (e.g., Prather et al., 2013).

Bigg et al. (1953) is employed only for homogeneous drop freezing when the temperature is colder than -37 ˚C. As discussed in Fan et al. (2014), the deposition-condensation freezing is turned off because the simulation with deposition-condensation freezing produces a large number of small ice particles, which is not consistent with the observed mixed-phase cloud properties in the study region. Contact freezing is also turned off due to negligible contributions (Fan et al., 2014).

2.2 Experiment design

Simulations are configured with two nested domains using the nesting down approach (i.e., the inner domain is run separately driven by the outer domain), covering most of the western US (Fig. 1). The outer domain consists of 399 × 399 grid points with a horizontal grid spacing of 3 km and the inner domain consists of 498 × 390 grid points with a horizontal grid spacing of 1 km. 50 vertical levels with stretched intervals are configured, with a grid spacing of 70 m at the lowest levels and ~400 m at the model top. The dynamics time step is 15 seconds for the outer domain and 5 seconds for the inner domain.

The simulation for the outer domain starts at 00:00 UTC on February 3 and runs for 48 hours for chemistry spin-up using the WRF-Chem-SBM model, driven by global WRF-Chem simulation as the initial and boundary conditions of gas-phase species and aerosols and the

Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA2; spatial resolution of 0.5 by 0.5 degree and temporal resolution of 6-hourly) as the initial and boundary conditions of meteorological fields. Then the outer domain simulation is reinitialized at 00:00 UTC on February 5 using the meteorological data from MERRA2 to avoid the large error growth in meteorology associated with long-time model integration, although the chemistry simulation is a continuation from the spin-up run and runs until 23:00 UTC on February 8. Given that running the WRF-Chem-SBM fully-coupled model is extremely computationally expensive for 1-km grid spacing in the inner domain, we interpolate aerosol-related quantities such as aerosol composition, hygroscopicity, and mass and number concentrations from the outer domain simulations using bilinear interpolation for the inner-domain simulation to reduce computational cost. This means that we conduct the inner-domain simulation separately with chemistry turned off, and aerosol information is updated hourly using data from the outer domain simulations. The inner-domain simulation is run from 00:00 UTC on February 5 to 23:00 UTC on February 8, and the initial and boundary meteorological conditions are from MERRA2. To validate this approach, we compared the simulation with fully coupled WRF-Chem-SBM for the inner domain simulation and found that the two simulations resemble each other in terms of precipitation (Fig. S1). Therefore, it is a valid approach that saves computation time by about 40%.

For emissions data, the U. S. Environment Protection Agency (EPA) National Emission Inventory (NEI) with a 4 km by 4 km horizontal resolution based on the year 2011 rates (NEI2011) is commonly used for anthropogenic emissions in the United States. However, using NEI2011 predicts too large anthropogenic aerosol mass compared with observations. Since the emissions of gaseous species and particulate matter decreased significantly from 2011 to 2015 in California (Table S1), the California Air Resources Board emission inventory in 2015

(CARB2015) is used for anthropogenic emissions input for California, while NEI2011 is used for other states in the simulation domain. The use of NEI2011 for other states is acceptable since the lower and middle atmosphere in the simulation domain is dominated by southwesterly winds during the simulation period that transport air pollutants from coastal to inland regions. The use of CARB2015 reduces the simulation of aerosol number concentrations mainly below 2 km. The aerosol concentration averaged over 1-2 km altitudes is about 160 cm^{-3} with CARB2015 and 317 cm^{-3} with NEI2015, which is 26% lower and 47% higher than aircraft observations (215 cm^{-3}), respectively. Thus, the simulated aerosol concentrations with CARB2015 are in better agreement with observations.

The Model of Emissions of Gases and Aerosols from Nature (MEGAN) with a monthly temporal and 1 km horizontal resolution (Guenther et al., 2012) is used for biogenic emissions. The Rapid Radiative Transfer Model for application to GCMs (RRTMG) is used for shortwave and longwave radiation schemes (Iacono et al., 2008), the Noah Land Surface Model for land surface physics (Chen and Dudhia, 2001), and the Mellor-Yamada-Janjic (MYJ) scheme for planetary boundary layer parameterization (Mellor and Yamada, 1982; Janjić and Prediction, 2001). Cumulus parameterization is not considered for the simulations over both domains.

Three simulations were carried out over the inner domain for this study to investigate the impacts of marine INPs: (1) The reference case is Bigg, using the default immersion freezing parameterization of Bigg et al. (1953) in SBM which is temperature-dependent only; (2) DM15+MC18, in which both DeMott et al. (2015) and MC2018 parameterizations are used for ice nucleation from dust and marine aerosols, respectively; (3) DM15, using the parameterization of DeMott et al. (2015) for dust aerosols (diameter > 0.5 μm) with MC2018 turned off. The impacts of marine INPs are derived by comparing the DM15+MC18 and DM15 simulations.

3 Case description and measurements

As introduced earlier, our study case is the AR event occurring during 5 - 9 February 2015 during the ACAPEX campaign and made landfall on the coast of Northern California, producing heavy rainfall. Marine aerosols were the main aerosol type. Dust and biological particles were rather scarce in and around the AR (Levin et al., 2019).

The AR evolution has three distinct stages: before AR landfall (from 06:00 UTC 5 to 18:00 UTC 6 February), after AR landfall (from 18:00 UTC 6 to 12:00 UTC 7 February), and post-AR (from 12:00 UTC 7 to 09:00 UTC 8 February). The three stages can be identified from the change of the integrated water vapor (IWV) with time during the event (Fig. 2a). Before AR landfall, IWV in most of California was relatively low (Fig. 2a, left). The IWV in northern California increased as the AR made landfall at about 18:00 UTC on 6 February and brought ample water vapor to California (Fig. 2a, middle). Heavy orographic precipitation along the Sierra Nevada Mountains occurred during this period. At 12:00 UTC 7 February, the AR started to retreat (Fig. 2a, right), and postfrontal cloud cells formed, with relatively small cloud fraction and precipitation.

Vertical profiles of the thermodynamic and kinematic environments at the three stages are shown in Figs. 2b-d. The thermodynamic and kinematic environments significantly varied with the AR stages. After AR landfall, water vapor increased significantly in the lower atmosphere (below 5 km), but the middle and upper levels became drier (dashed, Fig. 2b) compared with the stage before AR landfall (solid). The vertical motion also weakened after AR landfall (Fig. 2d), suggesting that the atmosphere became more stable. At the post-AR stage, moisture above 2-km altitude was reduced compared to after AR landfall. Note that the

292 temperature below 8 km was colder by up to 6 ºC at the post-AR stage compared to the previous
293 two stages (Fig. 2c). These differences in the meteorological conditions among the different
294 stages are very important to understand the cloud and precipitation properties and their responses
295 to marine INPs.

296 Extensive in-situ and remote-sensing measurements are used to understand aerosol and
297 cloud properties and evaluate model results. The G-1 aircraft sampled the postfrontal clouds on
298 February 7 during 20:20-20:30 UTC.

299 Aerosol instruments on board the G-1 aircraft included (1) a Droplet Measurement
300 Technologies (DMT) ultrahigh sensitivity aerosol spectrometer (UHSAS), measuring dry fine
301 mode aerosol size spectra of 55–800 nm with sizing uncertainty of 2.5% (Uin, 2016); (2) a
302 Passive Cavity Aerosol Spectrometer Probe (PCASP) for coarse model aerosol spectra (0.1-3
303 μm) with +/-20% uncertainty in size and +/-16% in concentration (Goldberger, 2020), and (3)
304 Aerosol Time of Flight Mass Spectrometry (ATOFMS) measurements provided the mean
305 fractional number contributions of aerosol source classifications (Levin et al., 2019). Cloud
306 instruments include an FCDP (1.5-50 μm) with ~3 μm uncertainty in size (Glienke and Mei,
307 2020), and the two-dimensional stereo (2DS) probe with +/-10 μm size uncertainty to provide
308 cloud particle size spectra (Glienke and Mei, 2019). Uncertainty in the number concentration for
309 both probes follows Poisson's counting statistics. The LWC and IWC are derived from the Water
310 Content Monitor (WCM) on board the G-1 aircraft, an instrument that uses the impact of water
311 on several heated wires as the basis for measuring cloud total water content (TWC) and liquid
312 water content (LWC) from which the ice water content (IWC) can be derived (Baumgardner et
313 al., 2011; Matthews et al., 2015). Wind tunnel measurements indicate that ice contributes <1% to
314 the LWC elements response.

The Next Generation Radar (NEXRAD) radar reflectivity measurements were processed and used for model evaluation. The original NEXRAD Level 2 data (polar coordinate) were downloaded from AWS-NOAA NEXRAD S3 data service (https://registry.opendata.aws/noaa-nexrad/). We mapped the data to a Cartesian coordinate with 2 km horizontal resolution and approximately 5 min frequency using the Python ARM Radar Toolkit (Py-ART; Helmus and Colis, 2016). The operational NEXRAD radar reflectivity uncertainties are 2 - 3 dB (Gourley et al., 2003) and theoretical demonstrations with differing raindrop shape models yield radar reflectivity biases of 1.2 dB (Gourley et al., 2009). The observed precipitation rates are from the rain gauge measurements, provided by the NOAA Earth System Research Laboratory's Physical Sciences Division (https://psl.noaa.gov/data/obs/datadisplay).

4 Results

4.1 Model evaluation with observations

We evaluate the model simulations of aerosol and cloud properties and surface precipitation. Figure 3a shows a comparison of modeled aerosol properties including aerosol number concentration and chemical composition from the simulation of DM15+MC18 intended to represent the observed case, with the G-1 aircraft measurements on 7 February. Aerosol properties in all three simulations are similar, and thus only DM15+MC18 is shown. Overall, the simulated aerosol number concentration over the size range of 0.067 - 3 μm is comparable to the observations over the same size range estimated by combining data from UHSAS and PCASP at below 2-km altitude. The simulation overestimates the total aerosol number concentrations by ~ 2-times averaged over the altitudes of 2.2-3.2 km. At 2.8 km, the difference between the simulation (219 cm^{-3}) and observations (55 cm^{-3}) is about 4 times. The mean fractional number contributions of aerosol composition classifications measured from ATOFMS are shown in Fig.

