Abstract. Black carbon aerosols are the second largest contributor to global warming while also being linked to respiratory and cardiovascular disease. These particles are generally found in smoke plumes originating from biomass burning and fossil

15 fuel combustion. They are also heavily concentrated in smoke plumes originating from oil fires exhibiting the largest ratio of black carbon to organic carbon. In this study, we identified and analyzed oil smoke plumes derived from 30 major industrial events within a 12-year timeframe. To our knowledge, this is the first study of its kind that utilized a synergistic approach based

20 on satellite remote sensing techniques. Satellite data offers access to these events which, as seen in this study, are mainly located in war prone or hazardous areas. This study focuses on the use of MODIS (Moderate Resolution Imaging Spectroradiometer) and CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations) products regarding these types of aerosol while also highlighting their intrinsic limitations. By using data from both MODIS instruments onboard

Terra and Aqua satellites we addressed the temporal evolution of the smoke plume while assessing lidar specific properties and plume elevation using CALIPSO data. The analysis method in this study was developed to better differentiate between oil

25 smoke aerosols and the local atmospheric scene. We present several aerosol properties in the form of plume specific averaged values. We believe that MODIS values are a conservative estimation of plume AOD since MODIS algorithms rely on general

aerosol models and various atmospheric conditions within the look-up tables, which do not reflect the highly absorbing nature of these smoke plumes. Based on this study we conclude that the MODIS land algorithms are not yet suited for retrieving

30 aerosol properties for these types of smoke plumes due to the strong absorbing properties of these aerosols. CALIPSO retrievals rely heavily on the type of lidar solutions showing discrepancy between constrained and unconstrained retrievals. Smoke

plumes identified within a larger aerosol layer were treated as unconstrained retrievals and resulted in conservative AOD estimates. Conversely, smoke plumes surrounded by clear air were identified as opaque aerosol layers and resulted in higher lidar ratios and AOD values. Measured lidar ratios and particulate depolarization ratios showed values similar to the upper ranges of biomass burning smoke. Results agree with studies that utilized ground-based retrievals, in particular for Ångström

exponent (AE) and effective radius (R_{eff}) values. MODIS and CALIPSO retrieval algorithms disagree on AOD ranges, for the
35 most part, due to the extreme light absorbing nature of these types of aerosols. We believe that these types of studies are a strong indicator for the need of improved aerosol models and retrieval algorithms.

1 Introduction

Atmospheric aerosols are chemically complex mixtures of solid and liquid particles dynamically suspended in air. They originate from both natural and anthropogenic emissions. More common naturally occurring aerosols can be observed in
40 the form of fog, dust, sea salt spray, biological exudates and grey smoke (biomass burning). Haze, smog and black smoke are typically a result of industrial and transportation activities (Stocker et al., 2014; Wei et al., 2020). Distinct species such as black carbon (BC), organic carbon (OC), sulphates, nitrates, trace elements, sea salt, mineral dust and biological matter suffer atmospheric alteration resulting in different combinations of compounds. Defining aerosol types is a difficult task as they possess a large degree of variance in composition and concentration due to different atmospheric residence times, dry
45 deposition and wet scavenging, emission rates and sources, transport trajectories and seasonal variability (Dutkiewicz et al., 2009; Li et al., 2015; Samset et al., 2018).

Health effects associated with both short and long-term exposure to aerosol have been widely documented in scientific literature (Brauer et al., 2015; Laumbach and Kipen, 2012; Zhang and Batterman, 2013; Pascal et al., 2013; Lee et al., 2014; Guarnieri and Balmes, 2014; Zhang et al., 2017). Aerosols have been linked to respiratory and cardiovascular diseases due to
50 fine particulate matter (PM2.5; $<2.5 \mu\text{m}$ in diameter) that can penetrate the lungs resulting in increased rates of morbidity and mortality (Brunekreef and Holgate, 2002; Pope III et al., 2002; Lim et al., 2012; Beelen et al., 2014; Hoek et al., 2013).

Global circulation of aerosols is a known transport vector of minerals and nutrients to the biosphere (McTainsh and Strong, 2007; Maher et al., 2010; Lequy et al., 2012). Aerosols have a direct effect on radiation distribution by scattering, absorbing and emitting light thorough the atmosphere. In addition, they can affect the climate system through indirect effects
55 acting as cloud condensation nuclei, impacting cloud lifetime and properties, atmospheric stability and precipitation factors (Popp et al., 2016; Samset et al., 2018; Stocker et al., 2014). They can disrupt circulation patterns, impact air temperatures and severe weather systems (Fan et al., 2016), reduce visibility (Deng et al., 2012; Wang et al., 2015) and lead to ozone depletion (Popp et al., 2016).

Because of their complex influence on the environment and climate system, assessing aerosol key parameters is
60 essential for any atmospheric study. Aerosol optical depth (AOD), the extinction vertically integrated throughout the atmospheric column, is strongly correlated to PM concentrations. Together with other properties such as Ångström exponent (AE), single scattering albedo (SSA), size distribution and vertical distribution we can better describe their atmospheric impacts. Between ground stations and spaceborne observations, satellite remote sensing offers a more comprehensive global view of aerosols. Since the 1970s onwards, there has been a significant number of satellite sensors used successfully for
65 retrieving AOD and other aerosol properties (Li et al., 2015, 2016; Dubovik et al., 2019; Schutgens et al., 2020; Wei et al.,

2020; Sayer et al., 2020). When choosing between different aerosol products one must take into account the wide variety of sensors and their characteristics such as spatial, temporal and spectral resolutions, single or multi-view retrieval methods, intensity or polarimetric design and different retrieval algorithms (Wei et al., 2020; Fan and Qu, 2019; Sogacheva et al., 2020; Li et al., 2020). In addition to sensor characteristics, other factors such as cloud coverage, surface type, aerosol models and retrieval algorithms contribute to overall retrieval uncertainties (Wei et al., 2020; Li et al., 2015; Virtanen et al., 2018). Most sensors can retrieve a wide variety of aerosol properties however they rely on inversions techniques and complex radiative transfer computations (Schutgens et al., 2020).

Smoke aerosols are primarily composed of two distinct carbonaceous species: BC, highly absorbent in all visible wavelengths and OC highly scattering of solar radiation (Ramanathan and Carmichael, 2008; Dutkiewicz et al., 2009). Recent studies suggest black carbon (BC) is the second largest contributor to global warming after CO₂, however their impact on global radiative budget is still a subject of debate posing significant uncertainties (Bond et al., 2013; Andreae and Ramanathan, 2013; Stocker et al., 2014; Boucher et al., 2016). BC (or soot) is generated from incomplete combustion processes with 59% accounting from biomass burning while the rest is attributed to fossil fuel combustion (Bond et al., 2013). Particle morphology of BC is significantly affected by multi-phase processes shortly after being emitted (Kokhanovsky, 2019; Noyes et al., 2020). Aging/coating processes further change optical and microphysical properties of BC with direct impacts on their radiative effects (Riemer et al., 2010; He et al., 2015; Fierce et al., 2015; Peng et al., 2016). In practice, many remote sensing studies use rough estimations of particle shapes for fresh and aged BC further inducing uncertainties (Kokhanovsky, 2019). Other considerations such as fuel type and emission sources need to be address as smoke plumes largely differ in composition and thus may exhibit different absorption/scattering efficiencies. This study will focus mainly on oil fire smoke plumes which are far less debated in scientific studies as opposed to biomass burning smoke.

The most abundant source of atmospheric data on oil smoke plumes was gathered from the Kuwait oil fires in 1991. An estimated 700 oil wells were set on fire while smoke plumes engulfed large areas of the Gulf region (Cahalan, 1992). The amount of burned oil was estimated between 1.2 and 7.5 million barrels per day (Sadiq and McCain, 1993). Satellite images of visible smoke where first acquired on the 9th of February spanning until November when the last fires were extinguished (Draxler et al., 1994; Limaye et al., 1992). Several international research teams conducted extensive field campaigns concentrating their efforts on atmospheric, environmental and health related issues focusing on the potential impacts on global climate (Sadiq and McCain, 1993; Husain, Tahir, 1995; World Meteorological Organization, 1993). Studies on health effects related to the Kuwait oil fires suggest that smoke exposure lead to acute respiratory illnesses with some suspecting long-term effects (Etzel and Ashley, 1994; Brain et al., 1998; Smith, 2002; Lange et al., 2002; Kelsall, 2004; Heller, 2011; Barth et al., 2016). Valuable atmospheric data was also collected from smaller events such as oil depot fires, most notably the Buncefield incident on 11 December 2005. A number of explosions led to a large fire engulfing 20 storage tanks until the 15th of December. The fire burned 58000 tons of fuel while injecting a large smoke plume above the boundary layer at 3000 m (Vautard et al., 2007; Health and Safety Executive and Buncefield Major Incident Investigation Board (Great Britain), 2008). An initial report on air quality concluded that the smoke plume remained aloft over cold and stable atmospheric layers, thus reducing the

100 potential impacts at ground level (Targa et al., 2006). Health studies related to the event concluded no long-term impacts on people exposed to the smoke, however acute respiratory symptoms were reported (Hoek et al., 2007; Morgan et al., 2008).

105 Oil fires and biomass burnings (BB) smoke plumes significantly differ by OC/BC ratios. Studies show values ranging from 3 to 20 for BB (Andreae and Merlet, 2001; Ichoku et al., 2012; Konovalov et al., 2018; Andreae, 2019; Akagi et al., 2011) largely dependent on fuel types. This ratio also relates to higher single scattering albedo (SSA) values of 0.7-0.96 for light grey visible smoke plumes (Radke et al., 1991; Dubovik et al., 1998; Eck et al., 1998; Leahy et al., 2007; Pokhrel et al., 2016). However OC/BC ratios are much lower for oil fires: 0.83 – 1.05 (Laursen et al., 1992; Daum et al., 1993; Ferek et al., 1992) also depending on fuel types and have low SSA values: 0.3 – 0.65 (Johnson et al., 1991; Hobbs and Radke, 1992) (Mather et al., 2007; Mikhailov et al., 2006; Gullette et al., 2017) for dark black visible smoke plumes. Studies also report large BC content in smoke plumes with PM (particulate matter) ranging from 46 - 50% for Kuwait pool fires (Hobbs and Radke, 110 1992; Laursen et al., 1992; Stevens et al., 1993) to 50 – 75% for the Bouncefield plume (Mather et al., 2007; Targa et al., 2006) and 75 – 82% for plumes generated by burning oil on the ocean (Gullette et al., 2016, 2017; Ross et al., 1996). These findings suggest that oil smoke plumes heavily absorb light in visible wavelengths and thus require adequate adjustments to any models used for retrieving optical and microphysical properties via remote sensing techniques.

1.1 Objectives

115 One objective of this study is to highlight the importance of satellite remote sensing techniques in identifying these types of events. As opposed to ground-based data, satellite data offers access to remote areas all over the globe which would otherwise be very difficult to achieve. As seen in Table 1, oil installations may be situated in desert areas, at sea or in secluded locations far away from air quality monitoring stations or AERONET (AErosol RObotic NETwork) sites (Holben et al., 1998). In addition to this advantage, a synergistic approach using different types of satellite instruments can offer three-dimensional 120 space coverage. While in situ, ground stations and modelling tools are viable options for smoke plume research, these methods have limitations in areas prone to armed conflicts or posing high health risks. Out of the aforementioned events, only event 10 was analysed by different techniques, as seen in local AERONET data (section 3.4). It goes without saying that retrieving optical and microphysical properties of petrochemical burnings may be challenging in most cases even with this approach. This study will focus on the use of MODIS and CALIPSO aerosol products regarding these types of aerosol while also 125 highlighting their limitations. By using data from both MODIS instruments on-board Terra and Aqua satellites we addressed the temporal evolution of the smoke plume while assessing lidar specific properties and plume elevation using CALIPSO data. The low number of studies on petrochemical smoke plumes, especially in the last decade, further encourages us to address these issues. While biomass burning and industrial haze are abundantly discussed in scientific literature, the same cannot be said for petrochemical smoke plumes resulting from major technological accidents. To our knowledge, we have not identified 130 any similar studies focused specifically on retrieving aerosol properties from major petrochemical accidents by using synergistic satellite techniques.

