# **Abstract**

2122

23 We present an Arctic aerosol optical depth (AOD) climatology and trend analysis for 2003-2019 spring and summertime periods derived from a combination of multi-agency 24 aerosol reanalyses, remote sensing retrievals, and ground observations. This includes 25 the U.S. Navy Aerosol Analysis and Prediction System ReAnalysis version 1 (NAAPS-26 27 RA v1), the NASA Modern-Era Retrospective Analysis for Research and Applications, 28 version 2 (MERRA-2), and the Copernicus Atmosphere Monitoring Service ReAnalysis 29 (CAMSRA). Space-borne remote sensing retrievals of AOD are considered from the 30 Moderate Resolution Imaging Spectroradiometer (MODIS), the Multi-angle Imaging 31 SpectroRadiometer (MISR), and Cloud-Aerosol Lidar with Orthogonal Polarization 32 (CALIOP). Ground-based data include sun photometer data from Aerosol Robotic 33 Network (AERONET) sites and oceanic Maritime Aerosol Network (MAN) 34 measurements. Aerosol reanalysis AODs and space-borne retrievals show consistent 35 climatological spatial patterns and trends for both spring and summer seasons over the 36 lower-Arctic (60-70°N). Consistent AOD trends are also found for the high Arctic (north 37 of 70°N) from reanalyses. The aerosol reanalyses yield more consistent AOD results than climate models, verify well with AERONET, and corroborate complementary 38 climatological and trend analysis. Speciated AODs are more variable than total AOD 39 40 among the three reanalyses, and a little more so for March-May (MAM) than for June-41 August (JJA). Black Carbon (BC) AOD in the Arctic comes predominantly from biomass 42 burning (BB) sources in both MAM and JJA, and BB overwhelms anthropogenic 43 sources in JJA for the study period.

AOD exhibits a multi-year negative MAM trend, and a positive JJA trend in the Arctic during 2003-2019, due to an overall decrease in sulfate/anthropogenic pollution, and a significant JJA increase in BB smoke. Interannual Arctic AOD variability is significantly large, driven by fine-mode, and specifically, BB smoke, with both smoke contribution and interannual variation larger in JJA than in MAM. It is recommended that climate models should account for BB emissions and BB interannual variabilities and trends in Arctic climate change studies.

# 1. Introduction

The Arctic is warming faster than the overall global climate, a phenomenon widely known as Arctic amplification (Serreze and Francis 2006; Serreze and Barry 2011). This has led to rapid changes in regional sea ice properties. September sea ice coverage is shrinking at an unprecedented rate (Comiso 2012; Meier et al., 2014). Younger and thinner ice is replacing thick multi-year sea ice (Kwok and Rothrock 2009; Hansen et al, 2013; Rosel et al. 2018). Mechanisms contributing to sea ice changes include increased anthropogenic greenhouse gases (Notz and Stroeve 2016; Dai et al., 2019), sea ice-albedo feedback (Perovich and Polashenski 2012), increased warm and moist air intrusion into the Arctic (Boisvert et al. 2016; Woods et al., 2016; Graham et al. 2017), radiative feedbacks associated with cloudiness and humidity (Kapsch et al. 2013; Morrison et al. 2018), and increased ocean heat transport (Nummelin et al., 2017; Taylor et al. 2018). However, one of the least understood factors of Arctic change is the impact of aerosols on sea ice albedo and concentration (IPCC 2021).

Atmospheric aerosol particles from anthropogenic and natural sources reach or can be found in the Arctic region as the result of long-range transport and local emissions respectively. This affects regional energy balance through both direct and indirect radiative processes (Quinn et al., 2008; Engvall et al., 2009; Flanner, 2013; Sand et al., 2013; Markowicz et al., 2021; Yang et al., 2018). Aerosol particles influence cloud microphysical properties as cloud condensation nuclei (CCN) and/or ice nucleating particles (INP), affecting cloud albedo, lifetime, phase, and probability of precipitation (e.g., Lubin and Vogelmann, 2006; Lance et al., 2011; Zamora et al, 2016; Zhao and Garrett 2015; Bossioli et al., 2021). Additionally, deposition of light-absorbing aerosol species such as dust and black/brown carbon on the surface of snow and ice can trigger albedo feedbacks and facilitate melting and prolong melting seasons (Hansen & Nazarenko, 2004; Jacobson, 2004; Flanner et al., 2007; Skiles et al., 2018; Dang et al., 2017; Kang et al., 2020). However, the impact of aerosol particles on polar climate change is still not well characterized, and their relative importance compared to other warming factors is difficult to isolate and quantify.

82 C 83 a

Climate modeling studies show that due to stronger feedback processes between the atmosphere-ocean-sea-ice-land the Arctic region is more sensitive to local changes in radiative forcing than tropical and mid-latitude regions (Shindell and Faluvegi 2009; Sand et al., 2013). Furthermore, there seems to be an emerging agreement on a higher sensitivity of Arctic clouds by aerosol particles than lower-latitude regions due to the very low aerosol amounts compared to lower latitudes (Prenni et al., 2007; Mauritsen et al. 2011; Birch et al., 2012; Coopman et al., 2018; Wex et al., 2019). Both underscore the important role aerosol particles may play in the Arctic weather and climate, and the urgency to better quantify the amount of aerosols in the Arctic.