338 3b. For comparison with the model, the mean mass contributions of the corresponding aerosol
339 source classifications are computed since the number concentrations of individual aerosol
340 components are not predicted by WRF-Chem (Fig. 3c). Both the observed fractional number
341 contributions and the simulated mass contributions show that marine aerosols are dominant
342 during the AR event, accounting for more than 60% of the total aerosol number based on
343 ATOFMS measurements and total aerosol mass based on the simulation. Although the simulated
344 dust mass fraction is ~14%, the derived number concentration for sizes larger than 0.5 μm is very
345 low (less than 0.02 cm^{-3}, shown in a later figure). This is because the dust number concentration
346 is dominated by small particles (14.71 cm^{-3} for the sizes smaller than 0.5 μm). The number
347 concentrations of the sea salt aerosols are generally three orders of magnitude higher than those
348 of dust, and these numbers populate smaller bins of the aerosol distribution (97% from the first
349 two aerosol size bins) even though the sea salt mass is predominately at larger sizes (96% from
350 the last two size bins).
351 Figure 4 presents an evaluation of precipitation, showing the accumulated precipitation
352 during the AR event from 06:00 UTC 5 February to 09:00 UTC 8 February 2015 (Fig. 4a) and
353 the time-series of mean precipitation rates averaged over the observation stations (Fig. 4b). The
354 model generally captures the spatial pattern of the observed accumulated precipitation (Fig. 4a)
355 and reproduces the temporal evolution of precipitation (Fig. 4b). Two major precipitation periods
356 in the observations, including AR-induced orographic precipitation and postfrontal precipitation,
357 are generally captured in the simulations, although the simulated postfrontal precipitation occurs
358 several hours later in the simulations compared to the observations. All three simulations predict
359 a narrower but higher peak precipitation compared with the observed wider peak with lower
360 values (Fig. 4b). However, the overestimation of the peak value by DM15+MC18 is lower than

361 the other two (30% vs. 45% for DM15 and 58% for Bigg; Fig. 4b-c). The accumulated
362 precipitation in the southern mountain range (the southern part of white boxes in Fig. 4a) is
363 generally less than 100 mm in observations and less than 120 mm in DM15+MC18 but more
364 than 140 mm in the other two simulations. The mean precipitation over the white box
365 accumulated over the AR period are 89, 128, 130, and 116 mm for observations, Bigg, DM15,
366 and DM15+MC18, respectively. Again, although all three simulations overestimate the
367 precipitation, DM15+MC18 simulates the lowest value and is closer to observations. There is a
368 clear spillover effect caused by marine INPs (white box in the right panel of Fig. 4a). That is,
369 with marine INPs, more ice/snow formed over the windward side falls slower than rain and more
370 of them are transported to the lee side. This will be discussed in more detail in section 4.2. In the
371 northern part of the domain (> 40º N), DM15+MC18 predicts more precipitation (i.e., 48 mm for
372 the mean accumulated precipitation) than the other two simulations (i.e., 45 mm in Bigg and 42
373 mm in DM15). The simulated precipitation between Bigg and DM15 is very similar (Fig. 4a),
374 suggesting that in a low dust environment, the temperature-dependent Bigg (1953)
375 parameterization simulates similar ice formation as DeMott et al. (2015).

376 Cloud phase is crucial to radiation and precipitation for mixed-phase clouds, and the
377 glaciation ratio is usually used to represent the cloud phase states. The glaciation ratio is defined
378 as IWC/(IWC+LWC), where LWC and IWC denote liquid and ice water content, respectively.
379 Values less than 0.1 and larger than 0.9 denote the liquid phase and ice phase, respectively, with
380 values between 0.1 and 0.9 for the mixed-phase (Korolev et al., 2003). The G-1 aircraft sampled
381 the postfrontal clouds on February 7 as shown in Fig. 5a. All three simulations cannot capture the
382 observed size of the precipitation cell (Figs. 5b and S2). In the simulations, precipitation is
383 dominated by a few heavy precipitation clusters instead of the observed wide precipitation area.

384 The simulated cells also do not reach the high altitudes found in the observations. The deviations
385 of the simulation from observations for the postfrontal clouds could be because of various
386 reasons such as (a) the long-time model integration time (the 4th day after model initiation) and
387 (b) the spatial mismatch of simulated and observed clouds since those postfrontal clouds are
388 small. Anyhow, DM15+MC18 simulates the largest size of the precipitation cell, with the
389 highest vertical extent among the three simulations.

390 LWC and IWC along both horizontal and vertical flight segments are displayed in Figs.
391 6a-b. IWC is generally 2-4 times larger than LWC in the postfrontal clouds. To compare with
392 observations, the model data are processed by: (a) selecting the grids at a distance from the
393 simulated cell center similar to the distance of the airplane position from the observed postfrontal
394 cell center, and sampling the data at a similar ambient temperature as observed by the aircraft
395 (around -10 ^{o}C along the horizontal segment shown in Fig. 6a); (b) accounting for the location
396 mismatch and increasing the sample size in the simulation to be more representative by
397 extending the sampling area to include 20 grids at the front and back of a selected grid along the
398 flight track, mimicking approximately the distance traveled by the G-1 airplane in five minutes;
399 (c) filtering out the sampled grids with values of (LWC + IWC) below the detection limit of
400 WCM (i.e., 0.02 g m^{-3}, Thompson et al., 2016). Both horizontal and vertical flight segments are
401 incorporated for comparison.

402 Figure 6c and d shows comparisons of LWC, IWC, and the glaciation ratio of
403 IWC/(IWC+LWC) between the simulations and aircraft measurements. The LWC is
404 overestimated in all three simulations with DM15+MC18 of the largest overestimation (6 times
405 higher than observations), while IWC is underestimated in Bigg and DM15 (nearly an order of
406 magnitude lower in DM15 than observations) (Fig. 6c). DM15+MC18 predicts much higher

IWC than the other two simulations, with an overestimation of IWP by ~3 times. The mean glaciation ratios fall in the range of 0.1- 0.9 among the simulations (Fig. 6d), indicating that the observed mixed-phase cloud feature is simulated by the model. DM15+MC18 shows a mean ratio of ~ 0.70, similar to the observed value of 0.74. This shows that the mixed-phase state is well captured when the marine INP effect is considered. In contrast, in Bigg and DM15 with a glaciation ratio of 0.41 or less, the mixed-phase state is liquid-dominated. The inclusion of the marine INP effect improves the simulation of cloud phase states via enhancing heterogeneous ice formation through immersion freezing. These results also show that post-frontal clouds are very sensitive to marine INPs. A detailed examination of how the marine INPs impact ice nucleation and cloud properties will be discussed in the following section.

4.2 Marine INP effects under different AR stages

Impacts of the marine INPs transported from the Pacific Ocean on orographic clouds and precipitation are revealed by comparing the simulation of DM15+MC18 with the simulation of DM15.

As described in Section 3 about the AR evolution, before AR landfall (from 06:00 UTC 5 to 18:00 UTC 6 February), precipitation occurred in northern California. After AR landfall (from 18:00 UTC 6 to 12:00 UTC 7 February), heavy orographic precipitation along the Sierra Nevada Mountains occurred (Fig. 7a). At the post-AR stage (from 12:00 UTC 7 to 09:00 UTC 8 February), scattered postfrontal cloud cells formed, with relatively small cloud fractions and precipitation (Fig. 7a). The mean water vapor and temperature profiles are very different between different AR stages, but the two simulations – DM15 (blue) and DM15+MC18 (red) – predict very similar results as seen from the overlapping blue and red lines.

From the time series of average precipitation rates (Fig. 7a), the effect of marine INPs varies with the different AR stages, from the large increases of precipitation (over 50% in general) before AR landfall (the red dotted line, second y-axis) to no significant effects (a very small increase) after AR landfall. In the first stage (before AR landfall), the total precipitation increases by 36% on average due to the marine INP effect (Fig. 7a and Table 1). There is only a 4% increase in the total precipitation after AR landfall. Note that precipitation is very small at some point before AR landfall, so the large increases might not mean that much. The total precipitation at the post-AR stage is also small and the change in domain-mean precipitation from DM15 and DM15+MC18 is negligible. Thus, the marine INP effect only significantly increases the total precipitation over the domain at the stage before AR landfall when a moderate amount of precipitation occurs in northern California (Fig. 8a). After AR landfall, precipitation increases significantly. Although the total precipitation is not changed much by the marine INPs, the marine INPs produce a spillover effect featuring reduced precipitation on the windward slope of the mountains but increase precipitation over the lee side (Fig. 8b and Fig. 9e). This is because with the marine INPs, the larger amount of ice/snow that forms on the windward slope is transported to the lee side (Fig. 9d) and grows to a larger size and precipitates as snow. This spillover effect is accompanied by a large reduction of cloud water and rain over the windward side because of the conversion of liquid to ice (Fig. 9b-c). Since the water vapor transport along the cross-section is very similar between DM15 and DM15+MC18 (Fig. 9a), the spillover effect by marine INPs is mainly the result of different cloud microphysical properties instead of meteorological conditions.

Even though the total domain precipitation is not changed much by the marine INPs at the latter two stages, the cloud phase and the near-surface precipitation type (i.e., rain or snow)

453 are notably changed (Table 1). The mean glaciation ratio in the mixed-phase is very low in
454 DM15 (0.14, 0.16, and 0.001 for the 1st, 2nd, and 3rd stages, respectively) and is increased in
455 DM15+MC18 to 0.74, 0.59, and 0.36, respectively. We examine the ratio of snow/(rain+snow)
456 in mass mixing ratio at the lowest model level for the changes of the near-surface precipitation
457 type (Fig. 7b). There is negligible snow precipitation near the surface in DM15 and the ratios of
458 snow precipitation are very small during the entire AR event. The snow precipitation ratios
459 increase in DM15+MC18 and the magnitudes vary significantly with different AR stages. On
460 average, the ratio of snow precipitation increases from 0.002, 0.001, <0.001 in DM15 to 0.08,
461 0.04, and 0.13 in DM15+MC18 before AR landfall, after AR landfall, and post-AR, respectively
462 (Table 1). This shows that marine INPs increase snow precipitation and the effect is particularly
463 significant before AR landfall and post-AR. Correspondingly, rain precipitation is reduced
464 (Table 1). This has an important implication for the regional hydrological resource since more
465 snow accumulation in winter increases freshwater resources in the summer while less rain
466 reduces flood risks.

467 The increased snow and reduced rain at the surface correspond to the increased ice water
468 path (IWP) and decreased liquid water path (LWP; Fig. 7c). The mean LWP in DM15+MC18 is
469 reduced by 66%, 46%, and 26% for the three stages relative to DM15, respectively (Table 1). We
470 showed an increased LWC from DM15 to DM15+MC18 in Fig. 6c in the postfrontal cells. Here
471 the decrease in LWC/LWP averaged over the entire post-AR stage is dominated by the strong
472 decrease over the time before the postfrontal cloud formed. Both LWC and IWC are increased by
473 marine INPs as shown in Fig. 6 (see section 4.3 for more discussion). IWP is greatly enhanced
474 by about 8, 5, and 440 times at the three stages, respectively. Interestingly, the total condensate
475 water path (TWP) is increased by the marine INPs (Fig. 7d). On average there are 45%, 29%,

476 and 35% increases in TWP in DM15+MC18 at the three AR stages relative to DM15,
477 respectively (Table 1). The increases in the total condensate water path and the increased surface
478 precipitation (or no change) suggest that marine INPs enhance the conversion of water from the
479 vapor phase to the condensate phase, which will be further discussed later. This is particularly
480 the case before AR landfall, with water vapor content notably reduced in DM15+MC18
481 compared with DM15 (Fig. S3a).