1.2 Event synopsis

This section summarizes a collection of events ranging from 2008 to 2019 that were successfully identified by satellite remote sensing techniques. Table 1 also provides the coordinates and the number of MODIS observation for each of the events 135 covered in this study.

Events similar in nature to the Kuwait oil fires took place in Northern Iraq as oil fields at Qayyara and Najma were intentionally set ablaze by Islamic State of Iraq and Syria (ISIS) militants in an attempt to deter coalition air strikes. The first fires were detected East of Baiji in early January 2016. Other oil wells burned intermittently from May to June close to Mosul and Kirkuk. The bulk of smoke plumes were observed largely between June and November, however smoke plumes were 140 continuously detected from Qayyara oil fields for a total of 225 days ranging from 13th of June 2016 to the 27th of March 2017. As a result of these events an estimated 1.33 million barrels of oil were burned (Bulmer, 2018; Tichý and Eichler, 2018). Residents South of the Qayyara oil fields were exposed for a number of 103 days to smoke plumes. Short-term health effects were reported especially for patients with pre-existing respiratory conditions (Bulmer, 2018).

The Gulf of Sidra has seen extensive episodes of smoke plumes as oil terminals at As Sidr and Ra's Lanuf, Libya 145 have been repeatedly set on fire over the course of a decade. These events have been captured by MODIS sensors through the last decade all the way since 2008. All events were characterized by dark plumes suggesting high contents of BC. On 19th of August 2008 a tank fire erupted in Fiba tank farm at Ra's Lanuf after workers failed a maintenance operation (Piafom, 2018; The Telegraph, 2011). The fire lasted 9 days in which smoke plumes could be detected from the 19th to the 22nd. In March 2011 the terminal was struck by air artillery in the battle of Ra's Lanuf as the country was engaged in civil war (BBC, 2011; 150 The Christian Science Monitor, 2011; The Guardian, 2011). Smoke plumes were visible on the 12th and 14th. In December 2014 the tank farm at As Sidr oil terminal was struck by rockets as rebels fought to seize control of the city port. Seven storage tanks were engulfed in flames burning 1.8 million barrels of crude oil (Reuters, 2014; BBC, 2014; Al Jazeera, 2014). Smoke plumes covered large areas of the Gulf between the 26th and 30th and could be seen as far east as Timimi and Crete. In January 2016 both tank farms at As Sidr and Ra's Lanuf were struck by Islamic State militants. On 5th of January As Sidr suffered five 155 tank fires, while two tanks were hit at Ra's Lanuf amounting to 850,000 barrels of oil. A week later IS militants struck oil infrastructure connecting Ra's Lanuf terminal to other installations in the area (Tichý & Eichler, 2018; Tichý, 2019). A second attack at Ra's Lanuf tank farm was conducted on the 21st (Business Insider, 2016). Throughout the month, extremely dense smoke plumes could be seen in the region from the 5th all the way to the 23rd. The most recent incident at Ra's Lanuf took place in June 2018 when rival armed groups clashed. The fire which started on the 14th was contained at two storage tanks 160 before it was extinguished several days later (Reuters, 2018). Visible smoke plumes were detected on the 17th and 18th (Bellingcat, 2018).

165 2 Methods and techniques

2.1 MODIS aerosol data

The MODerate resolution Imaging Spectroradiometer (MODIS) is a passive remote sensing instrument on-board NASA's Earth Observing Satellites (EOS). The instrument has been collecting climate related data, including aerosol products, since 2000 from Terra and 2002 from Aqua satellite platforms. To achieve a vast catalogue of products MODIS uses its wide spectral range, 36 channels between 0.41 μm and 14.5 μm , fine spatial resolution (250 to 1000 m) broad swath width (2330 km) and daily temporal resolution.

Herein we will summarize the aerosol retrieval algorithms dark target (DT) over land and ocean (Kaufman et al., 1997; Tanré et al., 1997; Levy et al., 2007a, b, 2009, 2013; Remer et al., 2005, 2008, 2013), and Deep Blue (DB) over land (Hsu et al., 2004, 2006, 2013) with some emphasis on the atmospheric parameters used in the construction of lookup tables (LUT) and aerosol model selection as these properties/assumptions are crucial for proper AOD retrieval in oil smoke events.

The DT land algorithm is used over dark vegetated surfaces with low surface reflectance. DT makes use of the “VIS to 2.1” relationship to distinguish surface contributions to the top-of-atmosphere (TOA) reflectance, as aerosols have a low absorbing and scattering effect in shortwave infrared (2.12 μm) band compared to the visible blue (0.47 μm) and red (0.66 μm) bands. After applying several pixel screening and selection techniques the algorithm chooses specific aerosol models and types based on seasonal and geographical characteristics. From here it determines aerosol related atmospheric parameters as a function TOA, surface and gas contributions to the apparent reflectance. To achieve AOD inversion these parameters are matched to values within predetermined look up tables (LUT) as an attempt to describe the most likely aerosol conditions. The land algorithm uses five aerosol types composed of two or more models (fine or coarse), each with its specific aerosol optical properties. Primary products retrieved are AOD at 0.55 μm , fine model aerosol type (FMF) and spectral fitting error (ϵ).

The DT ocean algorithm works in much the same way as the land algorithm although it requires masking sediments and filtering out strong glint areas. It uses the spectral dependencies of six bands, 0.55, 0.65, 0.87, 1.24, 1.63 and 2.12 μm for retrieving surface reflectance while it finds the exact match between the observed and the predetermined LUT reflectance values for the 0.87 μm band. It then attempts the best fit for the remaining bands. The 0.87 μm band is a good indicator of aerosol loading as it is less impacted by water radiance. Preliminary data such as AOD 0.55 μm , reflectance weighting parameter (η) at 0.55 μm , and aerosol effective radius (R_{eff}) are determined before the LUT inversion. DT ocean retrieves the same products as DT land, however it assumes aerosol properties based on a combination of two models, one fine model (four possible modes) and one coarse model (five possible modes). These models are combined by the weighting factor (η) such that the solution yields the lowest fitting error.

Aerosol properties within the LUT such as size distribution parameters, refractive indexes and SSA are crucial for proper aerosol typing and subsequent AOD retrieval. LUT information and model selection is critical for deriving other optical properties, such as Ångström Exponent (AE) which can also be used to describe size distribution.

The DB algorithm was developed to retrieve AOD over arid, semi-arid and urban areas where surface reflectance values are higher than those over dark target regions. The principle behind the algorithm suggest that surface reflectance in these areas show higher values in red and near infrared bands and lower values in the blue band. The algorithm uses reflectance values from 9 bands through each step of the retrieval. After screening and pixel selection surface reflectance values are determined based on three bands (0.412, 0.490 and 0.67 μm) using either a database or a dynamic approach. The approach is selected based on the normalized difference vegetation index (NDVI) and may be a function of region, season, scattering angle and land type. DB matches observed to LUT radiance values using a maximum likelihood method to determine the mixing ratio for a dust and a smoke model. The method retrieves two types of aerosol products: AOD and SSA from the dust model; AOD and AE from the smoke model.

2.2 CALIPSO aerosol data

The Cloud Aerosol Lidar with Orthogonal Polarization (CALIOP) on-board the CALIPSO satellite has been observing vertically distributed aerosol and cloud properties since 2006. CALIOP is an elastic backscatter lidar operating at two wavelengths (532 and 1064 nm) equipped with a polarization channel at 532 nm (Hunt et al., 2009; Winker et al., 2009).

210 Calibration is achieved through a molecular normalization technique for night-time measurements at 532 nm which is subsequently the basis for daytime calibrations at both channels (Powell et al., 2009; Kar et al., 2018). The latest CALIOP Version 4 data is significantly improved thanks to the refined calibration algorithms (Getzewich et al., 2018; Kar et al., 2018; Vaughan et al., 2019).

CALIOP data requires several processing sequences, handled by different algorithms, to achieve the desired aerosol and cloud properties (Winker et al., 2009). The first algorithm (selective iterative boundary locator - SIBYL) starts by analysing calibrated level 1 data averaged horizontally (at resolutions from 0.33 km to 80 km) through the use of an adaptive threshold scheme establishing layer boundary limits (Vaughan et al., 2009). The next steps require the use of scene classification algorithms (SCA). Firstly, the cloud-aerosol discrimination (CAD) algorithm uses multidimensional probability density functions (PDFs) to distinguish clouds from aerosol layers (Liu et al., 2005, 2009). The primary inputs from the CAD algorithm 220 is later used for subtyping aerosol species throughout the troposphere and stratosphere (Omar et al., 2009; Kim et al., 2018). Finally, SCA uses the attenuated backscatter and volume depolarization ratios (both layer-integrated) to distinguish between water and ice clouds (Hu et al., 2009; Avery et al., 2020). To extract aerosol properties (particulate backscatter and extinction coefficients, optical depth) the classified layer data is fed through several hybrid extinction retrieval algorithms (HERA) (Young and Vaughan, 2009; Young et al., 2013, 2018).

225 Lidar ratios are essential for calculating extinction coefficients, and throughout these sequences of algorithms lidar ratios are selected in one of two ways. For unconstrained retrievals, lidar ratios are selected based on the aerosol subtype classification which is a function of surface type, location, particulate depolarization ratio, integrated attenuated backscatter (Omar et al., 2009; Kim et al., 2018). For each aerosol subtype a lidar ratio is assigned based on AERONET data, direct measurements and theoretical scattering calculations (Omar et al., 2009; Tackett et al., 2018). The second approach, known as 230 constrained retrievals, is based on measured layer two-way transmittance (Young and Vaughan, 2009; Young et al., 2018). Selection between these two approaches is done based on scene complexity and feature classification (Young and Vaughan, 2009; Young et al., 2018). In most cases aerosol lidar ratios are determined using unconstrained retrievals (e.g., layers in contact with the surface) however constrained solutions are possible in certain situations (Young and Vaughan, 2009; Young et al., 2018).

235 2.3 Synergic approach

Figure 1 summarizes the steps of the analysis in detail. Events reported in scientific literature as well as events that drew significant media attention within a period of 12 years (2008-2019) were selected, a period for which both MODIS and

CALIPSO were operational. MODIS (aboard Aqua and Terra satellites) RGB composite images are used to visually identify the plume. Plumes larger than 500 km² were only studied to ensure sufficient pixel count. Subsequently, cloudy scenes, with 240 over 50% cloud coverage, were discarded. Next, aerosol retrievals were grouped into successful and unsuccessful based on the AOD values. Successful retrieval is considered when the AOD values of the pixels that are flagged as smoke yield some degree of variation (for at least 50% of pixels, the AOD differences should vary at least by 0.01), whereas unsuccessful retrieval is considered when either AOD values are below 0.1 or are constant throughout the plume (over 90% of plume pixels with a 245 fixed AOD value of 0.09 as seen in figure 3). We used successful and unsuccessful retrievals to highlight the capabilities and limitation of MODIS. The MODIS 6.1 collection was used in this study (MODIS Atmosphere Science Team, 2017a, b) and the algorithm for the AOD was selected based on surface type (DT over ocean and land) and locations (DB over desert and arid areas) for both successful and unsuccessful retrievals. We took advantage of the higher resolution 3 x 3 km² level 2 AOD products for statistical relevance in successful retrievals over ocean. For unsuccessful retrievals we used the 10 x 10 km² level 250 AOD products (DB over desert and arid areas) and the 3 x 3 km² level 2 AOD products over land.