- 91 A variety of atmospheric aerosol species exist in the Arctic region. Anthropogenic
- 92 pollution contributes significantly to the formation of the Arctic haze, which generally
- 93 occurs in later winter and spring due to wintertime build-up in the shallow boundary
- layer with effective transport and reduced removal (e.g., Law and Stohl, 2007; Quinn et
- 95 al., 2008). Biomass burning (BB) smoke, originating from wildfires in boreal North
- 96 America and Eurasia, are often observed and/or modeled being transported into the
- 97 Arctic (Eck et al. 2009; Eckhardt et al. 2015; Stohl et al. 2007; Warneke et al. 2009;
- 98 Iziomon et al., 2006; Evangeliou et al. 2016; Kondo et al., 2011; Brieder et al., 2014;
- 99 Markowicz et al. 2016; Khan et al., 2017; Engelmann et al., 2021). Airborne dust,
- 100 emitted from exposed sand or soils due to glacier retreat (Bullard et al., 2016; Groot
- Zwaaftink et al., 2016), are likely on the rise as the Arctic warms. Dust can also
- originate from lower latitude deserts, e.g., Sahara and Asia, and arrive in the Arctic
- through long-range transport (Stone et al., 2007; Breider et al., 2014; AboEl-Fetouh et
- al., 2020). As the Arctic sea-ice melts and the ice-free surface increases, emissions of
- sea salt and biogenic aerosols (e.g., from dimethylsulfide; Dall et al., 2017; Gabric et al.,
- 106 2018) are expected to increase. There are also ultrafine particles nucleated from
- gaseous precursors, though in small amounts (Baccarini et al., 2021; Abbatt et al.,
- 108 2019).
- 109 Because of the harsh surface environment endemic to the Arctic, aerosol field
- measurements are limited in comparison with the mid-latitude and tropical
- environments. Despite an increasing number of field campaigns carried out over the
- past two decades (e.g., review by Wendisch et al., 2019; and more recently the
- MOSAiC, https://mosaic-expedition.org) and their usefulness in improving process-level
- understanding, field measurement periods tend to be short and limited to certain areas
- and thus are not necessarily representative spatially and temporally of the whole Arctic.
- There are many Arctic-aerosol optical property studies that are based on long-term site
- measurements (e.g., Herber et al., 2002; Tomasi et al., 2007; Eck et al., 2009; Glantz et
- al., 2014; Ranjbar et al., 2019; AboEl-Fetouh et al., 2020). The number of sites is.
- however, limited and of irregular spacing (mostly located at the northern edge of the
- North American, Eurasian continents, and the Svalbard region).
- 121 Climate models that are not well constrained by observations exhibit large variations in
- basic aerosol optical properties: one finds, for example, an order of magnitude
- difference in simulated regional aerosol optical depth (AOD) and large differences in the
- simulated seasonal cycle of AOD over the Arctic (e.g., Glantz et al., 2014; Sand et al.,
- 125 2017). Such results will not reduce the uncertainty in the radiative impact of aerosols
- through direct (including surface albedo effect) and indirect forcings in the Arctic
- 127 climate. Impacts of aerosols and clouds, overall, constitute one of the largest sources of
- uncertainty in climate models (IPCC 2013). This is apparently exacerbated in a warming
- 129 Arctic (Goosse et al., 2018). A modeling study by DeRepentigny et al. (2021) shows that

- the inclusion of interannually varying BB emissions, compared with only climatological
- emissions, results in simulations of large Arctic climate variability and enhanced sea ice
- loss. This finding suggests the sensitivity of climate relevant processes to aerosol
- interannual variability in the Arctic.
- In this paper, we present an AOD climatology and trend analysis for the 2003-2019
- 135 Arctic spring and summertime, based on a combination of multi-national interagency
- aerosol reanalyses, satellite remote sensing retrievals, and ground observations. We
- define the Arctic and the high-Arctic as regions north of 60°N and 70°N respectively.
- The lower-Arctic is defined as regions between 60°N-70°N. To reference lower-latitude
- source influences, the area of 50°N-90°N is included for context.
- There are clear advantages to using aerosol reanalyses of chemical transport models in
- 141 comparison with climate models for Arctic aerosol studies. Smoke emissions are
- 142 frequently updated (hourly rather than monthly BB smoke emission sources for
- example) while satellite observations of both meteorological and aerosol data are also
- incorporated into those aerosol reanalyses through data assimilation. High-latitude fires
- are strongly influenced by weather patterns including large-scale transport patterns
- 146 (e.g., Flannigan and Harrington 1998; Skinner et al. 1999). Thus, BB smoke in
- particular, is more realistically accounted for in aerosol reanalyses.
- To our knowledge, this is the first time aerosol reanalysis products are evaluated and
- compared over the Arctic. The goal of the study is to provide a baseline of AOD
- distribution, magnitude, speciation, and interannual variability over the Arctic during the
- sea ice melting season. Statistics of Arctic extreme AOD events is provided in a
- companion paper (Part 2). The baseline can be used for evaluating aerosol models.
- calculating aerosol radiative forcing, and providing background information for field
- campaign data analysis and future field campaign planning in a larger climate context.
- 155 This paper is organized as follows: Sect. 2 and 3 introduce the data sets and methods
- respectively. Sect. 4 verifies the reanalyses. Results are reported in Sect. 5.
- Discussions and conclusions are provided in Sect. 6 and 7.

#### 2. Data

A combination of aerosol reanalyses, satellite-based aerosol remote sensing data, and ground-based aerosol measurements are used to describe source dependent AOD and its trend over the Arctic during spring (i.e., MAM) and summertime (i.e., JJA). The aerosol reanalyses include the Navy Aerosol Analysis and Prediction System reanalysis (NAAPS-RA; Lynch et al., 2016) developed at the Naval Research Laboratory, the NASA Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2; Randles et al., 2017), and the Copernicus Atmosphere Monitoring Service

ReAnalysis (CAMSRA; Inness et al., 2019) produced at ECMWF. The remote sensing

- data include AOD retrievals from the Moderate Resolution Imaging Spectroradiometer
- 169 (MODIS; Levy et al., 2013), the Multi-angle Imaging SpectroRadiometer (MISR; Kahn et
- al., 2010), and Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP). Sun
- 171 photometer data from Aerosol Robotic Network sites and oceanic Maritime Aerosol
- 172 Network measurements were employed as key validation components (respective
- citations of AERONET; Holben et al., 1998 and MAN, Smirnov et al., 2009). Overviews
- of remote sensing techniques for Arctic aerosols can be found in Tomasi et al. (2015)
- and Kokhanovsky et al. (2020). The analysis period is focused on 2003-2019, when all
- three aerosol reanalyses are available. A summary of the datasets is provided in
- 177 Appendix A.

# 179 2.1 MODIS AOD

- AOD data from MODIS on Terra and Aqua was based on Collection 6.1 Dark Target
- and Deep Blue retrievals (Levy et al., 2013). Additional quality control and some
- 182 corrections were applied as described in Zhang and Reid 2006, Hyer et al. 2011, Shi et
- al. 2011, and Shi et al. 2013, and were updated for the Collection 6.1 inputs. The 550
- nm quality-assured and quality-controlled MODIS C6 AOD data are a level 3 product
- that is produced at 1°x1° latitude/longitude spatial and 6-hrly temporal resolution. Those
- 186 6-hrly (averaged) MODIS AOD data were then monthly-binned in order to study long-
- term aerosol climatology and trends. Seasonnally-binned (year to year) means and
- trends were derived only when the total count of 1°x1° degree and 6-hrly data exceeded
- 189 10 for a season.