482 Cloud cover is slightly increased during the first two stages (4-5%) in the simulations
483 considering marine INPs, but the change at the post-AR stage is ~ 20% on average, which is very
484 significant. Because both TWP and cloud cover are increased due to the marine INP effect, the
485 cloud radiative forcing (CRF) at TOA gets stronger by 15%, 13%, and 10% for the three AR
486 stages, respectively. Although the cloud phase, precipitation type, and cloud fraction at the post-
487 AR stage have the largest changes among the three stages by the marine INP effect (Table 1), the
488 CRF does not change drastically probably because of the offset between the increase resulting
489 from the increased cloud fraction and TWP and the decrease from the reduced cloud liquid is the
490 largest.

491 Overall, the marine INP effects on TWP, IWP, and snow precipitation are more
492 significant at the first and third stages (i.e., before AR landfall and post-AR) than the stage after
493 AR landfall, but a notable spillover effect is seen after AR made landfall. Cloud and
494 precipitation quantities are more sensitive to marine INPs before AR landfall than after AR
495 landfall, and the responses of TWP/IWP and snow precipitation are particularly drastic at the
496 post-AR stage (Table 1). The reasons leading to the different responses at different AR stages are
497 now examined.

4.3 Explaining different marine INP effects at different AR stages

We first examine the temporal evolution of dust and marine aerosol number concentrations, which are derived based on the predicted mass mixing ratios as described in Section 2 and used as input to the DeMott et al. (2015) and MC2018 parameterizations (Fig. 10a, b), as well as their corresponding immersion freezing (i.e., ice nucleation) rates (Fig. 10c, d). The dust concentrations and the corresponding ice nucleation rates (Fig. 10a, c) are about three orders of magnitude lower than those of the marine aerosols (Fig. 10b, d) during the AR events. Ice nucleation from dust is negligible at temperatures warmer than -15 ºC but the ice nucleation from marine aerosols is notable. This is mainly because of three orders of magnitude higher marine aerosol number concentrations from the surface up to 8 km since ice nucleation efficiencies of marine aerosols are about three orders of magnitude lower than mineral dust at any temperature (MC2018). The deep marine aerosol layer during the AR allows notable ice nucleation at temperatures even higher than -15 ºC. Homogenous freezing (< -37 ºC; Fig. 10d vs. 10c) occurs less in DM15+MC18 because of a larger consumption of liquid drops and supersaturation in the heterogeneous freezing regime. This is commonly seen in convective clouds (e.g., Zhao et al. 2019). The clear-sky marine aerosol number concentrations increase from before AR landfall to post-AR as the AR evolved (Fig. 10b). After the AR made landfall, marine aerosols increase significantly as AR strong winds near the ocean surface produce more of them and also transport more to the Sierra Nevada Mountains (Fig. 10b). Despite the significant increase in marine aerosols after AR landfall, the marine INP effects on clouds and precipitation are small at this stage, because the increase of marine aerosols does not increase ice nucleation rates (Fig. 10d). However, at the post-AR stage, the ice nucleation rates from the marine INPs are up to a few

520 times larger than the earlier two stages (Fig. 10d), explaining why the effects on IWP and snow
521 precipitation at the post-AR stage are largest among the three stages.
522 To further understand how and why cloud and precipitation responses to marine INPs are
523 different at different AR stages, we separate clouds into three cloud regimes: a shallow warm
524 cloud regime with cloud top temperature (CTT) warmer than 0 ^{o}C, a mixed-phase cloud regime
525 with CTT between -30 and 0 ^{o}C, and a deep cloud regime having CTT colder than -30 ^{o}C and
526 cloud base temperatures above 0 ^{o}C. Figure 11 shows that the marine INP effect consistently
527 shifts the cloud occurrences from the shallow warm cloud regime to mixed-phase and/or deep
528 cloud regimes among the three AR stages. It is noted that the deep cloud regime is enhanced
529 much more at the first and third stages than the second stage, i.e., 22% before AR landfall and
530 235% at the post-AR stage but only 8% after AR landfall. The post-AR stage also has the largest
531 increase in mixed-phase cloud occurrences.
532 Accordingly, the mean cloud depth for each cloud regime is changed by marine INPs,
533 with a decrease for the shallow warm clouds and an increase for the mixed-phase and deep
534 clouds (Fig. 11b). Before AR landfall, the increase in the deep cloud depth is largest while at the
535 post-AR stage, the increase in the mixed-phase cloud depth is the largest. Consistent with a shift
536 in cloud regimes, the total precipitation produced by shallow warm clouds is reduced by 9%,
537 22%, and 16% while the total precipitation produced by deep clouds is increased by 66%, 4%,
538 and 350%, respectively, at the three AR stages (Fig. 11c). Therefore, the large increase in the
539 surface accumulated precipitation by marine INPs before AR landfall (36%) is mainly because of
540 the increase in deep cloud precipitation. The larger occurrence of deep clouds at this stage is
541 consistent with a larger increase in TWP and reduction in moisture. Although the relative
542 increases in deep cloud occurrences and precipitation by marine INPs are very large at the post-

AR stage, their occurrences are so small that their contribution to the total precipitation is negligible.

How do marine INPs reduce shallow warm clouds but increase mixed-phase and deep clouds and why is this effect larger at the first and third stages? Marine INPs greatly enhance ice and snow number concentrations and mass mixing ratios through immersion freezing, which converts drops to ice or snow particles (Figs. 12a and 13a). The mean number concentrations and mass mixing ratios of ice particles (ice +snow) in mixed-phase and deep cloud regimes are several orders of magnitude higher in DM15+MC18 than in DM15. As detailed in Fan et al. (2017a) which studied the same type of mixed-phase clouds in the same region, more ice/snow particles forming from the immersion freezing enhance the Wegener–Bergeron–Findeisen (WBF) and riming processes (Table 2), converting supercooled drops to ice or snow and leading to more ice/snow but fewer cloud droplets and raindrops (Figs. 12b, c and 13b, c). The reductions of cloud droplet and raindrop number concentrations and mass mixing ratios from DM15 to DM15+MC18 are larger before AR landfall and during post-AR relative to the stage after AR landfall, corresponding to a larger shift to the mixed-phase and deep clouds. Thus, the larger increases in deposition/WBF and riming rates are seen (Table 2).

As discussed earlier, the largest ice nucleation rates from marine aerosols at the post-AR stage explain the largest marine INP effects among the three stages. The factors contributing to the larger ice nucleation rates include the increased abundance of marine aerosols compared to the previous two stages (Fig. 10b). In addition, with the ~ 6 ºC colder temperatures below 8-km altitudes during the post-AR stage compared to the other two stages, ice nucleation from marine aerosols becomes more efficient (Fig. 10d). The most significantly invigorated postfrontal cloud cells by the marine INP effect (i.e., the increase in both LWC and IWC and a large increase in

cloud fraction) might also be related to small scale thermodynamic changes through the feedback of microphysical changes over the first two AR stages.

As for why increases of deep cloud occurrence and precipitation are less significant after AR landfall compared to before AR landfall, first, the moisture increase after AR landfall occurs in the lower atmosphere while the middle- and upper-level atmosphere are much drier than before AR landfall (Fig. 2d), which favors more warm clouds and rain but is less favorable to ice cloud development as indicated by the smallest ratio of snow precipitation (Fig. 7b). For more warm clouds/rain-dominated situations, the enhancement of ice formation would have less influence. Furthermore, in the drier conditions aloft, more ice formation means less efficient growth, thus the impacts on IWC/IWP and precipitation would be smaller. Cloud dynamics (vertical velocity) is not changed much by the marine INP effect at all three stages, indicating that the feedback from the increased latent heating resulting from enhanced deposition and riming does not play an important role here, likely because this is not a convective environment.

5 Conclusion and discussion

We have explored the effects of INPs from sea spray aerosols transported from the Pacific Ocean on wintertime mixed-phase stratiform cloud properties and precipitation associated with atmospheric river (AR) events. This is done by carrying out simulations at a cloud-resolving scale (1 km) using WRF-Chem coupled with the spectral-bin microphysics (SBM) scheme for an AR event observed during the 2015 Atmospheric Radiation Measurement Cloud Aerosol Precipitation Experiment (ACAPEX). We have implemented ice nucleation parameterization for sea spray aerosols (McCluskey et al. 2018a) into SBM to account for the marine INP effect. By comparing with available airborne and ground-based observations, we

588 show that considering the marine INP effect in the model improves the simulation of cloud phase
589 states (i.e., increased glaciation ratio) and precipitation.

590 Through enhancing ice and snow formation, marine INPs greatly enhance WBF and
591 riming processes, which convert liquid clouds to mixed-phase and ice clouds. There is a notable
592 shift in cloud occurrences with reduced shallow warm clouds (44%, 26%, and 7% for before and
593 after AR landfall and the post-AR stages, respectively) and increased mixed-phase (10%, 7%,
594 and 38%) and/or deep cloud regimes (~ 22%, 8%, and 230%) because of the marine INP effect.
595 As a result, large increases in the ice water path (5 times or more), total condensate water path
596 (29% or more), and the ratio of snow precipitation (40 times or more) are seen. There is an
597 enhanced conversion of water from the vapor phase to the condensate phase so the water vapor is
598 generally reduced with the marine INP effect considered.

599 The significance of the above-described marine INP effects varies with the AR stages,
600 with a larger effect before AR landfall and post-AR than after AR landfall that has the dominant
601 precipitation. Note that the marine INP effects on cloud properties and snow precipitation are
602 still notable even at the stage after AR landfall. Although the total precipitation is not much
603 changed, the drastic increase of snow precipitation and reduced rain precipitation at the surface
604 have an important implication for the regional water resources and flood risks since more snow
605 increases freshwater resources while less rain reduces flash flood risks. In addition, at this stage,
606 the marine INPs produce a notable spillover effect with a precipitation decrease (up to 30%) over
607 the windward slope of the mountains but precipitation (snow) over the lee side is doubled,
608 because more ice/snow formed over the windward side falls slower than rain and is more easily
609 transported to the lee side.

Several factors can be responsible for the smaller marine INP effects on cloud properties (particularly reduction of shallow warm clouds and increased mixed-phase and deep clouds) and snow precipitation after AR landfall compared with before AR landfall. First, after AR landfall, the moisture is heavily concentrated at the lower atmosphere while the middle- and upper-level atmosphere is much drier than before AR landfall. Therefore, the environment is more warm cloud and rain dominated, limiting the effects of enhanced ice formation. Furthermore, in drier conditions, more ice formation means less efficient growth, thus the impacts on IWC/IWP and precipitation would be smaller.

The post AR stage has the largest response of the cloud regime shift and snow precipitation among the three stages, because of the largest ice nucleation rates from the marine aerosols. The larger ice nucleation rates compared with the other two stages are probably because the abundance of marine aerosols is increased and also with ~ 6 ºC colder temperatures below 8-km altitudes than the other two stages, ice nucleation from the deep marine aerosol layer is more efficient.