Aerosol properties were only analysed for successful retrievals. The following aerosol properties were used in our 250 analysis: AOD at 0.55 μ m, AE and R_{eff} . For successful retrievals, we developed an averaging technique to remove background aerosol from the identified smoke plume. Since both RGB and AOD images show a clear transition from background aerosol to oil smoke areas, as seen in Figs. 2a and 2b, we identify the plume edge based on the AOD pixel gradient. Conversely, the plume edge pixels have AOD values different from the neighbouring background pixels by a value of at least 0.03, a value 255 that has been decided with a simultaneous inspection of RGB and AOD maps. The averaged AOD within the plume edge is called “total plume AOD” and comprises oil smoke and background aerosols. The “plume specific AOD” is a result of subtracting the local background AOD from the “total plume AOD”. The local background AOD is defined as the average AOD from a smoke-free area, this area needs to contain between 3 to 10 times the pixels of the smoke plume. This decision stems to the local geography and meteorological conditions (see Fig. 7a, event 13, on 29.12.2014, for high pixel count and Fig. 260 7.a, event 16, on 21.10.2016, for low pixel count). In section 3.2, detailed discussions of successful MODIS retrievals are presented.

CALIPSO is used complementary as it provides important insight into the plume monitoring, being an active sensor. Moreover, CALIPSO flies as part of the A-Train constellation and follows MODIS/Aqua observations by 2 minutes, thus 265 similar atmospheric volume is sampled. The particulate backscatter coefficient (532 nm), is used to define the extent of the plume cross section. Smoke plumes have higher backscatter values than the background aerosol and are easily identifiable in the backscatter profiles. The minimum plume horizontal extent is set to 5 km as this is the standard level 2 data output (Winker, David, 2018). For daytime, Aqua/MODIS RGB images prior to the CALIPSO overpass are used for visual confirmation. Whereas, for night-time, one MODIS image before and one after the CALIPSO overpass are used to assess the plume spatial 270 continuity.

To retrieve detailed information on the aerosol optical properties, we use CALIPSO Level 2 data - 5 km Aerosol Profile (532 and 1064 nm), standard version 4.20 (Winker, David, 2018). The methodology to quality-assure the CALIPSO

profiles is mostly similar to the rubric used by Tackett et al. (2018). For cloud-free scenes, only aerosol profiles with a cloud-aerosol-discrimination (CAD) score of $-100 < \text{CAD score} < -20$ are selected. Furthermore, aerosol profiles directly below any type of clouds are discarded as these may be affected. Smoke plumes above 4 km (mean surface level) in contact with ice 275 clouds were discarded to prevent misclassifications as cirrus fringes. For the extinction coefficient filtering procedure, QC flag values not equal to 0, 1, 16, or 18 are discarded as low-confidence retrievals. Extinction coefficients where the uncertainty is equal to 99.9 km^{-1} are rejected as well as the values in bins directly below this range.

In this analysis, the particle backscatter coefficient is used to identify the geometrical properties of the smoke plume. The plume is defined as the area where the values are at least 2 times higher than the background, which is considered as an 280 area of identical thickness located either above or below the plume. The plume AOD (532 nm and 1064 nm) is calculated by integrating the particle extinction coefficient in the plume region, and the plume mean AOD is the average of the individual (i.e., 5-km) plume AODs that comprise the plume. Additionally, the plume extinction-to-backscatter (i.e., lidar ratio), Ångström (532/1064 nm) exponent, and particle depolarization ratio are assessed to investigate the type-dependent characteristics of the plume and whether oil smoke presents distinctive intensive properties.

285 AERONET observations, when available, are also investigated and compared with the satellite measurements. Lastly, in case of events that have already been investigated by means of ground-based or airborne observations, we compared the published results with our methodology reflecting on the implications of oil smoke plumes that have on current satellite retrieval capabilities.

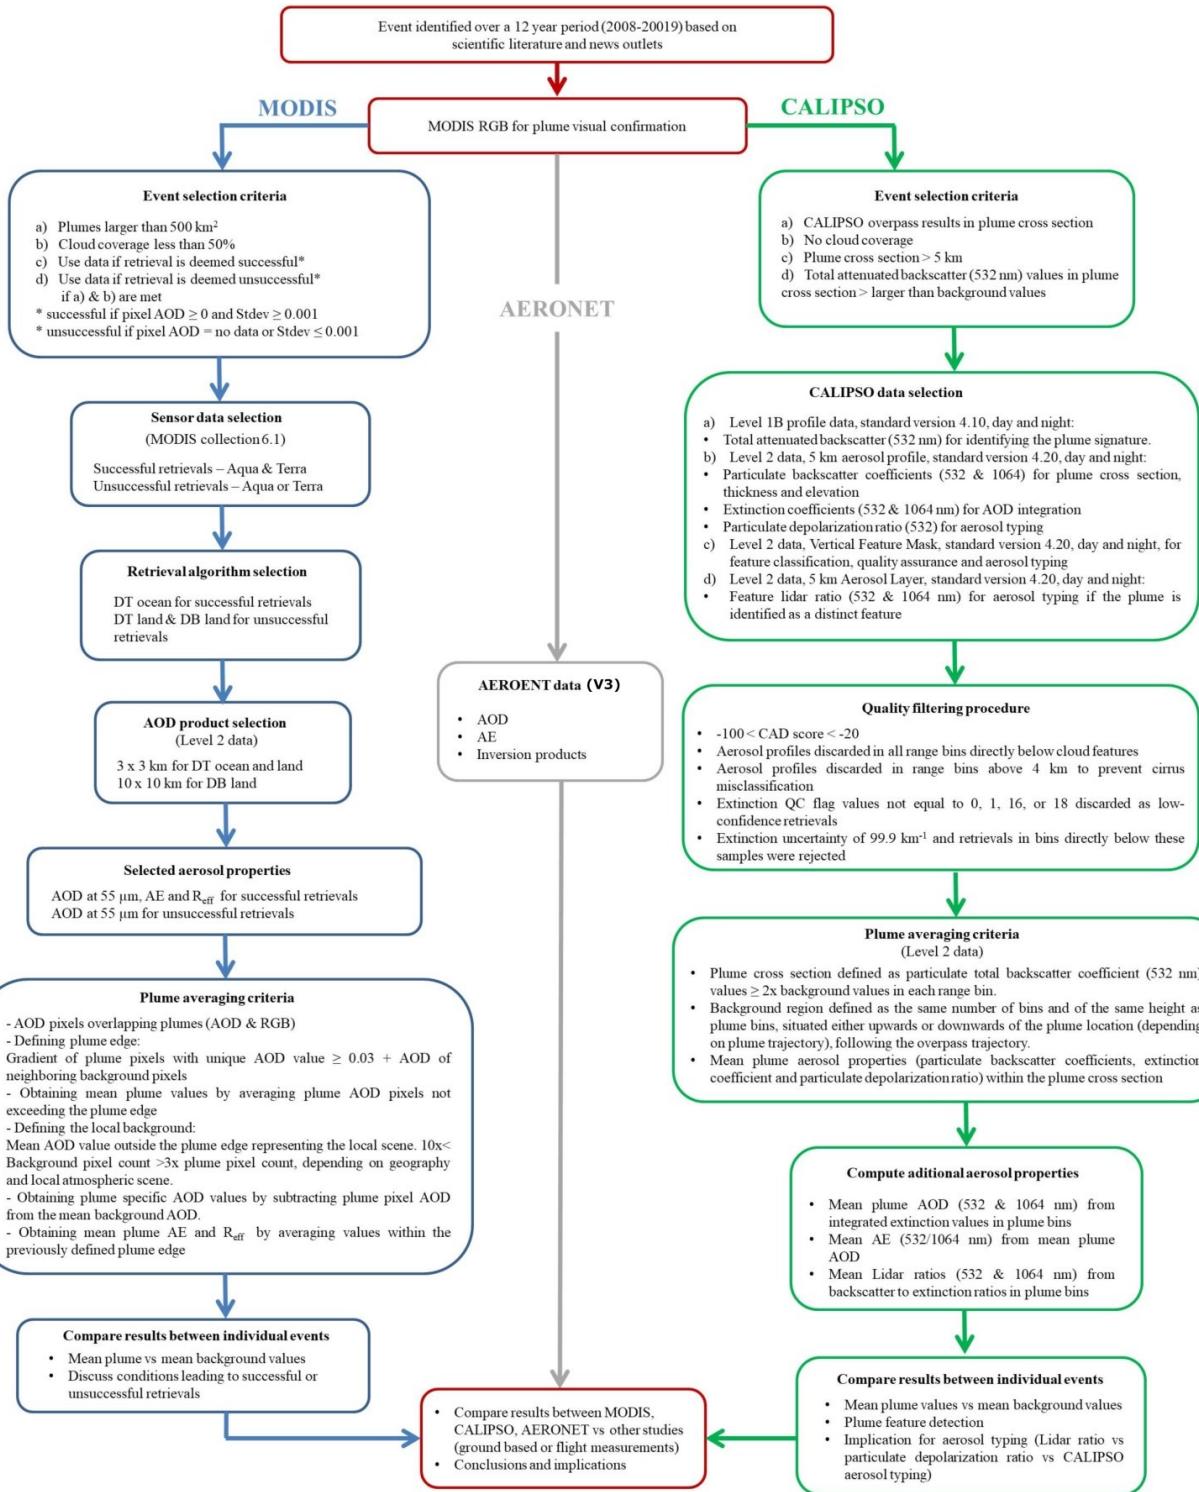

Fig. 1

3 Results and discussions

3.1 Case study illustration

Based on the information given in table 1 we filtered a total of 375 days in which oil smoke plumes were observed by the MODIS sensors. After applying the selection criteria for the MODIS sensor we obtained a total of 10 days with 295 successful retrievals. The majority of oil plumes resulted in unsuccessful retrievals, 70.7% while 26.7% of plumes were screened out due to high percentage of cloud coverage. When applying the selection criteria for CALIPSO we obtained a number of 6 plume sections suitable for analysis. Table 2 shows the dates for both MODIS and CALIPSO retrievals suitable for analysis.