190 191

#### 2.2 MISR AOD

- The MISR instrument onboard the Terra satellite platform provides observations at nine
- different viewing zenith angles across four different spectral bands ranging from 446 to
- 194 866 nm. These instrumental configurations facilitate AOD retrievals over bright surfaces,
- such as desert regions (Kahn et al., 2010). MISR Version 23 AOD data at 558 nm
- 196 (Garay et al., 2020) were analyzed. No MISR AOD is available over Greenland due to
- snow and ice coverage. Monthly gridded MISR AOD data were created by averaging
- only MISR data with 100% clear pixels (as defined by each pixel's 'cloud screening
- parameter') at a spatial resolution of 1°x 1° latitude/longitude. Only monthly grid cells
- 200 whose number of MISR 100%-cloud-clear AODs was greater than 20 were used to
- 201 derive the climatology and trend.

202203

# 2.3 CALIOP AOD

- 204 Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP), the primary instrument on
- 205 the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO)

206 satellite, is a polarization-sensitive lidar that operates at two wavelengths (532 and 1064 207 nm; Winker et al. 2003). It has, since its launch in 2006, collected a continuity of vertical 208 aerosol and cloud profiles. We primarily used daytime and nighttime 532 nm aerosol 209 extinction coefficient data from the Version 4.2 (V4.2) Level 2 (L2) aerosol profile 210 product (Kim et al., 2018). The product resolution is 5 km in horizontal and 60 m in 211 vertical. The aerosol layer product was used for quality assurance (QA) procedures. 212 The CALIOP aerosol profiles are rigorously QAed before analysis (Campbell et al. 2012; 213 Toth et al. 2016; 2018). Only cloud-free CALIOP profiles are used: this was determined 214 through the atmospheric volume description (AVD) parameter included in the aerosol 215 profile product (i.e., we excluded CALIOP profiles with any range bin classified as cloud 216 by the AVD parameter). A significant portion of CALIOP aerosol profile data consists of 217 retrieval fill values (-9999s, or RFVs) that are, in part, due to the minimum detection 218 limits of the lidar. In fact, over 80% of CALIOP profiles consist entirely of RFVs in some 219 Arctic regions (Toth et al. 2018). These result in zero-valued column AODs: their 220 inclusion in composites would artificially lower the mean AOD. They were thus excluded 221 from our analysis. We also tested retaining AOD=0 values in our analysis and that did 222 not change the AOD trends (see more discussions in section 6). Lastly, the cloud-free 223 QAed profiles without AOD=0 profiles were used to compute mean CALIOP AODs at 2° 224 x 5° latitude/longitude resolution. To ensure spatial and temporal representation, 225 seasonally-binned means and trends were derived only when the total count of gridded 226 data in any season exceeded 20.

#### 227 2.4 AERONET

234 235

236

237

238

239

240

241

242

243 244

245

The AErosol RObotic NETwork (AERONET) is a ground-based global sun photometer 228 229 network. AERONET instruments measure sun and sky radiance in spectral bands 230 ranging from the near-ultraviolet to the short-wave-infrared. This network has been 231 providing daytime aerosol-property measurements since the 1990s (Holben et al., 1998; Holben et al., 2001). Only cloud-screened, quality-assured version 3 Level 2 AERONET 232 233 data (Giles et al., 2019) are used in this study.

The 500 nm fine mode (FM) and coarse mode (CM) AODs from the Spectral Deconvolution Method (SDA) of O'Neill et al. (2003), along with the FM spectral derivative at 500 nm are used to extrapolate FM AOD to 550 nm (assuming equal CM AOD at 500 and 550 nm). Total AOD is simply the sum of FM and CM AODs. The SDA product is an AERONET product that has been verified using in situ measurements (see for example Kaku et al., 2014) and a variety of co-located lidar experiments (see, for example, Saha et al., 2010 and Baibakov et al., 2015). The FM and CM separation is effected spectrally: this amounts to a separation of the FM and CM optical properties associated with their complete FM and CM particle size distributions. This optical separation, characterized by the ratio of FM AOD to total AOD at 550 nm is referred to as the fine mode fraction (FMF). An analogous FM and CM AOD separation in terms of

a cutoff radius applied to a retrieved or measured particle size distribution is referred to as the sub-micron fraction (SMF; where the numerator of the SMF is the FM AOD associated with the AOD contribution of particles below a cutoff radius). The SMF is the basis for separating FM and CM components in the AERONET (AOD & sky radiance) inversion. The SDA algorithm and the AERONET inversion generate FM and CM AODs that are moderately different (see, for example, Sect. 4 of Kleidman et al., 2005). The advantage of the SDA is its significantly shorter intersampling time and thus retrieval numbers (~ 20 / hour vs ~ 1 / hour for the AERONET inversion), its independence from a variable cut off radius and its greater operational generality (being applicable to other networks such as the MAN sunphotometer network).

AERONET data were binned into 6-hr intervals centered at normal synoptic output times of the reanalyses (0, 6, 12, and 18 UTC) and then averaged within the bins. Monthly-mean temporal representativeness was rendered more likely by only including means with more than 18 6-hr data bins. Ten AERONET sites (Table 1, Fig. 1) were selected based on regional representativeness (coupled with the reality of the sparsity of AERONET sites in the Arctic), the availability of data records between Jan 2003 and Dec 2019, and for easier comparison with other Arctic studies (e.g., Sand et al., 2017). To explore the potential impact of different sampling resolutions on the results (e.g., Balmes et al., 2021), we generated daily AOD statistics (Table S1) that could be compared with Table 1 6 hrly statistics. In general, the mean and median of MAM or JJA AODs (including total, FM and CM AODs) at the ten AERONET sites change very slightly (mostly 0.00, or <=0.01). The daily AOD standard deviation was less than its 6 hrly analogue.

We found that thin clouds could occasionally be identified and retrieved as CM aerosols in level 2, version 3 AERONET data. These retrievals were manually removed by identifying such thin clouds using Terra and Aqua visible-wavelength imagery from <a href="NASA Worldview">NASA Worldview</a> and comparing 6-hrly NAAPS-RA with AERONET AODs. CM AODs greater than the 3-sigma level were then also removed (as per AboEl-Fetouh et al., 2020).