This study suggests that the inclusion of marine INPs enhances orographic precipitation mainly through more efficient growth (deposition and riming) of a larger number of ice particles than liquid droplets, which is consistent with literature studies (Mühlbauer and Lohmann, 2009; Fan et al., 2014, 2017; Xiao et al., 2015). The spillover effect by the increase of CCN has been presented in several previous studies (e.g., Mühlbauer and Lohmann, 2008, 2009; Saleeby et al., 2011, 2013; Carrio and Cotton, 2014; Letcher and Cotton, 2014). To our knowledge, this study is the first to show the spillover effect associated with the INP effect. The prominent spillover effect by the marine INP is different from Fan et al. (2014, 2017) that did not find such an effect by dust INPs. There are a couple of factors that might be responsible for the difference. First,

633 marine INPs are mainly brought by ARs so the windward side gets INP first while dust INPs are
634 not associated with AR so there is no temporal sequence to have dust between the windward and
635 Lee sides. Second, the AR event is different with a different wind direction and speed, which
636 makes the transport of ice/snow to the lee side easier in this case.

637 The marine INP effect revealed in this study is clearly manifested due to the very low
638 dust INP concentrations for this particular situation and the high abundance of marine aerosols
639 during the AR which allows notable ice nucleation even at temperatures higher than -15 ºC. This
640 higher abundance of marine aerosols overcomes the fundamental lower efficiency of marine
641 INPs compared to dust INPs. With high dust INPs, the effects of marine INPs might not be as
642 significant since they compete for supercooled liquid drops. Although this is a single case study,
643 the AR event and its evolution are representative. Thus, the study suggests the importance of
644 accounting for marine aerosols as INPs, in addition to long-range transported mineral dust, to
645 simulate winter clouds and precipitation in the western United States in regional and global
646 climate models. We employ an empirical parameterization for marine INPs developed from the
647 data collected over the northern Atlantic Ocean and use sea salt aerosols as a surrogate of sea
648 spray aerosols, which might produce some uncertainties. Nevertheless, the marine INP
649 parameterization appears representative of this region based on Levin et al. (2019). More
650 observational data are needed in the western U.S. for (a) developing ice nucleation
651 parameterizations for potentially variable marine organics and (b) understanding marine organics
652 emission and chemical mechanisms and accurately simulating marine organics in the model. As
653 discussed earlier, the conversion of mass to number concentrations over each aerosol bin might
654 introduce some uncertainty to this study, which calls for model developments of predicting the
655 number concentration of each aerosol component.

Data availability.

The observational data can be accessed from the ARM data archive, https://www.arm.gov/research/campaigns/amf2015apex. The model simulation data will be available through the NERSC data repository after the paper is accepted.

Supplement.

The supplement related to this article is available online at:

Author contributions.

JF designed the study and model experiments. YL, JF, and PL performed numerical simulations and analyses. JF and YL wrote the paper and other authors commented on it. LRL, PJD, LG, JF, JT, YL, and JHJ contributed by either processing data including model input and observational data or participating in the discussion of results.

Competing interests.

The authors declare that they have no conflict of interest.

Acknowledgments.

This research used resources of the PNNL Institutional Computing (PIC), and National Energy Research Scientific Computing Center (NERSC). NERSC is a U.S. DOE Office of Science User Facility operated under Contract No. DE-AC02-05CH11231. Funding for ACAPEX that provides data collected on the G-1 aircraft was supported by the Atmospheric Radiation Measurement (ARM) user facility, a U.S. Department of Energy (DOE) Office of Science user

facility managed by the Office of Biological and Environmental Research. The deployment of the G-1 also involved the assistance of many PNNL/ARM field staff including M. Hubbell and C. Eveland who flew the G-1 during ACAPEX. The authors acknowledge California Air Resources Board for providing the 2015 emission inventory data and Dr. Allen White from NOAA's Physical Sciences Laboratory for providing rainfall gauge data, and thank Alyssa Matthews and Jingyu Wang at PNNL and Yuan Wang at JPL for technical/data discussion.

Financial support.

This study was supported by the Office of Science of U.S. Department of Energy Biological and Environmental Research through the Regional and Global Model Analysis program area that supports the Water Cycle and Climate Extremes Modeling (WACCEM) Science Focus Area at PNNL and the DOE Early Career Research Program (project # 70071). PNNL is operated for the U.S. Department of Energy (DOE) by Battelle Memorial Institute under contract DE-AC05-76RL01830.

Figures

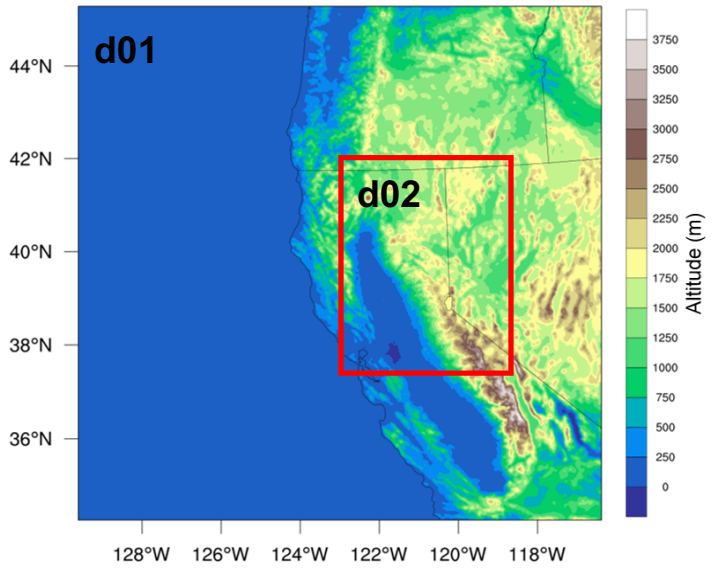

Figure 1. Two nested simulation domains: d01 and d02 centering over California. The color shading denotes the terrain elevation.

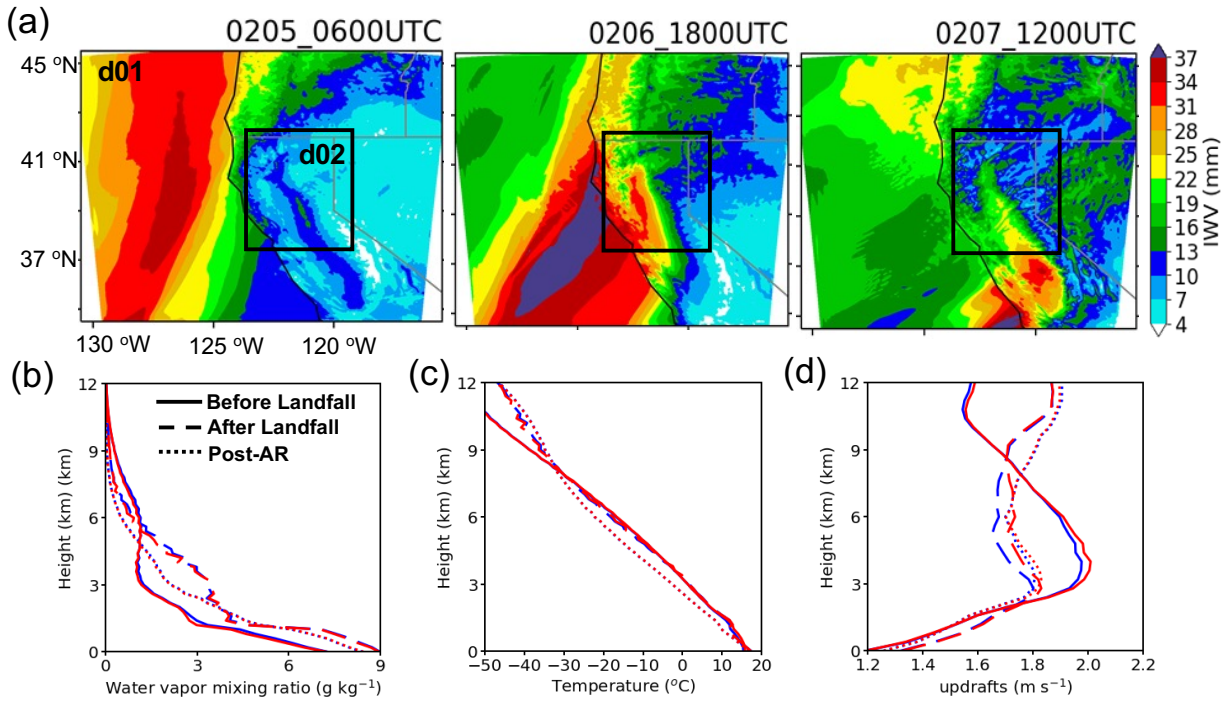
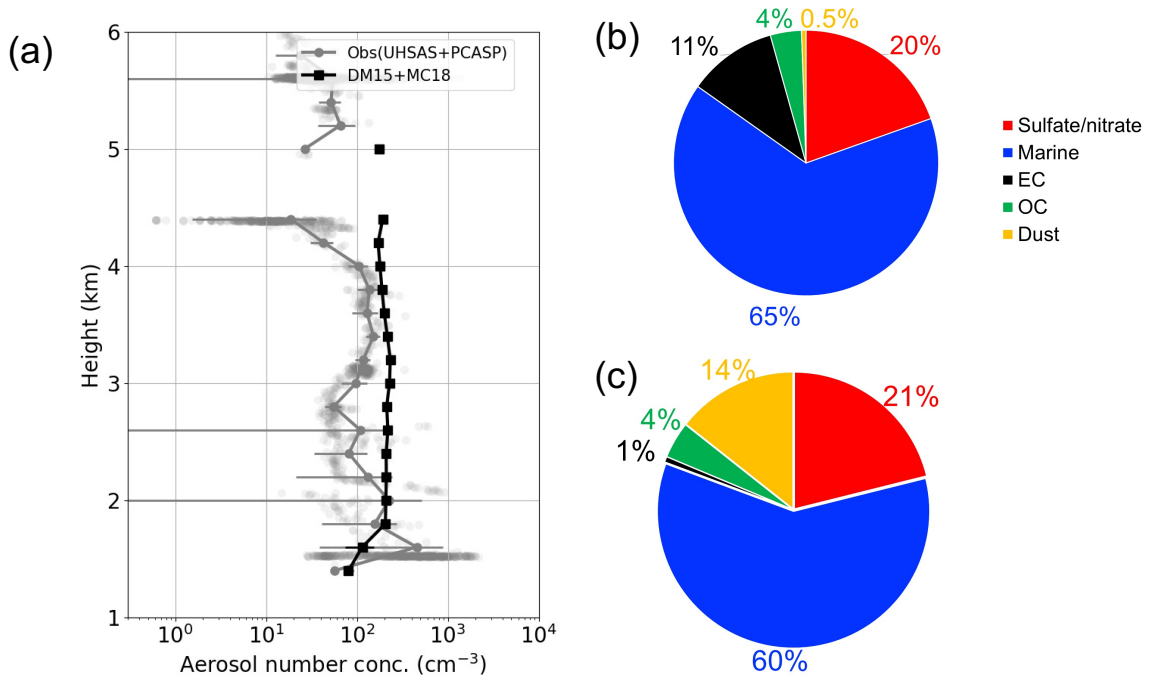


962

963 **Figure 2.** (a) Evolution of integrated water vapor (IWV) at 06:00 UTC 5 February (before AR
964 landfall), 18:00 UTC 6 February (after AR landfall), and 12:00 UTC 7 February (post-AR). The
965 black box (i.e., d02) in (a) is the domain of this study with the 5 lateral boundary grids excluded
966 for analysis at each side. (b-d) show the mean vertical profiles of (b) water vapor mixing ratio,
967 (c) temperature, and (d) updraft velocity at the three AR stages, i.e., before (solid lines) and after
968 (dashed lines) AR landfall and post-AR stages (dotted lines), for the simulations of DM15 (blue)
969 and DM15+MC18 (red). The water vapor mixing ratio and temperature are averaged for cloud-
970 free grids, and updraft velocity is averaged over the grids with a vertical velocity greater than 1
971 m s^{-1}.