300

21	04.01.2018 (only Aqua)	-

We selected a successful retrieval to better describe the method used for our analysis. Figure 2 shows event 14, the case at Ra's Lanuf and As Sidr tanks farms which caught fire on the 5th of January 2016 and burned throughout the 6th and 7th. The retrieval in the images was taken on the 6th by MODIS Aqua at 12:05 UTC. Figure 2a represents a true colour composite 305 image showing the smoke plumes emerging from both sites and travelling E-NE over the Gulf of Sidra. Judging by this image alone we can only distinguish parts of the smoke plume which appear to be less dispersed and thus present a smaller mixing ratio with the local background aerosols. In this study, we focused our attention on the plume areas where heavy concentrations of aerosol are present while discarding retrievals done at the edges of the plume where background aerosol may have a large influence on the retrieved values. Thus figure 2b was constructed based on the AOD (0.55 μ m) retrieval and a plume edge 310 selection technique. To determine the plume edge we constructed isolines of AOD values from the retrieval pixels. The 3 \times 3 km product is better suited for determining the AOD gradients and thus was selected over the standard 10 \times 10 km product. Figure 2b shows higher values of AOD in the selected plume area as opposed to the local background levels. At the time of

the retrieval, we can observe two distinct plumes of smoke, a thin plume originating from the As Sidr and the main plume (within the black contour, Fig. 2b) originating from Ra's Lanuf. Since the As Sidr plume did not meet the selection criteria the 315 analysis is made for the main Ra's Lanuf plume. To further discriminate between plume and background AOD values we averaged all non-plume pixel values, over water, within the gulf region without considering the pixels of the plume. Then, the averaged AOD values were subtracted from each pixel of the plume AOD values to determine the overall plume contribution. Consequently, Figure 2c illustrates the plume specific AOD gradient. Figures 2d and 2e show the AE ($0.55/0.86 \mu\text{m}$) and the 320 R_{eff} (μm) which were selected for aerosol typing. For AE and R_{eff} we used the same edge selection technique as described above without the background subtraction. The AE is shown to have very low values indicating a dominant coarse mode which is further evidenced by the large R_{eff} chosen from the LUT. It is also evident from both figures that both plumes extend further from the edge selection. In this case the mean plume specific AOD was 0.13, while the background values averaged 0.08. Figure 325 2c shows AOD values as high as 0.24 over the average AOD background level for the plume originating at Ra's Lanuf. The AOD gradient, in figure 2c, shows the largest values at the centre of the plume where aerosol mixing is expected to be lower. Mean plume AE was - 0.18 as opposed to the background value of 0.45 and plume R_{eff} showed $1.45 \mu\text{m}$ versus $0.51 \mu\text{m}$ for background values.

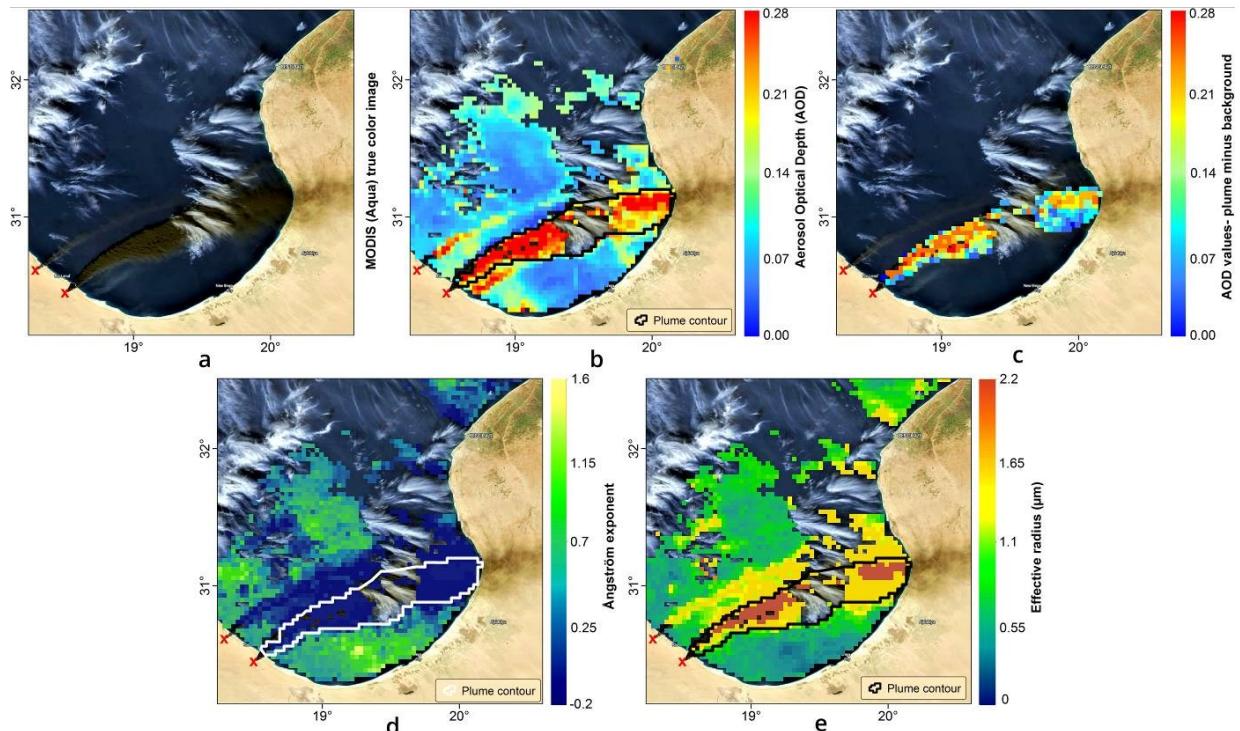

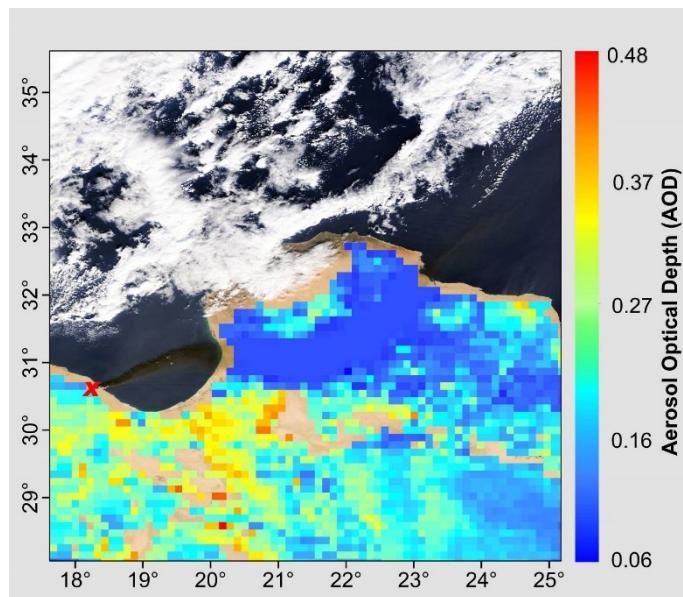

Figure 2. Visual representation of the analysis method for MODIS data: (a) - plume captured in true color; (b) - AOD retrieval over the plume area and background (Gulf of Sidra); (c) - AOD retrieval as a result of plume minus background values; (d) – Angstrom exponent for

330 plume and background area; (e) – Effective radius for plume and background area. The red coloured “x” indicates the event origin (Satellite imagery from the NASA Worldview application, <https://worldview.earthdata.nasa.gov>).

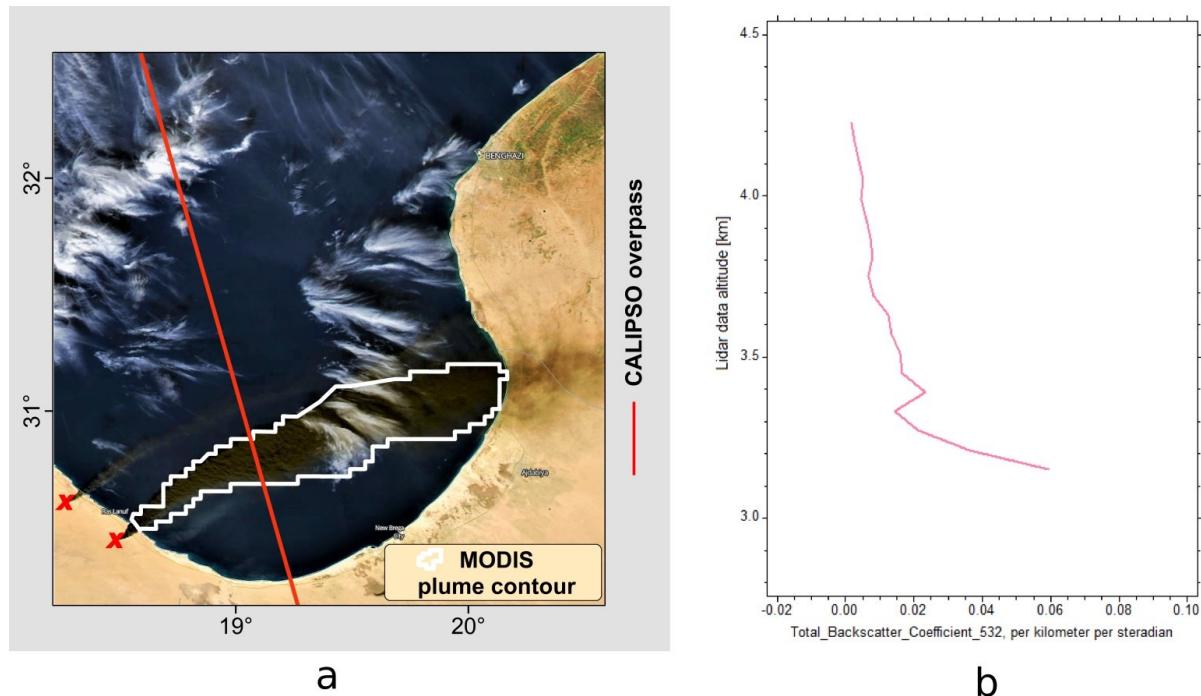

Figure 3 shows an example of an unsuccessful retrieval of the land algorithm for the event 13 plume on 30.12.2014. We can distinguish the plume from the RGB image over the Gulf of Sidra while also observing AOD values over land where the smoke plume drifted E-NE towards the island of Crete. However, there seems to be no distinguishable AOD gradient, over 335 land, in the plume section. A further inspection suggested that all pixels showed values of 0.095 which suggest that the lower radiance values did not match well with pre-existing LUT values. Consequently, the region is classified as “clean atmosphere” and thus, a unique AOD value is assigned to all the pixels. Conversely, the ocean algorithm retrieved AOD that varied between 0.1 and 0.37. Since these heavy smoke plumes are the result of extreme scenarios they are rarely observed and may not end up being a subject of research. Thus, we believe there are no cases within the LUT values describing extremely low atmospheric 340 transmission and radiance values, highly absorbent aerosol, low SSA and low reflectance values over a large spectral range including MODIS bands 1 through 7.