# 2.5 MAN AOD

The Marine Aerosol Network (MAN) is a hand-held Microtops sun photometer (research vessel based) counterpart to AERONET: ocean measurements are acquired where noland based AERONET site can exist (Smirnov et al., 2009, 2011). The products share AERONET product nomenclature and data processing is similar to that of AERONET. Level 2 data above 70°N for were employed in this study. SDA-based FM and CM AOD at 550 nm were derived and averaged over 6-hr time bins.

# 286 2.6 NAAPS AOD reanalysis v1

- 287 The Navy Aerosol Analysis and Prediction System (NAAPS) AOD ReAnalysis (NAAPS-
- 288 RA) v1 provides 550 nm, global-scale, speciated AODs at 1°x 1° spatial and 6-hrly
- temporal resolution for the years 2003-2019 (Lynch et al., 2016). This NAAPS-based
- 290 reanalysis incorporates assimilation of quality-controlled, MODIS and MISR AOD
- 291 retrievals (Zhang et al., 2006; Hyer et al., 2011; Shi et al., 2011). AODs from
- 292 anthropogenic and biogenic fine aerosol species (ABF; a non-BB sources mixture of
- 293 sulfate, black carbon or BC, organic aerosols and secondary organic aerosols), dust,
- 294 BB smoke, and sea salt aerosols are available. The aerosol source functions were
- 295 tuned to obtain the best match between the model FM and CM AODs and the
- 296 AERONET AODs for 16 regions globally. Wet deposition processes were constrained
- 297 with satellite-derived precipitation (Xian et al., 2009). The reanalysis reproduces the
- 298 decadal AOD trends found using standalone satellite products (e.g., Zhang et al., 2010;
- 299 2017 who excluded polar regions due to lack of verification data).

# 300 2.7 MERRA-2 AOD reanalysis

- 301 NASA Modern-Era Retrospective Analysis for Research and Applications, version 2
- 302 (MERRA-2) includes an aerosol reanalysis scheme that incorporates AOD assimilation
- of a variety of remote sensing data sources, including MODIS and MISR after 2000. The
- aerosol module used for MERRA-2 is the Goddard Chemistry, Aerosol Radiation and
- 305 Transport model (GOCART; Chin et al. 2000; Colarco et al., 2010). It provides
- 306 simulations of sulfate, black and organic carbon, dust and sea salt aerosols. A detailed
- description and global validation of the AOD reanalysis product can be found in Randles
- et al. (2017) and Buchard et al. (2017). Monthly mean speciated AODs and total AOD at
- 309 550 nm with 0.5° latitude and 0.625° longitude spatial resolution were used for this
- 310 study.

# 311 2.8 CAMSRA AOD reanalysis

- The Copernicus Atmosphere Monitoring Service (CAMS) Reanalysis (CAMSRA) is a
- new ECMWF-led global reanalysis of atmospheric composition (Inness et al., 2019). It
- followed on the heels of the MACC reanalysis (Inness et al., 2013) and CAMS interim
- reanalysis (Flemming et al., 2017). The dataset covers the period of 2003–2020 and is
- being extended to subsequent years. The model is driven by the Integrated Forecasting
- 317 System (IFS) used at ECMWF for weather forecasting and meteorological reanalysis
- 318 (but at a coarser resolution). It incorporates additional modules activated for prognostic
- trace gases and aerosol species, including dust, sea salt, organic matter, black carbon
- 320 and sulfate. Satellite retrievals of total AOD at 550 nm are assimilated from MODIS for
- 321 the whole period, and from the Advanced Along-Track Scanning Radiometer for 2003–
- 322 2012, using a 4D variational data assimilation system with a 12-hour data assimilation

- window along with meteorological and trace gas observations. The speciated AOD
- 324 products with monthly temporal resolution and a ~0.7° spatial resolution were used in
- 325 this study. Model development has generally improved the speciation of aerosols
- 326 compared with earlier reanalyses, and evaluation against AERONET globally is largely
- 327 consistent over the period of the reanalysis.
- 328 2.9 Multi-reanalysis-consensus (MRC) AOD
- 329 All three of the individual reanalyses are largely independent in their underlying
- meteorology and in their aerosol sources, sinks, microphysics, and chemistry. They
- were also generated through data assimilation of satellite and/or ground-based
- observations of AOD. The assimilation methods, and the assimilated AOD observations,
- including the treatments of the observations prior to assimilation (quality control, bias
- correction, aggregation, and sampling, etc.), often differ. There is, on the other hand,
- consistent use of MODIS data with its daily global spatial coverage.
- Based on the three aerosol reanalysis products described above, we made an MRC
- product following the multi-model-ensemble method of the International Cooperative for
- 338 Aerosol Prediction (ICAP, Sessions et al., 2015; Xian et al., 2019). The MRC is a
- consensus mean of the three individual reanalyses, with a 1°x1° degree spatial and
- monthly temporal resolution. Speciated AODs and total AOD at 550 nm for 2003-2019
- are available. This new product is validated here, along with the three component
- reananlysis members, using ground-based Arctic AERONET observations. Validation
- results in terms of bias, RMSE, and coefficient of determination (r<sup>2</sup>) for monthly-mean
- total, FM and CM AODs are presented in Tables 2, 3, 4. The MRC, in accordance with
- the ICAP multi-model-consensus evaluation result, is found to generally be the top
- performer among all of the reanalyses for the study region.

2.10 Fire Locating and Modeling of Burning Emissions (FLAMBE) v1.0

348349 FLAMBE is a biomass-burning emission inventory derived from a satellite-based active

fire hotspot approach (Reid et al., 2009; Hyer et al., 2013). FLAMBE can take satellite

351 fire products from either geostationary sensors, which offer faster refresh rates and

observation of the full diurnal cycle, or polar orbiters, which have a greater sensitivity.