972



973

974 **Figure 3.** (a) Vertical distributions of aerosol number concentrations from aircraft observations
975 (Obs, grey) and DM15+MC18 (black) for particles with a dry diameter over a range of 0.067~3
976 μm, (b) mean fractional number contributions of aerosol classifications based on measurements
977 of single-particle mass spectra of aerosols and cloud particle residuals reported in Levin et al.
978 (2019), and (c) mean fractional mass contributions of aerosols in DM15+MC18 (number
979 concentration for each aerosol component is not predicted by WRF-Chem). The aerosol number
980 concentration from aircraft observations in (a) consists of both measurements from UHSAS and
981 PCASP. The modeled data in (a) and (c) are sampled along the aircraft route on 7 February 2015.

982

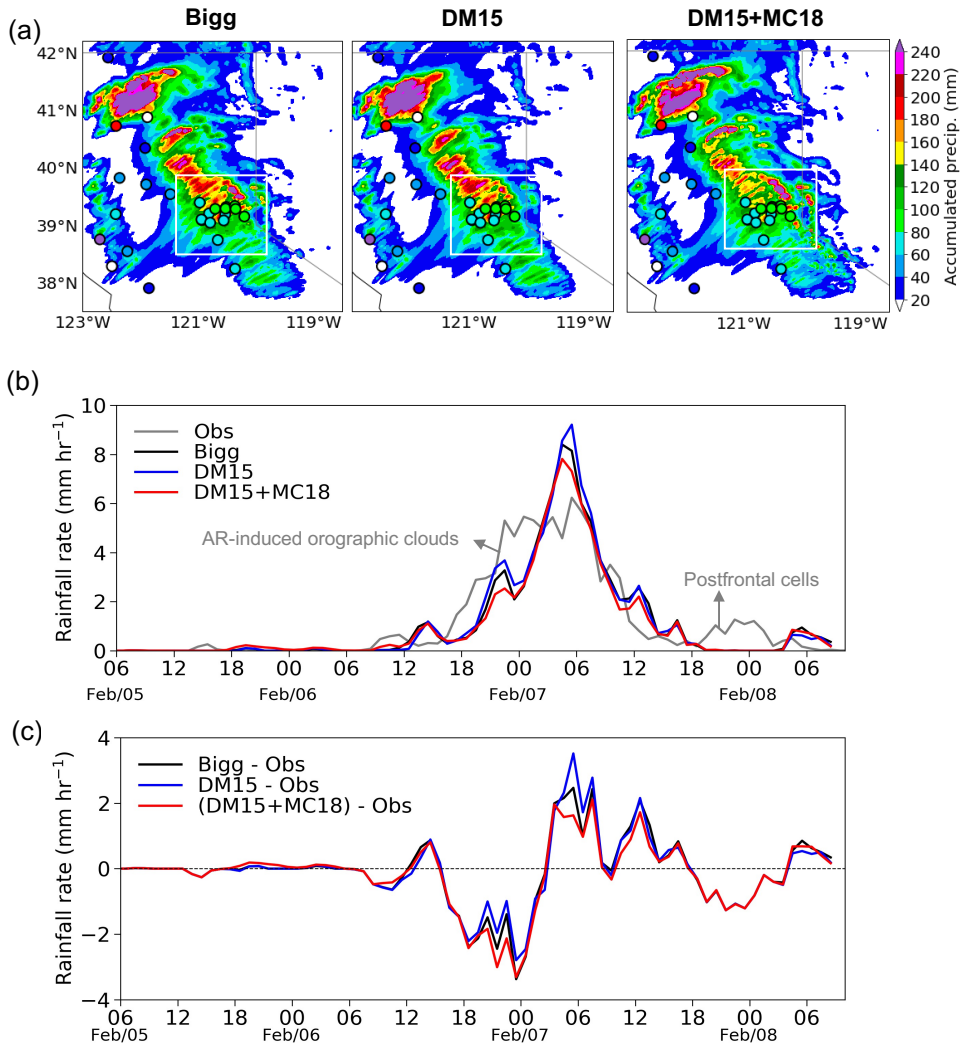


Figure 4. (a) Spatial distributions of accumulated precipitation during the AR event (5 Feb. 06:00 – 8 Feb. 09:00 UTC) from Bigg, DM15, and DM15+MC18. The color shading is for simulations and the circles denote the rain gauge measurements provided by NOAA Physical Sciences Laboratory. (b) Time series of precipitation rates during the entire AR event for rain gauge observations (grey line), Bigg (black line), DM15 (blue line), and DM15+MC18 (red line). (c) Differences between the simulations and observations based on the data of (b). The precipitation rates in (b) are averaged over all the rain gauge sites shown in (a). The white boxes in (a) mark the region where the precipitation simulation is improved by adding marine INPs.

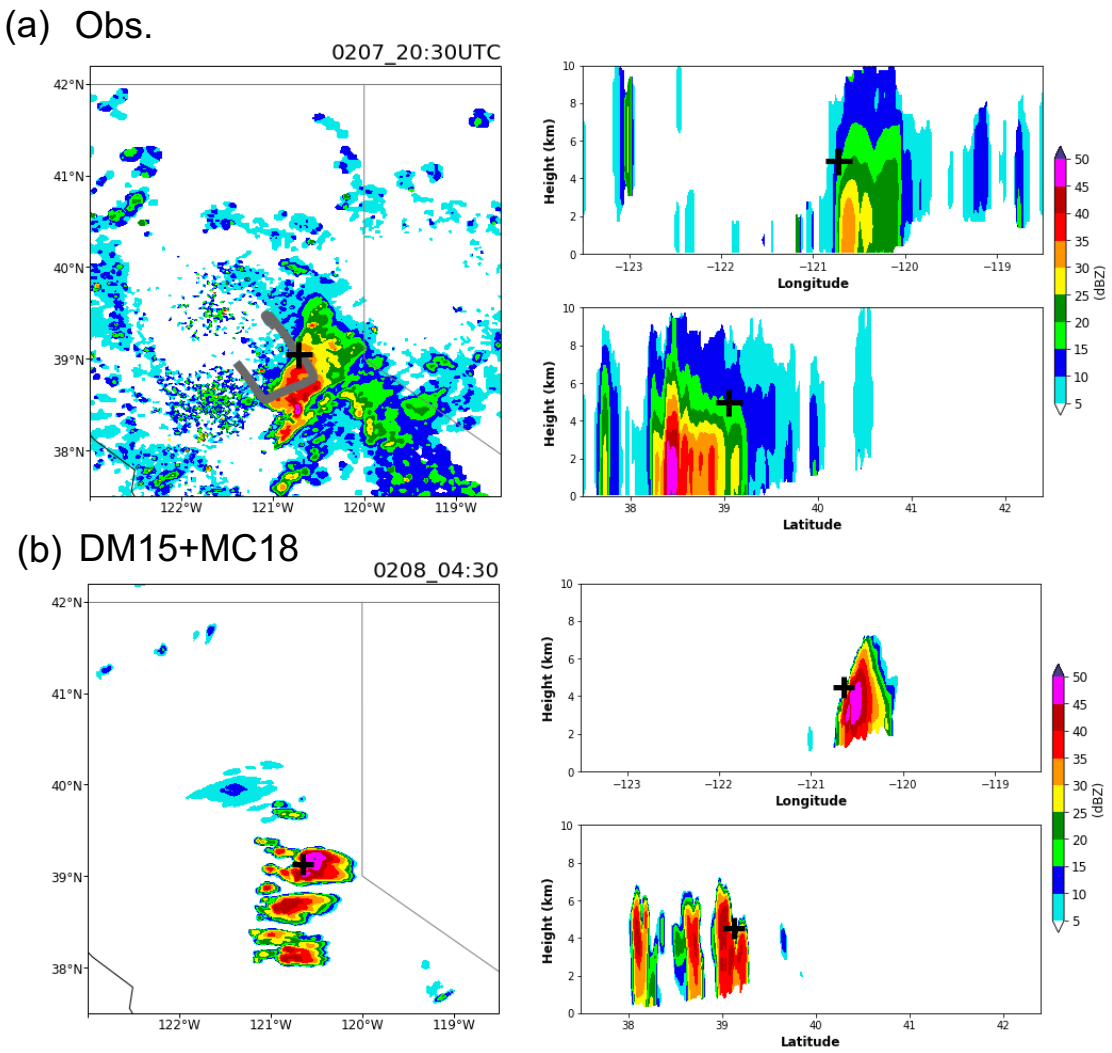

Figure 5. (a) Composite reflectivity of NEXRAD for the postfrontal clouds that the G-1 aircraft sampled, (b) composite reflectivity from the simulation of DM15+MC18 for the postfrontal clouds. The observation and simulation are compared at the peak reflectivity time which is 20:30 UTC 7 February for the observed clouds and 04:30 UTC 8 February for the simulated clouds. The black crosses in the left two panels denote the positions where the longitude-height and latitude-height cross-sections in the right panels are plotted. The grey line in the left panel of (a) shows the flight track of the G-1 aircraft.