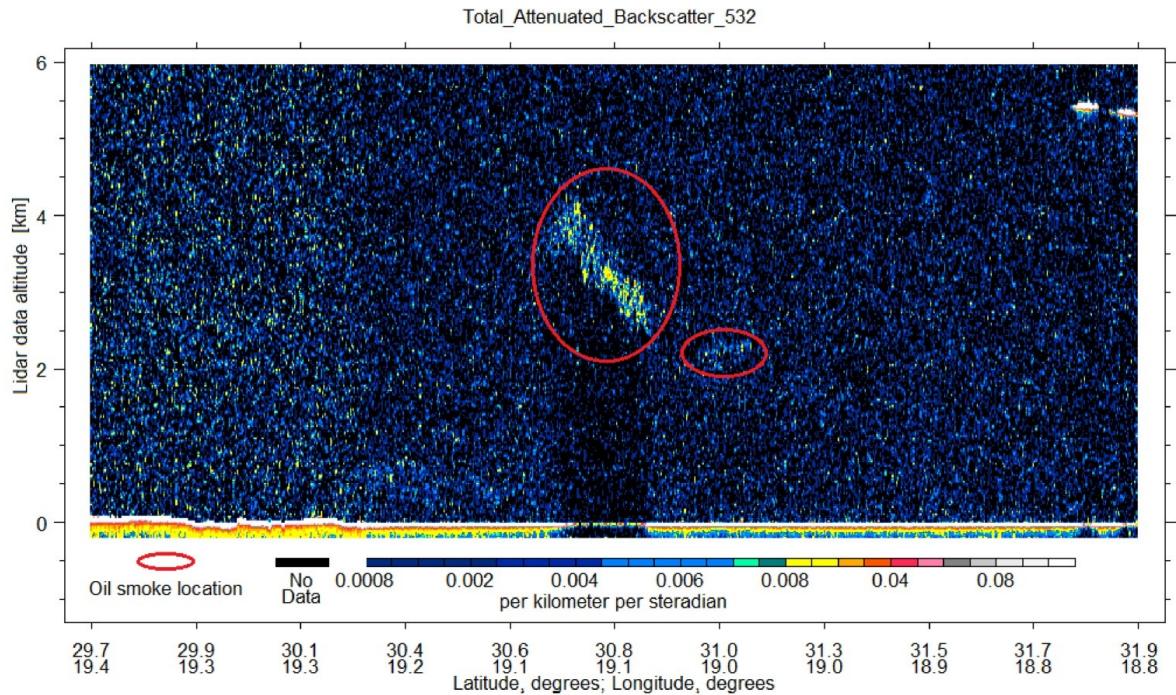

345 Figure 3. Retrieval of plume (unsuccessful) and background AOD values: event 13, 30.12.2014. The red coloured “x” indicates the event origin (Satellite imagery from the NASA Worldview application, <https://worldview.earthdata.nasa.gov>).

Event 14 at Ra’s Lanuf and As Sidr, 6th of January 2016, was also captured by CALIPSO lidar measurements as CALIPSO overpass matched a cross section of the plume area. Figure 4a shows this overlap in near-real time as CALIPSO succeeds Aqua within a 2 minute time frame. Within the 15 km plume cross section we selected a particulate backscatter coefficient profile for reference, figure 4b, and based on this parameter we determined plume elevation and thickness. The 350 average plume thickness was approximately 920 m. The layer base was situated between 2600 and 3100 m above the Gulf while the top was measured between 3300 and 4200 m. The entire plume cross section is presented in figure 5a. We observe

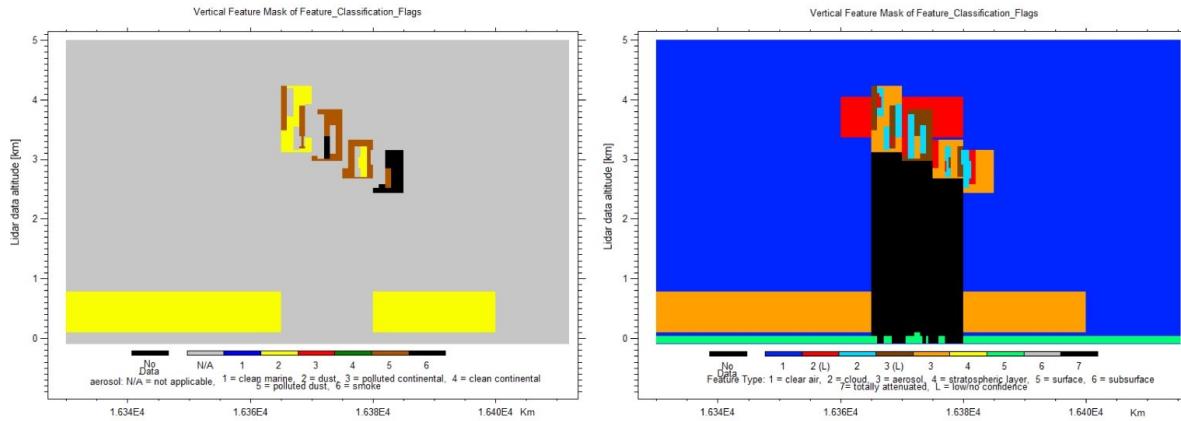

the main plume from Ra's Lanuf elevated between 2600 m and 4200 m. Figure 5a also shows the secondary plume from As Sidr, 0.2° north of the main plume situated around 2000 m. Based on CALIPSO measurements of the main plume, average particulate backscatter (532 nm) values measured $0.015 \text{ km}^{-1}\text{sr}^{-1}$ while values at 1064 nm measured $0.017 \text{ km}^{-1}\text{sr}^{-1}$. Average extinction coefficient values at 532 nm were measured at 1.65 km^{-1} while the 1064 nm channel yielded a value of 1.55 km^{-1} .
 355 This event is an example of an opaque aerosol layer, where the lidar did not penetrate the plume up to the sea surface over the Gulf of Sidra. This event recorded a lidar ratio of $109 \pm 47 \text{ sr}$ at 532 nm and $86 \pm \text{sr}$ at 1064 nm. These values are larger than the CALIPSO V4 aerosol subtype values for: elevated smoke 70 ± 16 (532 nm) and 30 ± 18 (1064 nm); polluted continental/smoke 70 ± 25 (532 nm) and 30 ± 18 (1064 nm) (Kim et al., 2018). The initial lidar ratios were reduced by 5%
 360 based on the scheme described by Young et al., 2018 for opaque aerosol layers. These events are described as occurring infrequently (1% of all unique aerosol layers, detected in 2012; Young et al., 2018) and may be subjected to further uncertainties. The initial value of the lidar ratio (S_p) is described by Young et al., 2018 in Eq. (1). This assumes a zero value
 365 of the two-way transmittance ($T_p^2 = 0$) and a multiple scattering factor value of 1 ($\eta = 1$). Young et al., 2018 also suggest that $\eta=1$ assumption may not be valid for opaque aerosol layers and may introduce bias errors. These errors can be propagated through the extinction and AOD retrievals and result in more conservative estimates. The particulate depolarization ratio for the Ra's Lanuf plume was 0.11 ± 0.43 that corresponds to moderately depolarizing smoke (Kim et al., 2018). Figure 5c shows the CALIPSO feature classification while figure 5b shows the aerosol typing results.

Figure 5 (a) Image of event 14 plume based on CALIPSO Total Attenuated Backscatter (532 nm) vs Lidar data altitude data; (b) Aerosol feature classification; (c) cloud feature classification

375 Judging from these images and from the average CAD score of – 48, the smoke plume represented a mixed feature of cloud and aerosols. This is to be expected as water vapour and particulate matter are primary components in emissions of petrochemical burnings (Johnson et al., 1991; Ferek et al., 1992; Daum et al., 1993). Cloud formations on top of oil smoke, plumes, such as pyrocumulonimbus, have been observed in other instances (Johnson et al., 1991), as seen in figure 6, a phenomenon which hinders AOD retrievals in both passive and active sensors.

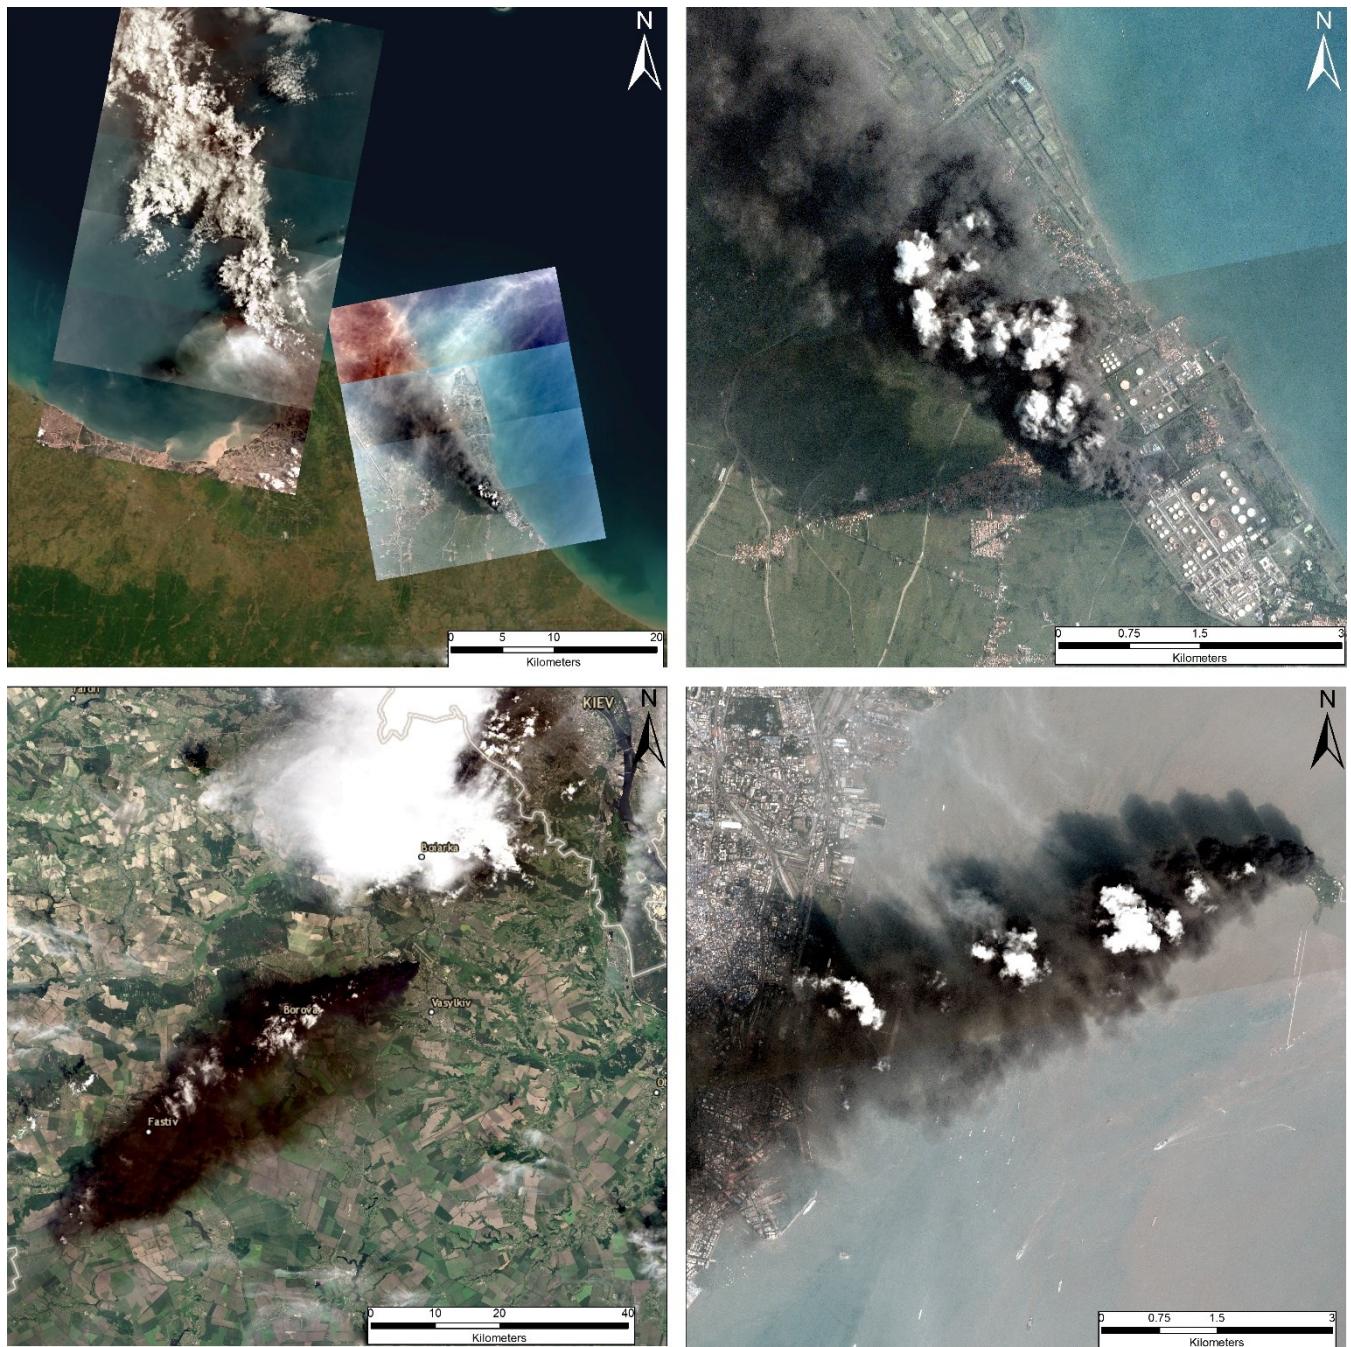

Figure 6. Cloud formation on top of oil smoke plumes. Upper images depicting the fire at Balogan, Indonesia, 29 March, 2021; Lower left image depicting the fire at Vasylkiv, Ukraine on the 9th of June, 2015; Lower right image depicting the fire at Butcher Island, India on the 7th of October, 2017 (Satellite imagery from OpenStreetMap © OpenStreetMap contributors, 2021. Distributed under the Open Data Commons Open Database License (ODbL) v1.0 and Planet Team, <https://www.planet.com/>).