353 There are significant daily sampling biases and additional artifacts induced by day to

day shifts in the orbital pattern for polar-orbiting satellites (e.g., Heald et al., 2003, Hyer

et al., 2013). However, the polar-only version of FLAMBE, which employed MODIS-

based fire data, is more appropriate for reanalysis and trend analysis. This is because

multiple changes in the geostationary constellation over the study period posed a

358 challenge in terms of smoke source-function consistency. The FLAMBE MODIS-only

359 smoke source was also used in the NAAPS-RA v1 because of the same temporal

360 consistency requirement. FLAMBE shows similar BB emission trends as the yearly BB

emission time series for the Arctic region based on other inventories for a similar study period (using BC emission of Fig. 2 in McCarty et al., 2021). These inventories include the Global Fire Assimilation System (GFAS; Kaiser et al., 2012), and the Global Fire Emission Dataset (GFED; Randerson et al., 2006; van derWerf et al., 2006).

#### 3. Method

The Arctic AOD climatology and trends are analyzed in this study using remote sensing products derived from MODIS, MISR, CALIOP, and AERONET (each sensor typically generating aerosol products of different native wavelengths). The 550 nm AOD was employed as the benchmark parameter since the three aerosol reanalyses AODs and the MODIS AOD are all available at 550 nm while the 558nm and 532nm AODs of MISR and CALIOP are appreciably close to 550 nm. AERONET and MAN modal AODs at 550 nm were derived using the SDA method as described in Sect. 2.4 and 2.5. Arithmetic means were employed for all the data processing in order to be consistent with the arithmetic statistics that are usually reported in the literature and with the arithmetic statistics of the monthly data from the aerosol reanalyses. Various studies have shown that geometric statistics are more representative of AOD histograms (see, for example, Hesaraki et al., 2017 and Sayer et al., 2019). However, Hesaraki et al. (2017) showed that arithmetic statistics could be employed to readily estimate geometric statistics less critical.

The species of interest are BB smoke, ABF in NAAPS, and its analogue of sulfate for MERRA-2 as well as CAMSRA and dust and sea salt aerosols. Anthropogenic aerosol particles, as external climate forcers, have drawn some attention in climate studies (e.g., Wang et al., 2018; Ren et al., 2020; Yang et al., 2018; Sand et al., 2016; Eckhardt et al., 2015; Brieder et al., 2017). However, BB smoke, which can be both natural and anthropogenic in origin, has been shown to be the largest contributor (over the last two decades) to Arctic summer AOD and concentration (Evangeliou et al. 2016; Sand et al. 2017 for modelling studies and Eck et al. 2009; Eckhardt et al. 2015; Stohl et al. 2007; Warneke et al. 2009 for observational-based studies). Recent BC measurements in Arctic snow also show a strong association with BB based on modelled tracer correlations with measured optical properties of snow (Hegg et al., 2009; Doherty et al., 2010; Hegg et al., 2010; Khan et al., 2017). A climate modeling study recently found that much larger Arctic climate variability and enhanced sea ice melting were introduced using BB emissions with interannual variability as opposed to fixed climatological monthly-mean BB emissions (DeRepentigny et al., 2021), a result that underscored the importance of quantifying the magnitude and interannual variability of BB smoke in

-

<sup>&</sup>lt;sup>1</sup> with an erratum: the equation (2) transformation to geometric mean should be  $\tau_{g,x} = \frac{\langle \tau_x \rangle}{\exp(\frac{\ln^2 \mu_x}{2})}$ 

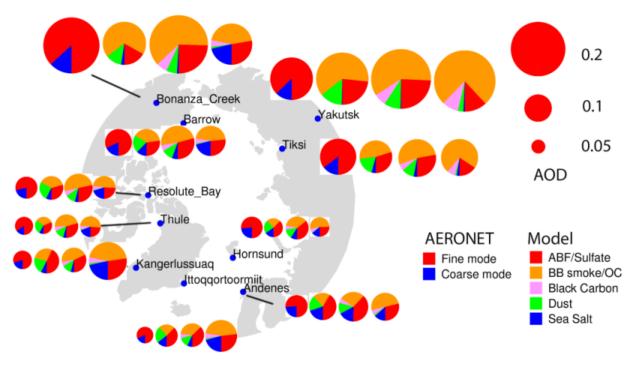

- 398 Arctic climate forcing estimates. Thus BB smoke AOD is separated out from the total
- 399 AOD as a singularly important species in this study.
- The separation of species in this analysis is a bit arbitrary since the representation of
- 401 different aerosol types and sources in each reanalysis is slightly different. The NAAPS
- 402 model is unique compared to other reanalyses and operational models in that it carries
- 403 aerosol species by source rather than chemical speciation. For example, biomass
- 404 burning and ABF are carried as separate species and permit explicit hypothesis testing
- about the sources, sinks, and optical properties. Conversely, MERRA-2 and CAMSRA
- 406 carry organic carbon (OC)/organic matter (OM), BC and various inorganic species
- 407 combining a multitude of anthropogenic, biogenic and biomass burning source
- 408 pathways. In this study the sum of OC/OM and BC AOD is used to approximate BB
- smoke AOD from CAMSRA and MERRA-2. The ratio of BC AOD to the sum of BC and
- 410 OC/OM AOD is, on average, about 10% for areas north of 60°N for both MERRA-2 and
- 411 CAMSRA for both MAM and JJA (the single exception to this is that the MERRA-2 ratio
- is about 18% in MAM). The ratios change little for area >70°N and area >80°N.
- 413 It is worth noting that the three reanalyses use either hourly or daily BB smoke emission
- 414 inventories: inventories that employ dynamic smoke sources detected by polar-orbiting
- satellites. Examples include FLAMBE (Reid et al., 2009) for NAAPS-RA, Quick Fire
- 416 Emissions Dataset (QFED) for MERRA-2 after 2010 (GFED with monthly BB emission
- before 2010 as per Randerson et al., 2006 and van derWerf et al., 2006), and Global
- 418 Fire Assimilation System (GFAS, Kaiser et al., 2012) for CAMSRA. This is expected to
- 419 yield a better spatial and temporal representation of BB smoke emissions compared to
- 420 climate models which use monthly mean BB inventories (e.g., Sand et al., 2017).
- We also assume all dust and sea salt are CM, while other model aerosol species,
- including ABF in NAAPS-RA, sulfate in MERRA-2 and CAMSRA, BB smoke in NAAPS-
- 423 RA, BC and OC/OM in MERRA-2 and CAMSRA are FM aerosol particles. This
- approximation (the sequestering of dust and sea salt to the CM regime) is based on the
- fact that FM dust and sea salt only contribute a small portion of the total dust or sea salt
- 426 AOD at 550 nm. For example, FM dust represents about 30% and 39% of total dust
- 427 AOD globally in MERRA-2 and CAMSRA respectively. The numbers are 17% and 10%
- for sea salt. NAAPS-RA makes the simplifying microphysical assumption that all dust
- 429 and sea salt are CM.
- 430 For verification purpose, bias, root-mean-square deviation (RMSE) and coefficient of
- determination (denoted r<sup>2</sup>) of reanalysis AODs compared to AERONET/MAN AODs are
- calculated. r<sup>2</sup> equals the square of the Pearson correlation coefficient between the
- observed and the modeled AODs. When estimating contributions of individual species
- 434 to total AOD interannual variability, r<sup>2</sup> is calculated as the square of the Pearson
- correlation coefficient between the seasonally-binned modeled speciated AOD and total