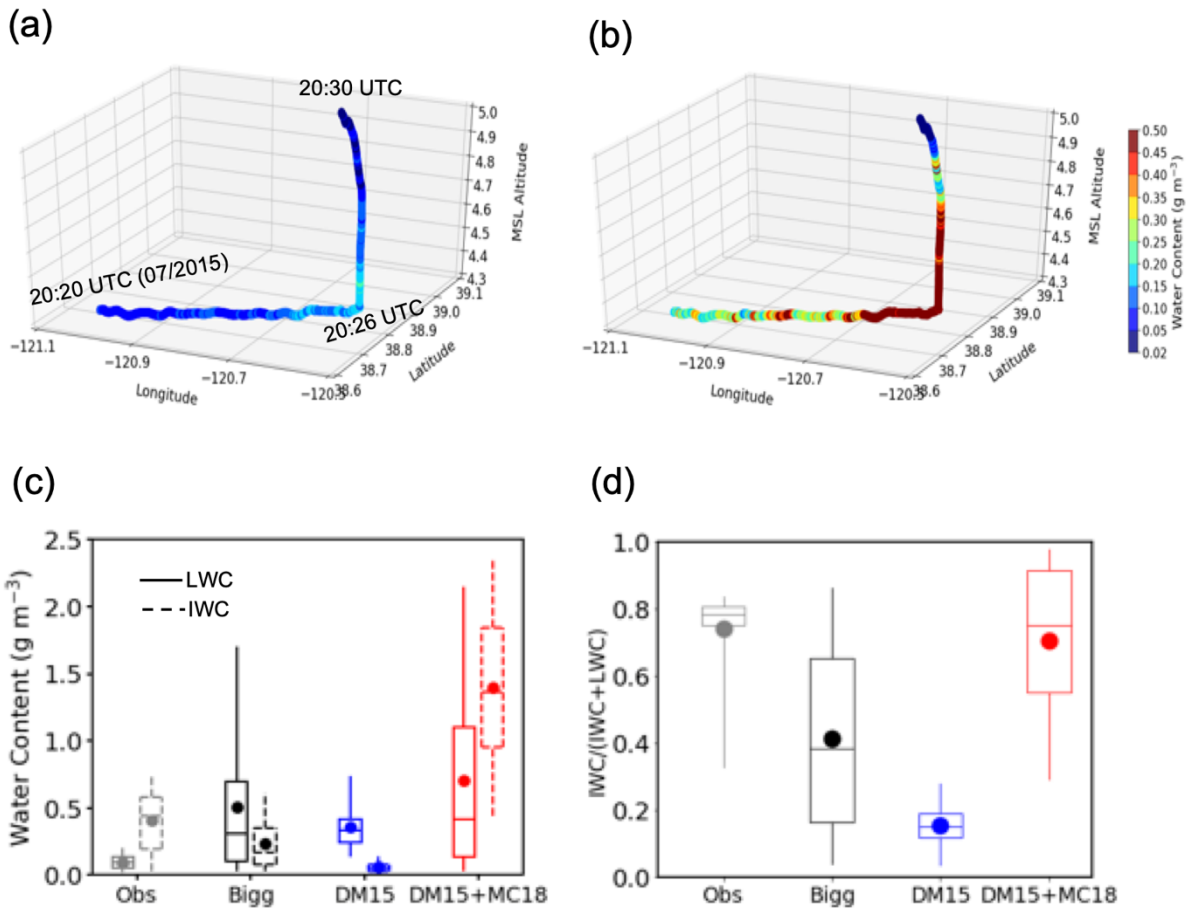

Figure 6. Comparisons of the simulations with aircraft observations. The observed (a) LWC and (b) IWC along the flight track during 20:20 – 20:30 on 7 February when the aircraft flew through the mixed-phase regime of the postfrontal clouds. (c) LWC (solid) and IWC (dashed) and (d) the glaciation ratios of IWC/(IWC+LWC) from the aircraft measurements (Obs, grey) and simulations of Bigg (black), DM15 (blue), and DM15+MC18 (red). The boxes show the 25th, median (horizontal lines in the box), and 75th percentiles of the data. The upper and lower whiskers show the 95th and 5th percentiles, respectively. The mean values are denoted by circles.

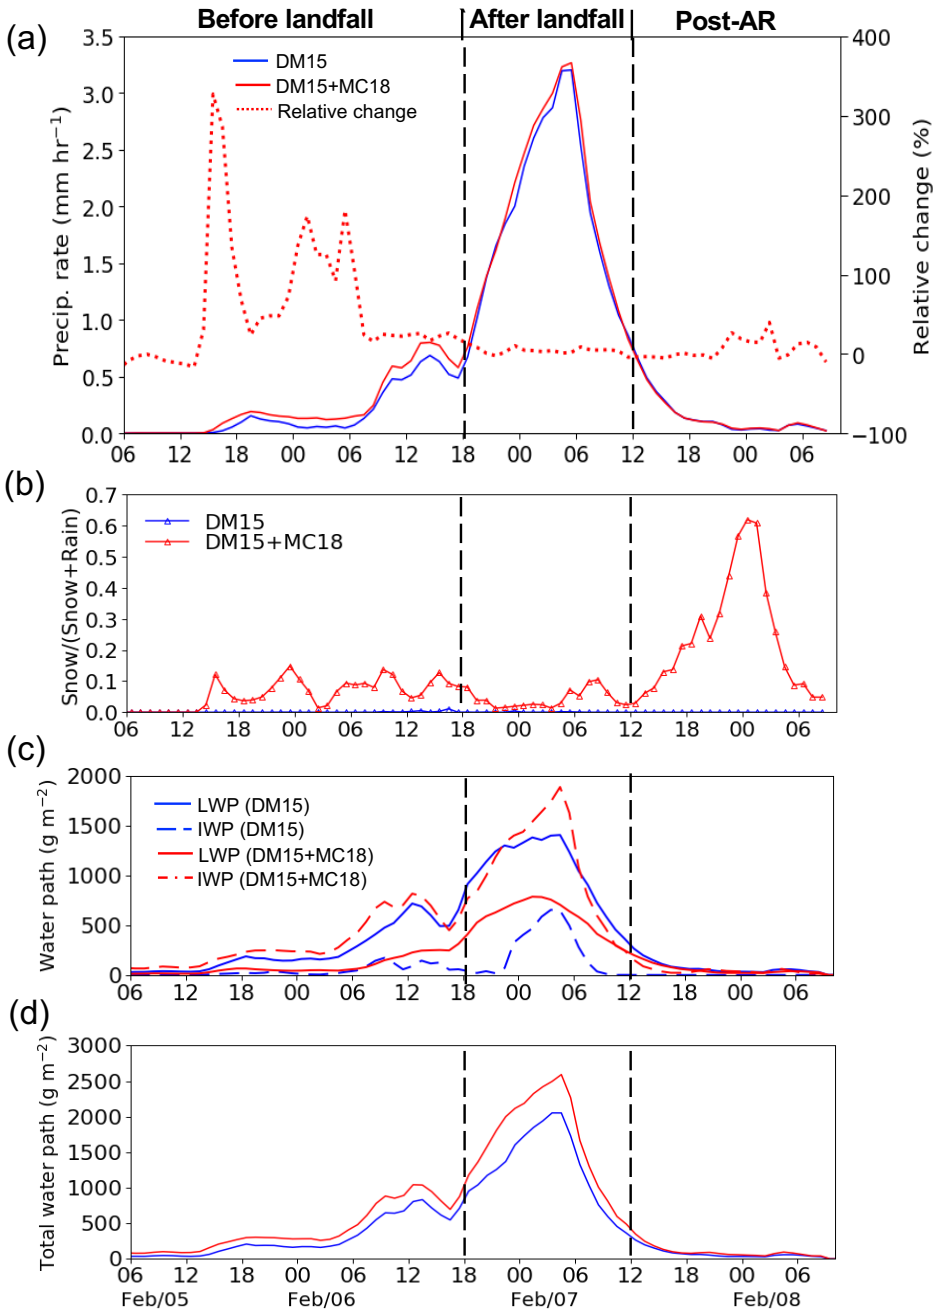

Figure 7. Time series of (a) precipitation rate (solid lines, left y-axis), (b) ratio of snow precipitation (i.e., snow/(snow+rain) in mass mixing ratio) at the lowest model level, (c) LWP (solid) and IWP (dashed) for DM15 (blue) and DM15+MC18 (red), and (d) total condensate water path (TWP). The relative changes in precipitation rate from DM15 to DM15+MC18 are shown in the red dotted line in (a) with values shown on the right y-axis. The vertical dashed lines divide the three AR stages.

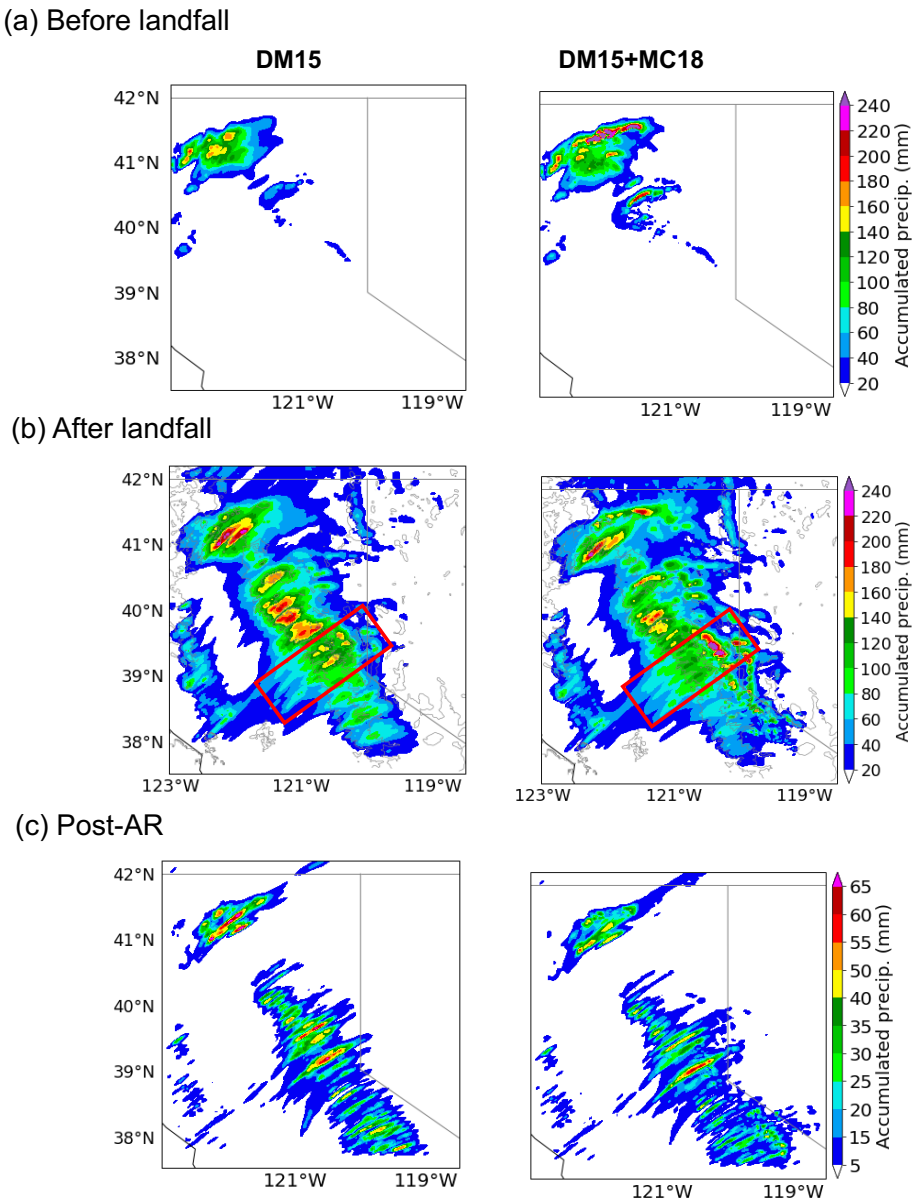

Figure 8. Spatial distribution of accumulated precipitation during the stages of (a) before AR landfall, (b) after AR landfall, and (c) post-AR in DM15 (left) and DM15+MC18 (right). The parallelograms marked in (b) denotes the area for the east-west cross-section analysis shown in Figure 9.