The current version of the Vertical Feature Mask gives a mixed result to aerosol typing comprised of dust, polluted dust and smoke aerosols for this oil smoke plume. The average values for plume AOD ranged between 1.52 ± 0.8 (532 nm) to 1.43 ± 0.47 (1064 nm). We also computed the plume AE (532/1064) which resulted in 0.09, indicating the presence of coarse particles.

390

3.2 MODIS successful retrievals

The results of the MODIS successful retrievals are presented in tables 3 and 4 in the form of mean and standard deviation values. The MODIS Aqua retrieval presented in section 3.1 was found to be in good agreement with the Terra retrieval. Event 14 showed a larger difference in plume specific AOD values between Terra and Aqua retrievals. However this was to be expected since the fire spread to several oil tanks between the two retrievals. Based on these results we identified no large discrepancies between the two sensors. For plume and plume specific AOD the majority of values fall within the expected uncertainty interval of the retrieval algorithm, $\pm (0.05 + 0.20 \times \text{AOD})$ when comparing between the two sensors (Gupta et al., 2018). Small changes in AOD values can also be attributed to plume dispersion. For the majority of cases the plume specific AOD is the main contributor to the total AOD in the atmospheric column, however all AOD values are generally low. In cases where background AOD is already low, a thin layer of black smoke can reduce atmospheric transmission and radiance values. This effect would result in lower TOA reflectance and plume specific AOD values.

Except for event 4, all the plumes exhibit AE values lower than 1. The larger AE values from event 4 may be attributed to the different fuel type since the event surrounding SOCAR's Platform no.10 also involved 4 gas wells (Business-humanrights, n.d.). While AE plume values are generally low, these extremely low values may not be primarily a direct result of particle size distribution. MODIS uses spectral reflectance relations to determine AOD and subsequently AE levels. While other types of aerosols have a varying spectral reflectance signature, heavy concentrated black carbon exhibit a flat and linear signature that result in low spectral reflectance values (Johnson et al., 1991; King, 1992; Pilewskie and Valero, 1992; Soulen et al., 2000). To further distinguish between these events and the atmospheric background we selected the effective radius based on MODIS LUT. For the ocean algorithm R_{eff} values range from 0.10 to 2.50 μm with lower values being a good indicator of fine dominant aerosols, whereas higher values of coarse dominant aerosol type. The results show plume values up to 3 times higher than background values. Both AE and R_{eff} values show the presence of large particles in the plume areas.

Following event 14 in figure 2, figure 7 shows a visual representation of MODIS successful retrievals from events 13 and 16. We choose to describe in detail the events from Libya as they are also analysed based on CALIPSO retrievals. 420 Moreover the plumes resulting from these events share the same locations (As Sidr and Ra's Lanuf). Figure 7a shows plume specific AOD values ranging from 0 to 0.28. Plumes from As Sidr, event 13, are visible in the first three rows of figure 7. This event was captured in multiple days while the fire engulfed several oil tanks and subsequently injected higher amounts of aerosols in the region. Depending on the local background levels, average plume specific AOD ranged from -0.03 to 0.15. Negative values can be explained by the presence of dust and marine aerosols in the atmospheric background. This is especially

425 evident for event 13 on 30th of December 2014 when high background levels were registered in the Gulf of Sidra while lower
levels were seen off the shores of At Tamimi, 600 km NE of As Sidr. The fourth row in figure 7 shows the plume from event
16, marking the second attack on the Ra's Lanuf tank farm in 2016. The plume section over the Gulf recorded AOD values
twice as high as the background level however the net contribution amounted, on average, to a value of 0.10. The AE values
below 0 seen in 7b suggest a coarse dominant scene. Figure 7b also shows low AE values identified further from the plumes
430 edge showing the spatial extent of these types of aerosols. The Gulf of Sidra is situated in one of the main pathways of long
range transported dust (Kallos et al., 2007) thus affecting AE local background values, as seen in table 3 and table 4. In figure
7c we identify high R_{eff} values consistently over 1 μm while, in some cases, values close to the fire and within the center of
the plume area reached the maximum 2.50 μm . These large values are consistent with the observed AE trend observed
indicating larger particles and coarse mode dominant aerosol type. Background values for these events fluctuated between
435 0.32 and 1.04 μm due to regional dust-like aerosols.

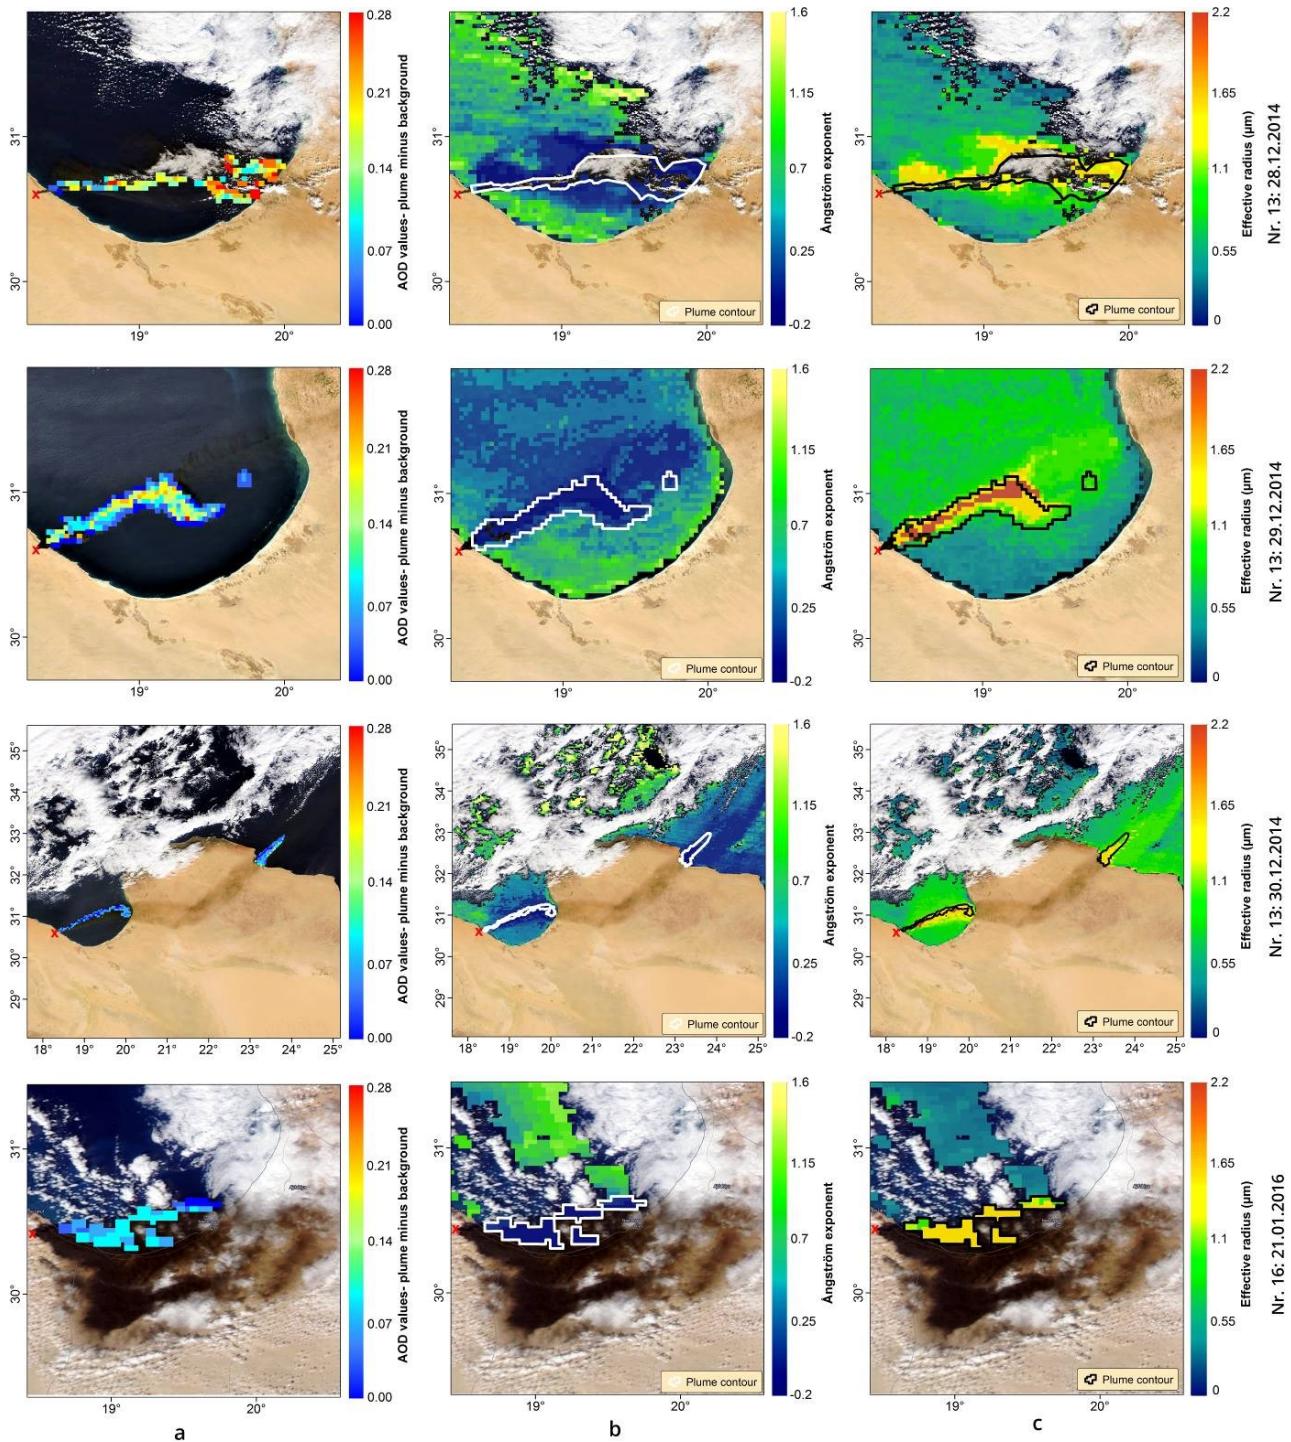

Figure 7. (a) Successful retrievals of aerosol properties for events 13 and 16. Plume specific AOD; (b) AE values for plume and the local background; (c) R_{eff} values for plume and the local background. The red coloured "x" indicates the event origin (Satellite imagery from the NASA Worldview application, <https://worldview.earthdata.nasa.gov>).