- 436 AOD. In that form, r<sup>2</sup> provides the percentage of "explained variance" of total AOD by a
- 437 speciated AOD. The statistical definition and interpretation of r<sup>2</sup> can be found
- 438 <a href="https://en.wikipedia.org/wiki/Coefficient\_of\_determination">https://en.wikipedia.org/wiki/Coefficient\_of\_determination</a>.
- The significance test for trend analysis applies the same calculation method as in Zhang
- et al. (2010; 2017), an approach which, in turn, was based on the method of
- Weatherhead et al. (1998). This trend analysis method requires a continuous time
- 442 series of data.

# 4. Comparison of AODs from aerosol reanalyses and AERONET

- The number of AERONET observations are tied to the increase in the number of
- daylight hours and are therefore more numerous during the summer than in the spring.
- This translates to their generally being more temporally representative of 6 hr or daily
- means in JJA. As a consequence, we preferentially used a JJA climatology to illustrate
- reanalyses vs AERONET comparisons. Fig. 1 shows the mean JJA FM and CM AODs
- from AERONET and the speciated AODs from NAAPS-RA, MERRA-2, and CAMSRA.
- 450 All three aerosol reanalyses appear to capture the total AOD magnitudes to varying
- extents. The AERONET retrievals show that total AOD during the Arctic JJA season is
- dominated by contributions from FM aerosols. Large FM AOD values (generally
- indicative of strong BB smoke influence) are found in Yakutsk and Tiksi in Siberia, and
- Bonanza Creek in Alaska. CM aerosols also contribute a substantial fraction, varying
- 455 from a minimum of 15% in regions close to BB smoke sources to a maximum of ~25%
- 456 at the Norwegian Sea and Greenland Sea coastal sites (Hornsund, Andenes, and
- 457 Ittoggortoormitt): these sites are likely impacted by sea salt aerosols lifted by North
- 458 Atlantic cyclonic events. NAAPS-RA produces AERONET-comparable FM and total
- 459 AODs in general while showing a tendency to overestimate CM AODs (see Table 2 for
- explicit biases). The other two reanalyses produce higher FM AOD and total AOD and
- lower CM AOD compared to AERONET (see also Table 2).
- Differences exist between the three reanalyses with respect to the FM and CM
- partitioning of aerosol species. For example, sea salt aerosols always dominate in the
- 464 CAMSRA (dust + sea salt) CM: this comment even applies to some inland sites (e.g.,
- Bonanza-Creek) and implies a modeling issue. Dust is the dominant CM species in
- 466 NAAPS-RA and MERRA-2. This is true at all AERONET site positions: it is likely
- attributable to elevated dust layers transported from lower latitudes (Stone et al., 2007;
- Jacob et al., 2010; Breider et al., 2014; Aboele-Fetouh et al., 2020). The proportional
- 469 contribution of dust to total AOD is at its largest in NAAPS-RA: a result that could have
- 470 contributed to its high bias in CM AOD (Table 2). The contribution of organic matter to
- 471 FM AOD is generally larger in CAMSRA than in the other two reanalyses. On the whole,
- 472 BB smoke is the largest contributing species to total JJA AOD over the Arctic. This is

consistent across all the reanalyses except for some sites in NAAPS-RA (e.g., Andenes, Hornsund, and Kangerlussuaq where ABF AOD is slightly larger than BB smoke AOD). This can be partially due to the different types of speciation employed in NAAPS-RA: ABF represents anthropogenic and biogenic pollution aerosols. The latter category includes sulfate, BC and (with the exception of BB aerosols) organic aerosols of all origins. It is also worth noting that mean AERONET AODs are, in general, higher (0.01-0.02, and can be ~0.1 higher for the sites close to BB sources) than their median counterparts (Table 1) as well as their geometric means. This is because AOD histograms are typically more lognormal than normal in form (asymmetric linear-AOD histograms with positively skewed tails as per, for example, Hesaraki et al., 2017): arithmetic means are, accordingly, often driven by extreme (>95% percentile for example) AOD events. Because these extreme events constitute an important part of the Arctic aerosol environment, the AOD means are presented here.

**Figure 1.** Polar projection map showing the locations of the AERONET Arctic sites (small solid blue circles) used in this study. Long-term (2003-2019) JJA-mean FM and CM AODs at 550 nm from AERONET (leftmost circle of each group of four circles) and respectively, the speciated pie-charts of 550 nm AODs from NAAPS-RA, MERRA2, and CAMSRA for each site. Warm colors (red, orange, and pink) represent FM and cool colors (green and blue) represent CM. Circle size varies with AOD magnitude (see the key to the top right).

**Table 1.** Geographical coordinates of AERONET sites used in this study and seasonally-binned mean, median and standard deviation of the total AOD and SDA-

derived FM and CM AOD at 550nm for MAM and JJA based on 2003-2019 data when available. "n" represents the number of 6-hrly AERONET data.