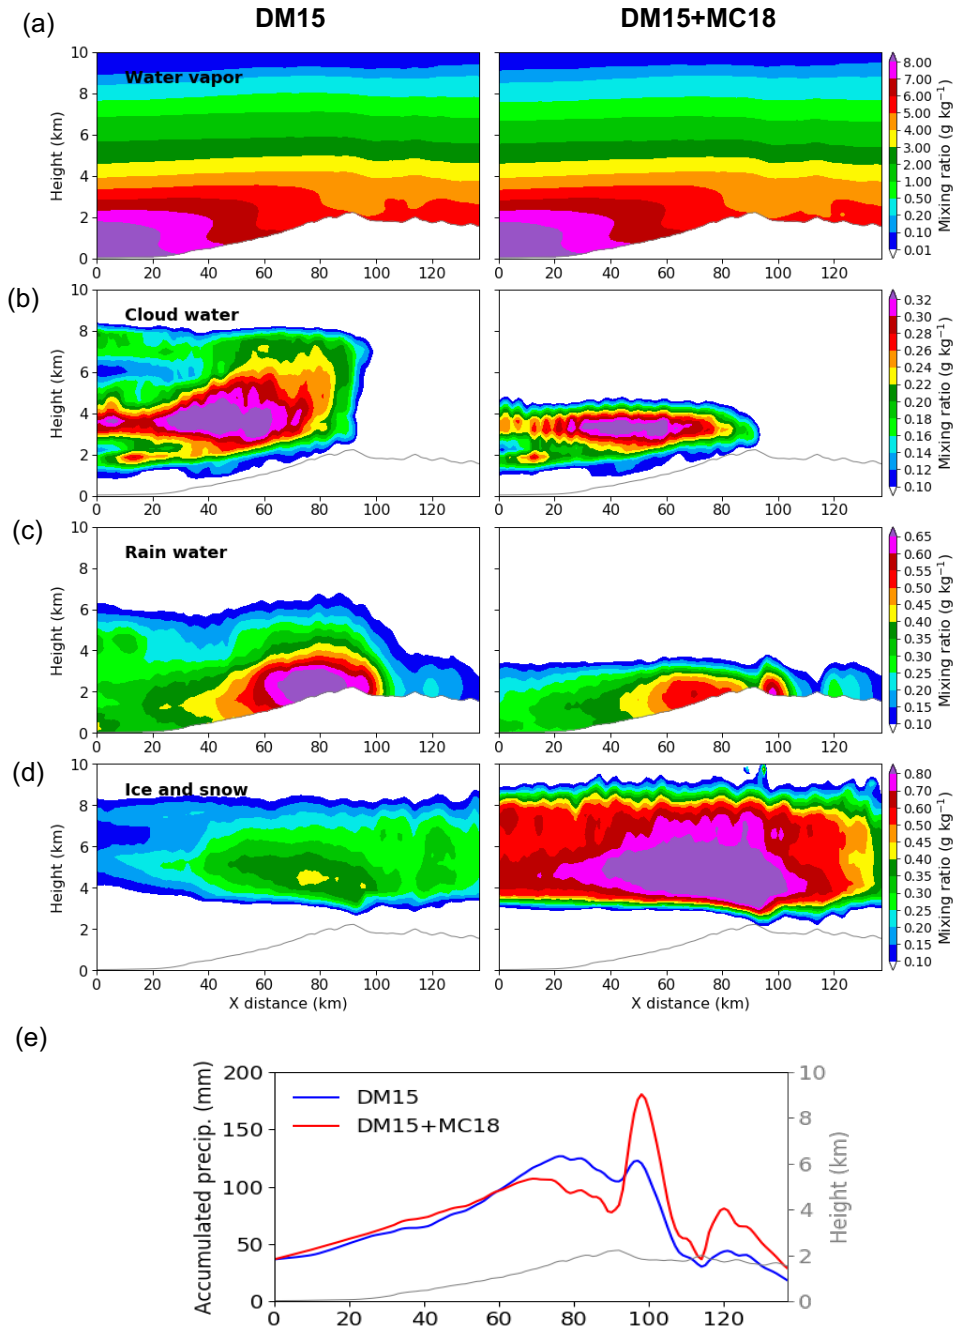

Figure 9. Mean mixing ratios of (a) water vapor, (b) cloud water, (c) rainwater, (d) ice + snow, and (e) surface precipitation at the stage after AR landfall in DM15 and DM15+MC18. The vertical cross-sections are averaged over the red boxes marked in Fig. 8b and the entire stage.

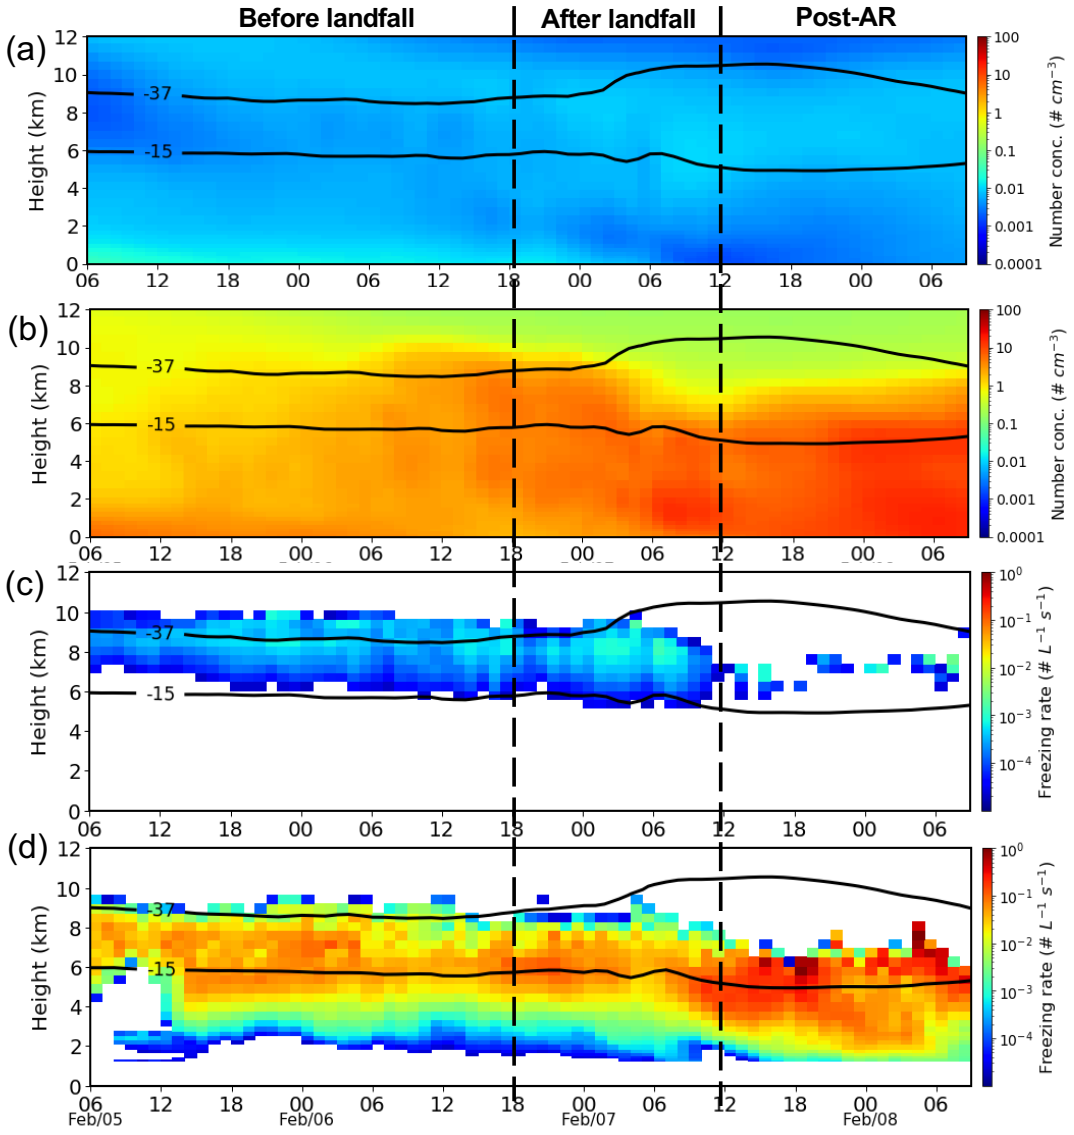

Figure 10. Time-height cross-sections of (a) dust particle (>0.5 μm) number concentration, (b) marine aerosol number concentration, (c) the freezing rate in DM15, and (d) the freezing rate in DM15+MC18. The number concentrations in (a) and (b) are derived from their corresponding mass mixing ratios under the clear-sky condition only. The freezing rates in (c) and (d) are the ice nucleation rates via immersion freezing at T > - 37 ºC and the drop homogenous freezing rates at T < - 37 ºC, and the values are for cloudy-points only. The black contour lines in each panel mark the temperature levels of -15 and -37 ºC, representing the efficient immersion freezing temperature in DM15+MC18 and the homogeneous freezing temperature in the model, respectively.