3.3 CALIPSO retrievals

Within the 12-year period we identified three events in the Gulf of Sidra, events 11, 13 and 14. Apart from event 14, previously described in section 3.1, all the remaining CALIPSO retrievals were unconstrained retrievals. Event 13, at As Sidra 445 on 29th of December 2014, was detected by a CALIPSO night-time overpasses which fell approximately 12 hours between the MODIS successful retrievals of 28th and 29th of December 2014. The plume at As Sidr can be observed in figure 8a. Off the coast of As Sidr a distinct feature above the sea surface reaching 650 m in altitude is observed. Figure 8b show a particulate backscatter profile where we can distinguish a plume thickness of approximately 240 m. This event was smaller in magnitude 450 with respect to event 14 where multiple storage tank fires contributed to the same plume mass. In this case, CALIPSO overflowed much closer to the tank farm also resulting in a narrower plume cross section. The SIBYL algorithm level 2 products were averaged over a larger 20 km area, as opposed to the 5 km averaging resolution, thus plume values are harder to distinguish from background aerosol levels. Backscatter and extinction values can be seen in table 5. The plume cross section measured approximately 3 km, as seen in figure 8c and d. Consequently, CALIPSO identified dusty marine aerosols within the Gulf region as evident from the plume lidar ratio of 37 ± 15 sr (both 532 and 1064 nm) within the atmospheric layer (Kim et al., 455 2018). The plume particulate depolarization ratio value, 0.12 ± 0.14 was similar to the values detected from event 14, however the plume and background values were indistinguishable, in part due to the larger averaging scheme. The local scene over the Gulf region was fairly clean judging by the low AOD values seen in table 7. One reason for low AOD retrievals was proposed by Jethva et al. (2014) (Jethva et al., 2014) and was shown in Deaconu et al. (2017) (Deaconu et al., 2017). In case of optically 460 thick aerosol layer, the sensitivity of the backscattered signal would be reduced or lost because of the strongly attenuated two-way transmission. As a result, the operational algorithm may position the base of the aerosol layer higher in altitude, thus underestimating the geometrical thickness of the aerosol layer and consequently the AOD. The selection of an inappropriate aerosol lidar ratio might also contribute to the underestimation of the AOD. AE values were also relatively low, 0.12; however these are again not indicative of plume optical properties as they are for the larger background layer. In any case, computing AE based on low AOD values may not be a good estimate for local aerosol particle size. Figure 8c shows a plume composition 465 similar to the event 14 plume. The vertical feature mask shows a mixt feature of clouds, aerosols and low confidence aerosol. Figure 8d shows the aerosol classification within the aerosol layer. Judging by these results the aerosol layer reaching up to 1.5 km above mean sea level was classified as a mixture of dust, polluted dust and smoke. The plume cross section was successfully identified as smoke aerosols however the background layer situated north of the plume was not typed as dusty marine, as seen from the lidar ratio of 37 ± 15 sr.

480

Event 11 was captured inland as the plume cross section was identified 170 km South of the Ra's Lanuf tank depot.

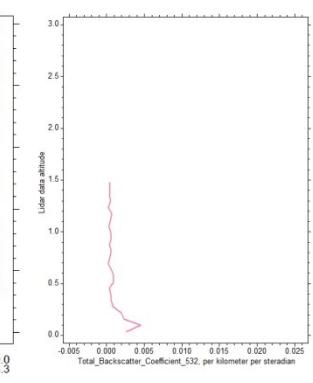

485

Figure 8f shows a particulate backscatter profile through the plume centre describing a fairly inhomogeneous mass of smoke particles. The main plume was concentrated between 500 and 900 meters, however lower concentration may have been mixed with local dust particles all the way up to 1500 meters. Figure 8e shows the extent of the plume as it travelled southwards inland. As was the case of the previous event, plume lidar ratios were determined by an unconstrained solution. Thus values of 55 ± 22 and 48 ± 24 sr from 532 and 1064 nm channels were determined within the plume feature as well as for the entire layer within figure 8e scene representing the local PBL. These values suggest a mixture of polluted dust within the local PBL (Kim et al., 2018). Plume particulate depolarization ratio values of 0.11 ± 0.18 are similar to the previous events while background values of 0.17 ± 0.35 are indicative of a polluted dust mixture (Omar et al., 2009). The average plume particulate backscatter (532 nm) measured $0.007 \text{ km}^{-1}\text{sr}^{-1}$ while the 1064 nm channel measured $0.008 \text{ km}^{-1}\text{sr}^{-1}$ which showed an increase of 6 to 9 times larger than the local background values. This large difference is also evident from the plume and background AOD. These plume values were directly influenced by the lidar ratio solution. A constrained solution may have resulted in larger values since smoke LR values are generally higher than polluted dust values (Kim et al., 2018). AE values remain low 490 0.05 and similar to the previous event at Ra's Lanuf suggesting a coarse dominant aerosol mixture, while background values were more indicative of polluted dust, averaging 0.71. Unlike event 13, this plume was averaged at 5 km resolution resulting in plume AOD values higher than background values. Similar to the previous events the feature classification algorithm shows a mixture of clouds and aerosols in the plume bins. This composition is evident in figure 8g and may affect the retrieval of smoke optical properties. Figure 8h shows the local aerosol layer up to approximately 2 km above local ground level. A significant portion of plume bins were discarded as cloud features even though the CAD score of -99 indicated high confidence 495 aerosols.

510 Event 1, at the Qayyara oil fields in Northern Iraq, was captured by CALIPSO in three distinct cases. In all three cases CALIPSO overpassed within less than 35 km South-west from the well fires. The plume particulate backscatter and extinction coefficients ranged from 2 to 5 times higher than local background values. The plumes were identified within the PBL and as a result, the lidar ratios between 44 ± 9 and 49 ± 15 suggested the presence of dust aerosols. Particulate depolarization ratio values were higher than the previous cases, ranging from 0.15 ± 0.24 to 0.32 ± 0.48 also suggesting dust dominance. AOD values observed in plume the bins remained generally low, < 0.1 . However these values were still up to 5 times higher than 515 background values. The AE values remain consistently low ranging between -0.03 and 0.39 indicating the presence of coarse dominant aerosol mixture. The local atmospheric scene on 21st of October 2016 was marked by a mixture of oil smoke and SO₂ plume as a result of the Islamic State setting fire to the Al-Mishraq Sulphur plant situated NNE of the burning oil fields. This mixed layer was also suggested by (Kahn et al., 2019) who used MISR Active Aerosol Plume-Height (AAP) to establish the SO₂ and oil smoke plume elevation on the same day (Khan and Zhaoying, 2020). Judging from the lidar ratios 49 ± 15 520 (532 nm) and 46 ± 19 (1064 nm) and the particulate depolarization ratio of 0.15 ± 0.24 the CALIPSO subtyping algorithm identified a mix of polluted dust aerosols.

525 Based on CALIPSO measurements, the smoke backscatter and extinction coefficient ranged from 2 to 9 times higher than background levels. In four out of six cases, particulate depolarization ratio revealed values between 0.11 and 0.15 resembling moderately depolarizing smoke while larger values in two cases were mostly due to the presence of dust particles in the local atmospheric scene. Apart from one case, all lidar ratios were obtained by unconstrained retrievals as the plume resided in the PBL. The opaque feature measured high lidar ratios of 109 ± 47 sr (532 nm) and 86 ± 10 sr (1064 nm) that 530 resembles smoke lidar ratio found in literature (Giannakaki et al., 2016; Haarig et al., 2018). We suspect these values are a strong indicator for the heavy light absorbing nature of the smoke plume. Average CAD scores ranged from -46 to -99 which would indicate a strong confidence for the presence of aerosols. The feature classification algorithm indicated the presence of small clouds in 3 out of 6 cases, suggesting mixed cloud-aerosol features. AE values were consistently low in all cases suggesting the presence of larger smoke particles in the plumes cross sections. AOD values measured between 0.02 and 1.52 and were directly influenced by fuel burning rates, local background aerosol loading and especially lidar ratio solutions. The event 14 plume was identified above the PBL up to 4200 m. This is a good indicator for the magnitude of the event as it involved several tank fires with higher burning rates simultaneously injecting larger concentrations of aerosol at higher 535 elevations in the troposphere. Based on this small number of events it is difficult to assign a separate aerosol type for these oil smoke plumes. However valuable information regarding size distributions, particulate depolarization ratio and to some extent lidar ratio can be retained from this study. It should be mentioned that these values reflect smoke plumes located very close to the fire sources and thus present low mixing ratios with other local aerosols.

3.4 AERONET case study

540 As discussed in the introduction section, oil smoke plumes have been rarely observed using ground based remote
 sensing instruments such as AERONET sun photometers. We used AERONET version 3 direct sun data to assess the presence
 of oil smoke plumes. Only one study was found in scientific literature (Mather et al., 2007) which measured aerosol properties
 of the Bouncefield plume at two distinct locations. Here we identified the smoke plume, at event 10, resulting from naphtha
 tank fires in Vasylkiv, Kyiv Oblast, Ukraine on 9th of June 2015. The smoke plume was also captured in RGB images as seen
 545 in figure 6, lower left image. Figure 9a shows the distinct signature of the oil smoke plume as AOD values increased
 significantly in all wavelengths. Figure 9c is a good indication of the increasing particle size with respect to the other days
 observed as well in MODIS and CALIPSO data. Figure 9d shows the daily evolution of AE with values between 0.45 and 0.9
 550 for the time frame in which the plume was observed. Figure 9b shows AOD values rising as the plume was travelling NE over
 Kiev. The AERONET station in Kiev is situated approximately 35 km NE of the Vasylkiv tank farm. The peak of the plume
 was detected at 9:45 UTC when the AOD was 0.68 at 500 nm. Unfortunately, no inversion products coinciding with direct sun
 measurements were available as the Kiev sky was partially cloudy at the time.