The geographical coordinates of the ten AERONET sites are provided in Table 1, as well as the mean, median and standard deviation of the total, FM and CM AODs at 550 nm for both MAM and JJA based on available data (the availability of AERONET data can be appreciated from the monthly time series in Fig. 2). Analogous MAN statistics are provided in the last row of Table 1 (see also Fig. S1 for geographical distributions of MAN measurements). The seasonal mean total AOD for Resolute Bay, the Greenland sites, Hornsund and the MAN measurements are < ~ 0.1 (0.06-0.10) while the Alaskan and Siberian site values are >~ 0.1 (0.10 to 0.15 with Bonanza Creek displaying a substantially larger JJA value of 0.21). All sites, except Bonanza Creek, tend to have moderately higher median AOD in MAM: this is consistent with other Arctic sunphotometer studies (Tomasi et al., 2015; Xie et al., 2018). The lesser values in JJA, according to the reanalyses (Fig. 4 and 5), is related to higher FM ABF/sulfate and/or CM dust and sea salt in MAM. This AOD seasonal difference may have evolved in the past two decades with a decreasing trend in ABF/sulfate as discussed in Sect. 5.3. The mean AOD is greater in JJA than in MAM for Yakutsk, Tiksi and Bonanza Creek: this is likely due to strong FM AOD variations associated with BB smoke events (see, for example, the discussions concerning the seasonal competition between FM AOD smoke and FM AOD Arctic haze, in AboEl-Fetouh et al., 2020). The standard deviations of the total and FM AODs are also high for those three sites.

The Table 1 median and mean of the FMF vary, respectively, between 0.60 to 0.88 and 0.61 to 0.85 with higher FMF in JJA than in MAM. The MAN measurements have higher CM AODs and lower FMF compared to AERONET measurements, due to possible contributions from sea salt aerosols. The MAM to JJA increase in FMF for all sites and MAN is coherent with the month-to-month increase of AboEl-Fetouh et al., (2020) although their 550 nm arithmetic means tend to be larger (monthly-binned extremes of 0.81 to 0.98). Most, or at least a significant part of this difference is likely attributable to differences between our FMF (SDA) separation of the product and the SMF (AERONET-inversion) separation of AboEl-Fetouh et al.'s climatology. The SMF is

generally larger than the FMF because it tends to attribute a fraction of the CM particle size distribution and thus a fraction of the CM AOD to the FM AOD (see, for example, the 550 nm SMF vs FMF comparisons Section 4 of Kleidman et al., 2005). More discussions about the differences in terms of FMF vs. SMF and arithmetic vs. geometric statistics are available in the supplement material.

**Figure 2.** Monthly-binned time series of FM, CM, and total AERONET AODs and MRC speciated AOD at a) Bonanza Creek, Barrow, Resolute\_Bay, Thule, Kangerlussuq, and b) Ittoqqortoormitt, Hornsund, Andenes, Yakutsk, and Tiksi sites. The JJA periods are highlighted with pink shading for easy reading. The legends of each time series show MRC bias, RMSE and r<sup>2</sup>.

548 The time series of monthly mean FM, CM and total AODs from the ten AERONET stations (CM AOD can be inferred from the difference between total AOD and FM AOD) 549 550 and the speciated AODs from MRC are provided in Fig. 2. Bias, RMSE, and r<sup>2</sup> 551 verification statistics versus AERONET for monthly-binned data of individual aerosol 552 reanalysis members and the MRC are presented in Tables 2, 3, and 4 respectively. The 553 MRC is consistently biased slightly high for FM AOD across all sites and about neutral 554 for CM AOD for most. As a result, total AOD tends to bias slightly high, with biases ranging from 0.00 to 0.03. RMSE values range from 0.02 to 0.03 for most sites, except 555 556 for Bonanza Creek, Yakutsk and Barrow with RMSE values of 0.06, 0.05 and 0.04 557 (driven mainly by FM variations). The r<sup>2</sup> values range from 0.53 to 0.84, with FM AOD r<sup>2</sup> 558 values ranging from much higher to marginally higher than the CM AOD values. This is 559 understandable as FM AOD displays large variabilities (which models are more capable 560 of capturing) while CM AOD displays relatively low values and smaller absolute 561 variabilities on seasonal and interannual time scales. Also, emissions of CM aerosols 562 like dust and sea salt, are driven dynamically by model or reanalysis surface winds where the surface wind dependency increases exponentially in amplitude: the 563 564 simulation of this dependency has been a challenge to all global aerosol models 565 (Sessions et al., 2015; Xian et al., 2019).

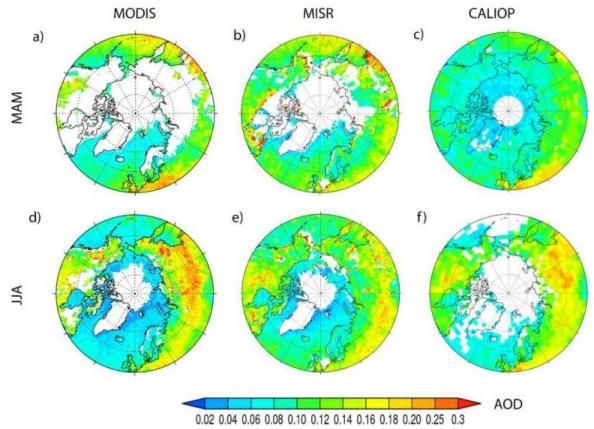

Our previous experience with multi-reanalysis and multi-model ensembles indicates, in 566 general, that the consensus of multi-reanalyses or multi-models show better verification 567 scores than individual component members (Sessions et al., 2015; Xian et al., 2019; 568 569 Xian et al., 2020). However, these studies are based on more global analyses for which 570 the Arctic impact is relatively weak because of the sparsity of observational Arctic data. 571 Tables 2, 3 and 4 indicate that the Arctic is rather unique inasmuch as the MRC is not 572 necessarily the top AOD-estimation performer. NAAPS-RA generally has moderately 573 better bias, RMSE and r<sup>2</sup> verification scores for the total and FM AODs compared to MERRA-2 and CAMSRA while CM AOD does not perform as well. In previous MRC and 574 multi-model consensus evaluations, all component members either performed 575 comparably in terms of AOD RMSE, bias and r<sup>2</sup> or the number of multi models was 576 577 relatively larger (e.g., 5 to 6 for the International Cooperative for Aerosol Prediction 578 multi-model consensus). This study is the first time that all three developing centers 579 have systematically evaluated their AOD reanalysis performance on an Arctic-wide climate scale. 580

# 5. Seasonal Analysis

581

In this section we present spring and summertime Arctic AOD climatologies derived from space-borne remote sensing retrievals and aerosol reanalyses. We then present the seasonal cycle, interannual variability and trends of total and speciated AODs.