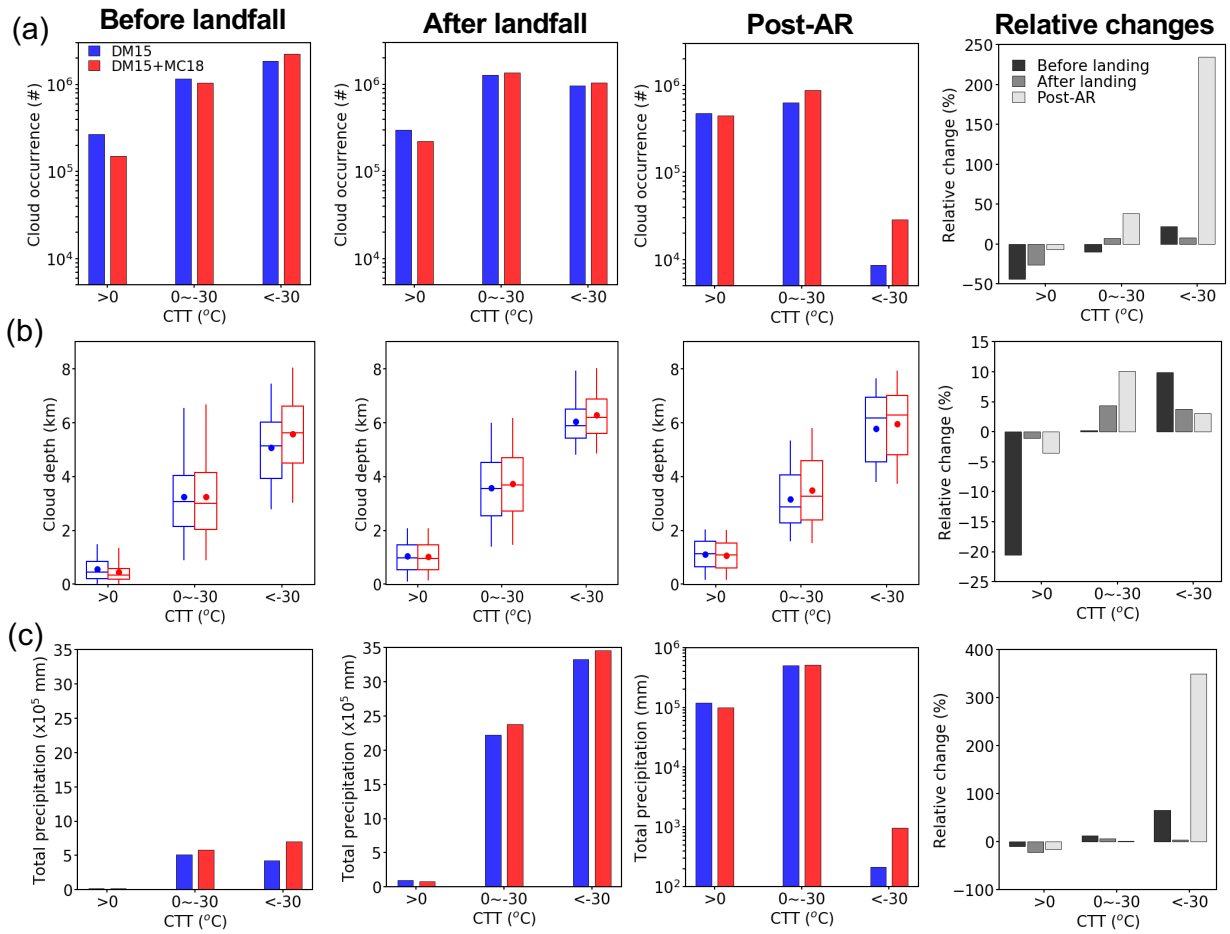

Figure 11. (a) Cloud occurrences, (b) cloud depth, and (c) total precipitation for three cloud regimes in DM15 (blue) and DM15+MC18 (red) at three AR stages from left to right: before AR landfall, after AR landfall, post-AR. The last column shows the relative changes caused by the marine INP effect, which are calculated as [(DM15+MC18) – DM15]/DM15*100%. Note that the total precipitation at the post-AR stage uses a log scale for the y-axis. The box-whisker plots follow the description in Figure 5c.

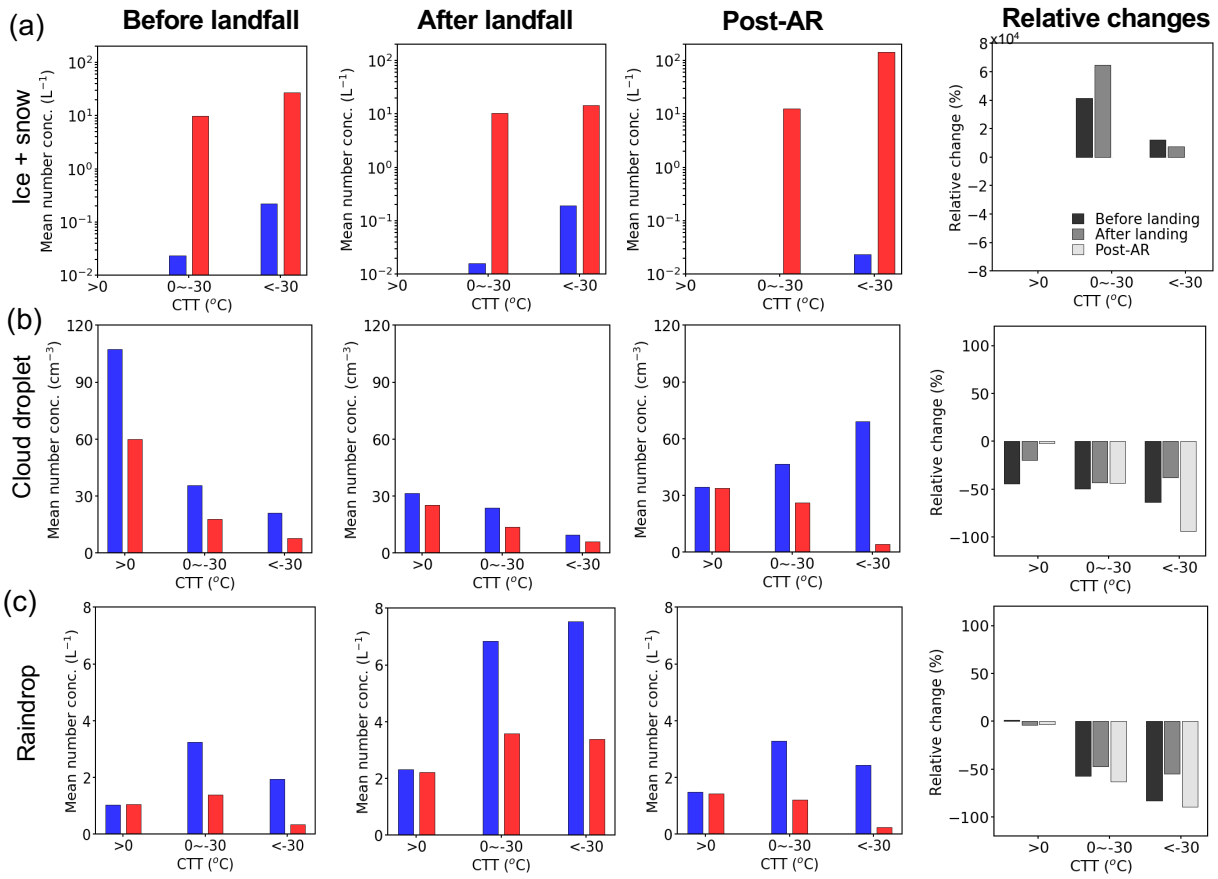

Figure 12. Hydrometeor number concentrations and their relative changes in three cloud regimes in DM15 (blue) and DM15+MC18 (red) at the three AR stages for (a) ice particles (sum of ice and snow), (b) cloud droplets, and (c) raindrops. The last column shows the relative changes caused by the marine INP effect, which are calculated as [(DM15+MC18) – DM15]/DM15*100%. Since ice particles are very limited at the post-AR stage in DM15, the percentage changes of ice particles from DM15 to DM15+MC18 are huge numbers that are omitted from the plots.

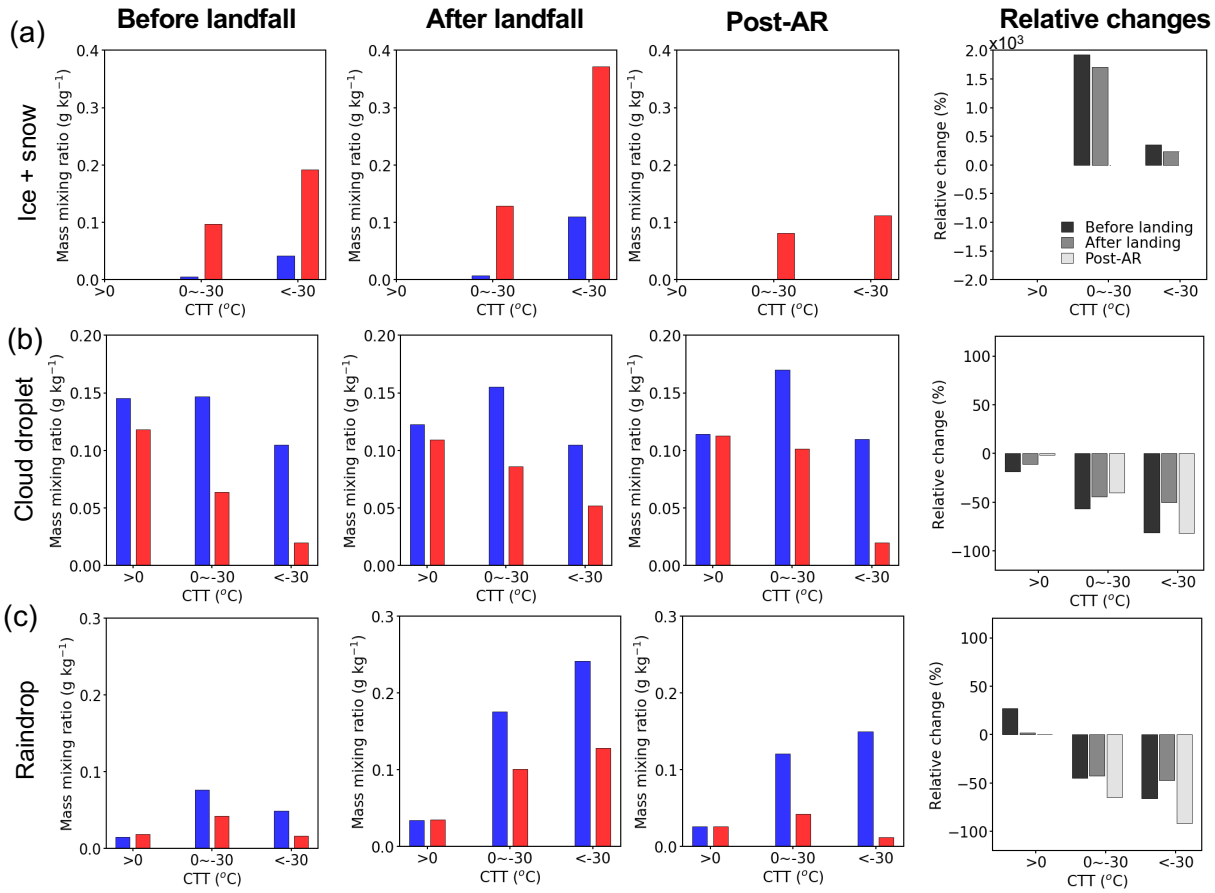

Figure 13. Same as Figure 12, except for the mass mixing ratios of (a) ice particles (sum of ice and snow), (b) cloud droplets, and (c) raindrops.

Table 1. The changes in total precipitation, total condensate water path (TWP), liquid water path (LWP), and ice water path (IWP), and cloud fractions (CF), net cloud radiative forcing (CRF) at TOA from DM15 to DM15+MC18 (i.e., the marine INP effect), as well as the glaciation ratio, i.e., IWC/(LWC+IWC), and the ratios of snow precipitation, i.e., snow/(rain+snow) in mass mixing ratio at the lowest model level from DM15 to DM15+MC18, at the three AR stages. The percentage changes are calculated following ((DM15+MC18)- DM15)/DM15*100.

AR stages		**Before landfall**	**After landfall**	**Post-AR**
Total precipitation		36%	4%	-1%
TWP		45%	29%	35%
LWP		-66%	-46%	-26%
IWP		8 times	5 times	440 times
CF		5%	4%	20%
Net CRF at TOA		15%	13%	10%
IWC/(LWC+IWC)	DM15	0.14	0.16	0.001
	DM15+MC18	0.74	0.59	0.36
Snow/(Rain+Snow)	DM15	0.002	0.001	<0.001
	DM15+MC18	0.085	0.042	0.131

Table 2. The domain-mean mass rates of deposition and riming in the mixed-phase and deep cloud regimes in DM15 and DM15+MC18 at the three AR stages.

AR stages		**Before landfall**		**After landfall**		**Post-AR**	
		Mixed-phase clouds	Deep clouds	Mixed-phase clouds	Deep clouds	Mixed-phase clouds	Deep clouds
Deposition ($mg\ kg^{-1}\ h^{-1}$)	DM15	44	171	81	388	7	8
	DM15+MC18	846	780	1128	1397	781	1013
Riming ($mg\ kg^{-1}\ h^{-1}$)	DM15	27	89	57	297	25	34
	DM15+MC18	377	228	575	858	505	361