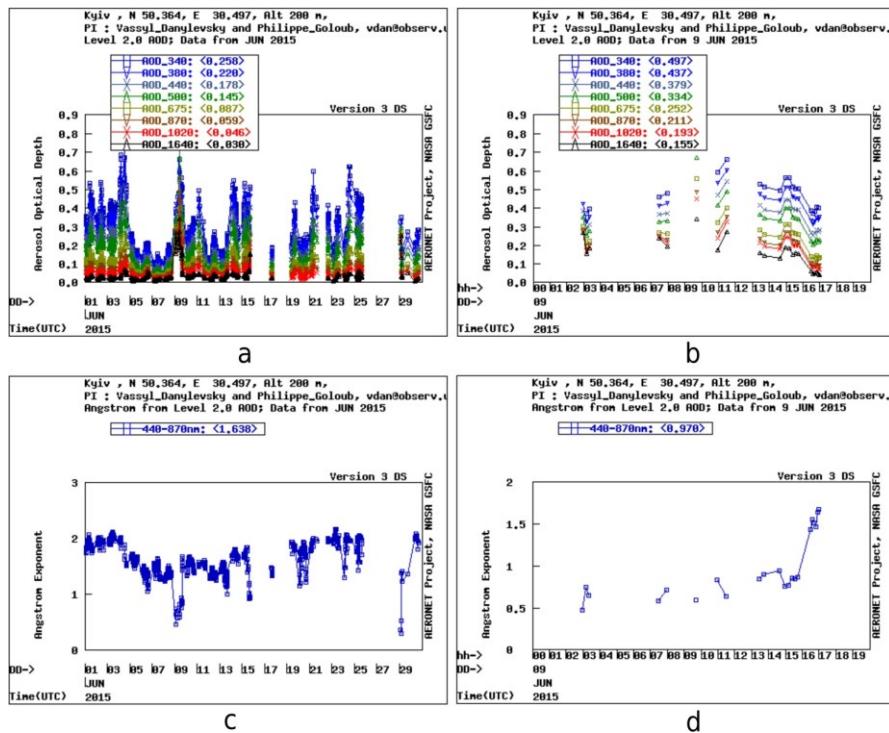

Figure 9. AOD and AE smoke plume values at Kiev on 9 June, 2015 and monthly values from June 2015

555

3.5 Data comparison between methods and other similar studies

The results presented in this study show a wide range of values that are attributed to a multitude of local factors such as: background aerosols, burning rates, weather conditions, fuel type, time of retrieval and local geography. Other factors can be attributed to the different types of methods and algorithms used to retrieve aerosol specific data. MODIS data showed 560 relatively low values of plume specific AOD ranging from -0.04 ± 0.04 to 0.16 ± 0.08 . The only event which was captured by both MODIS and CALIPSO retrievals, within 2 minutes apart, showed a large level of discrepancy. In particular, event 14, showed average column AOD values of 0.21 ± 0.09 over the plume area with a maximum pixel value of 0.32 ± 0.11 (550 nm). In contrast, CALIOP measurements revealed an average plume AOD value of 1.52 ± 0.8 (532 nm) which was plume specific 565 as no other extinction values were detected beneath or above the plume through the troposphere and stratosphere in the local scene. In the remaining 5 cases, CALIPSO retrieved AOD values ranging from 0.02 ± 0.01 to 0.16 ± 0.06 for average plume thickness ranging from 0.120 to 0.375 km. While these values more closely resemble the successful MODIS retrievals one 570 should restrain from a forward comparison. A reason is that MODIS did not successfully retrieved AOD values over land, thus no direct comparison can be made with CALIPSO for events 1 and 11. MODIS retrievals from event 13 on 28th and 29th of December 2014 were approximately 12 hours apart from the CALIPSO retrievals. Both sensors agreed to low AOD values for 575 the plumes in question. The high levels of uncertainty surrounding MODIS LUT values and CALIPSO unconstrained lidar solutions suggest the need for a more in depth analysis. The only case seen by an AERONET sun photometer (event 10) indicates AOD values ranging from 0.28 to 0.68 ± 0.01 (500 nm) however the satellite images suggest that these values were not indicative for the main plume which most likely did not reach Kiev. Nevertheless, MODIS did not successfully retrieve any AOD values from this event or any other over land while for other events over ocean it did not yield such high AOD 580 values. It is safe to say that MODIS AOD retrievals for oil smoke plumes may not produce satisfactory results since the predetermined LUT values may not contain similar events to the ones described in this study. The CALIPSO AOD measurements are directly influenced by the lidar ratio. For the events retrieved by CALIPSO, a correct estimate of lidar ratio is very difficult to achieve based on unconstrained solution. On one hand, these lidar ratios are not directly measured. On the other hand, lidar ratio for oil smoke plumes may exhibit a different behaviour, considering the high BC content, different from 585 biomass smoke or smoke/polluted continental aerosols. In cases of “clean” atmospheric conditions a constrained solution may result in better AOD estimates. However these conditions are rarely achieved, with less than 0.01% of all aerosol layers detected (Tackett et al., 2018). In the one case were the lidar ratios were directly estimated (event nr. 14) the uncertainties regarding opaque aerosol layers makes it difficult to assess if the AOD values are overestimated or underestimated. AE values seem to be more consistent between MODIS, CALIPSO and AERONET as all techniques suggest the presence of coarse 590 aerosol mixtures; however in conditions with low AOD values, one should restrain from direct comparisons.

Table 8 lists the oil smoke optical properties from different studies that utilised similar ground-based or air borne measuring techniques. Overall, the MODIS AOD estimates are very low compared to the reference studies given in table 8. It should be mentioned that AOD values from the Gulf war smoke plumes are larger for the most part due to the magnitude of

the event. These measurements describe super composite plumes resulted from a large number of well fires and pool fires. An event that more closely resembles the events in this study was analysed by Mather et al. (2007) who retrieved AOD values of 0.28 to 0.68 ± 0.01 (500 nm) at 50 km away from the oil depot (Mather et al., 2007). These values are similar to the AERONET values from Kiev (event 10) presented in this study as in both cases AOD was retrieved using sun photometers and the Kiev AERONET station is located at approximately 20 km from the oil depot. However, the Bouncefield event was significantly larger than the Vasylkiv event. Larger AOD values were measured by Pilewskie and Valero, 1992 and Nakajima et al., 1996 in both cases describing much larger smoke plumes than event 10. AE values from and Nakajima et al., 1996 and Mather et al., 2007 are in general in good agreement with our case studies. R_{eff} values from MODIS also show the presence of larger particles analogous to Mather et al. (2007).

CALIPSO AOD measurements from (event 14) are similar to the upper ranges measured by Laursen et al., 1992 while the unconstrained retrievals from this study more closely resemble the lower bounds from Laursen et al., 1992. The AOD values registered by Ross et al., 1996 fall out of the range of this current study. This may be a result of plume dimensions

605 as the Ra's Lanuf plume cross section was much larger and thicker than the plume described in Ross et al., 1996. In any case, event 14 is expected to measure the largest AOD values out of all smoke plumes solely based on the magnitude of the event. Judging by the results seen in figure 8.a, an aerosol feature exhibiting such heavy attenuation in the layers directly beneath would most likely yield higher AOD values. Particulate depolarization ratio for four out of six cases reflects the values shown by Okada et al. 1992 indicating that oil smoke particles are moderately depolarizing. Ceolato et al., 2020 showed PDR of 0.058
610 for super aggregates. However these values reflect early combustion particles unaltered by the effects of coating. The effects of coating on soot particles can results in PDR larger than 0.1 for oil smoke as suggested by Okada et al. 1992. The same effects are also visible in PDR of biomass burning evident in Kanngießer and Kahnert, 2018; Haarig et al., 2018 and references therein. The opaque feature indicated high lidar ratio values (109 ± 47 sr at 532 nm), even after a 5% reduction, much larger than Ross et al., 1996 which measured only 38 sr. High LR values, 125.3 ± 5.0 sr at 550 nm, are also suggested in Ceolato et
615 al., 2021 which closely resemble the values estimated from event 14. One would expect large lidar ratio values to be the result of the highly absorbent nature of these smoke plumes (high percentage of black carbon, high plume homogeneity and low mixing ratio) leading to larger extinction values.

4 Conclusions

In this study, we examined oil smoke plumes derived from 30 major industrial events within a 12 year period. To our
620 knowledge this is the first study that utilized a synergetic approach based on satellite remote sensing techniques. The MODIS ocean algorithm successfully retrieved aerosol properties in 10 cases, ranging on average from -0.06 to 0.16 for plume specific AOD, -0.18 to 1.25 for Angstrom exponent and 0.29 to 1.73 μm for effective radius. Apart from event 4, all the remaining smoke plumes exhibited AE values lower than 0.74 suggesting that the smoke plumes were coarse mode dominant. CALIPSO measurements showed values of plume AOD ranging from 0.02 to 0.16 (532 nm) and 0.02 to 0.15 (1064 nm) except for one
625 event where AOD values reached 1.52 (532 nm) and 1.43 (1064 nm). AE values ranged from -0.03 to 0.39 which agree with MODIS. A large discrepancy was found in event 14 where CALIPSO AOD values 5 times higher than MODIS. For this specific event, CALIPSO retrieved high lidar ratios of 109 ± 47 (532 nm) and 86 ± 10 sr (1064 nm) based on a constrained retrieval scheme for opaque aerosol layers. The high concentration of water vapour emitted by the oil fire may have contributed to instances of small cloud formation above the smoke plume and thus contaminating the retrievals. Typically, lidar ratio
630 ranged from 37 to 55 sr (532 nm) and 37 to 48 sr (1064 nm) however these unconstrained solutions were indicative of the local aerosol scene and not directly measured. Particulate backscatter coefficient values ranged from 0.002 to $0.015 \text{ km}^{-1}\text{sr}^{-1}$ (532 nm) and 0.002 to $0.017 \text{ km}^{-1}\text{sr}^{-1}$ (1064 nm). Particulate extinction coefficient values ranged from 0.10 to 1.65 km^{-1} (532 nm) and 0.10 to 1.55 km^{-1} (1064 nm). On average backscatter and extinction coefficient values were 2 to 9 times higher than the local background. Particulate depolarization ratios ranged from 0.11 to 0.15 for four out of six cases while the remaining cases
635 were 0.27 and 0.32. We suspect that this discrepancy in the two cases at Qayyara are a result of dust aerosols presented in the smoke plumes. The values presented agree with similar studies that used ground-based and airborne measurements. We believe

that MODIS gives a conservative estimate of the plume AOD since MODIS algorithms rely on general aerosol models and various atmospheric conditions within the look-up tables which do not reflect the highly light absorbent nature of these smoke plumes. Furthermore, the spectral reflectance relationship used by MODIS algorithms may hinder most retrieval attempts as
640 thick black plumes exhibit a distinct spectral signature. CALIPSO measurements are heavily dependent on unconstrained solutions, which in turn do not reflect the oil smoke plumes. Thus, we also believe that the AOD values based on CALPSO measurements are conservative in nature since strong absorbing smoke would yield larger lidar ratios and AOD values. In general, constrained retrievals would better reflect the actual smoke properties because they do not rely on an ad-hoc assignment of lidar ratio. However, assigning a constrained retrieval to oil smoke plumes requires 1: for the plume to be
645 surrounded by clear air; and 2: smoke concentrations should not exceed a threshold were total attenuation is achieved. The lidar ratios generated from event 14 represent an extremely rare occasion where the smoke plume was treated as an opaque aerosol layer. As such, it was difficult to assess whether the lidar ratios were over or underestimated although we believe that this current solution is still preferable to unconstrained solutions. We stress the need for further lidar measurements of oil smoke plumes since, based on this study we cannot conclude whether these aerosols belong to a different smoke subtype.
650 Future space-borne lidar mission such as EarthCare (Illingworth et al., 2015) will provide direct measurements of lidar ratios and the possibility of better AOD estimations with regard to these types of events. Based on this study we concluded that the MODIS land algorithms are not yet suited for retrieving aerosol properties for these types of smoke plumes due to the highly light absorbing properties of these aerosols. This study has shown a novel method of oil smoke plume identification and analysis, which does not require, in some cases, perilous fieldwork. We believe that these types of studies are a strong
655 indication for the need of improved aerosol models and retrieval algorithms. For these types of aerosols, better AOD estimates are important for both air quality and climate change implications.

Author contribution

675 AM, NA and AO carried out the conceptualisation and methodology. AM, AR and HS carried out the formal analysis. AM, AR and HS provided visuals for the paper. AM, NA and CB wrote the initial draft. NP, LD and DN reviewed and edited the initial draft. NA and CB acquired funding for the current research. AO provided supervision for the PhD students AM and AR.

Competing interests