# 5.1.1 Space-based remote sensing AOD climatology

**Figure 3.** Satellite-derived, mean climatological MAM (upper) and JJA (lower) MODIS AOD at 550 nm (left), MISR AOD at 558 nm (middle), and CALIOP AOD at 532 nm (right). The averaging period for MODIS and MISR was 2003-2019 while the CALIOP period was 2006-2019. The white areas correspond to a lack of data. The latitude circles are at 50°, 60°, 70° and 80° N.

Bright, snow- and ice-covered surfaces, large solar zenith angles (SZA) and extensive cloud coverage result in limited (quality assured) Arctic AOD retrievals from sensors like MODIS and MISR. The latitude limit of an active, downward-looking, polar-orbiting sensor like CALIOP results in a polar region profile gap above 82°N. Known CALIOP issues of retrieval filled values (RFVs) (Toth et al., 2018) and low signal to noise over the Arctic during the summertime also limit its aerosol retrievals during the JJA season. These challenges translate to substantial data-free MAM and JJA areas in the high Arctic and Greenland as well as North America and Siberia in the MODIS, MISR, and CALIOP AOD climatology maps of Fig. 3. JJA shows significantly larger MODIS and MISR area coverage over higher latitudes as aerosol retrievals from MODIS and MISR are acquired in continuous or nearly continuous sunlight conditions. The summertime melt season

means a greater presence of ice- and snow- free ocean and land surfaces as required for passive satellite-based AOD retrievals. Nevertheless, the long operation time of these sensors (about two decades) provides sufficient data to construct an AOD climatology, as well as emissions climatology for the near Arctic and the midlatitude regions where most sources of Arctic aerosols reside.

633

In general, the Fig. 3 AOD patterns are similar for all three sensors. Higher AODs of 0.15-0.25 can be observed in the 50°N-65°N latitude belt over land. These are associated with large boreal and subarctic areas in Siberia, east and central Europe and North America in both spring and summer. AODs, mostly higher than 0.2 over Siberia in JJA are associated with biomass burning events. The average AOD over water is considerably lower, ranging from 0.02 to 0.12, with lower AOD over the north Atlantic and relatively higher AOD in the northeast Pacific influenced by outflows from the Eurasian Continent. The lowest AODs (0.02-0.06) occur over the Arctic Ocean. AOD over water is slightly higher in MAM than in JJA, which is consistent with other observation-based studies within the Arctic circle (e.g., Tomasi et al., 2015). This result is possibly related to higher pollution levels from the upstream continents in MAM. CALIOP AOD exhibits spatial patterns similar to MODIS and MISR. AODs over Greenland (unique to CALIOP) range from 0.02-0.06: these minimal values are attributable to its high elevations (nearly 2km on average). CALIOP-derived AODs over Siberia and North America are distinctively higher in JJA than in MAM. This seasonal difference (also seen by MISR) is attributable to seasonal boreal fire activities, i.e., boreal fire is generally more active in JJA than in MAM (Giglio et al., 2013). The seemingly larger JJA vs MAM CALIOP difference over Siberia and North American as compared with MODIS and MISR could also be associated with different averaging times (2006-2019 vs. 2003-2019) as well as data sampling rate. The swath for MODIS and MISR is on the order of a few hundred to a few thousand kilometers, while the "beam diameter" for CALIPSO is on the order of 70m (Winker et al., 2009; Colarco et al., 2014). While MODIS and MISR yield more valid retrievals during JJA than MAM, the CALIOP data samples more during MAM due to decreased signal to noise ratio during the summer (c.f. O'Neill et al., 2012).

# 5.1.2 Arctic AOD climatology derived from aerosol reanalyses

634 The spatial distributions of 2003-2019 mean total AOD and speciated AOD from the three aerosol reanalyses and their consensus mean for spring and summer respectively 635 636 are shown in Figs. 4 and 5. Although there is limited AOD data available for data 637 assimilation in the Arctic, lower latitude AODs that are assimilation constrained can 638 affect Arctic AOD through transport and thus exert an indirect Arctic AOD constraint. 639 Additionally, all the reanalyses use satellite-fire-hotspot-based BB emissions with fine temporal resolution (hourly to daily). This exerts a source constraint, especially 640 641 temporally (emission magnitude differs more than timing among the different models).

As a result, there are significant similarities in the spatial distributions of total AODs among the three reanalyses. For example, MAM total AOD values are, for all reanlyses, high in the 50°N-65°N belt over the Eurasian continent and its downwind Pacific region (values of 0.16-0.30), low (of the order of 0.1 or less) for regions north of 70°N, and at a minimum over Greenland. The high AODs over boreal North America and the Siberian BB regions are more prominent in JJA compared to MAM. In general, we would note that the distribution patterns and total AOD magnitude are comparable to available retrievals from MODIS, MISR, and CALIOP.

671

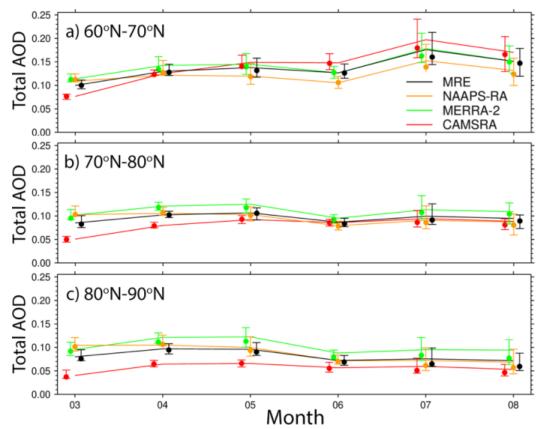

672

Speciated AODs have more variability than total AOD among the three reanalyses, and a little more so for MAM than for JJA as shown in Figs. 4, 5, 6. The lesser JJA variability follows because passive Arctic-AOD retrievals are more available in summer and reanalyses are therefore more constrained by those observations. The lesser total AOD variability is the result of it being constrained through data assimilation while speciated AOD is not: the latter AODs rely on model physics and boundary condition constraints. In general BB smoke and ABF/sulfate AODs largely dominate dust and sea-salt during MAM and JJA. The MRC MAM results show similar BB smoke and ABF/sulfate magnitudes. However, the NAAPS-RA and MERRA-2 results suggest an ABF/sulfate dominance over BB smoke while CAMSRA suggests the reverse. The high FM AOD vs AERONET bias of CAMSRA (Table 2) suggests OM and BC, and hence BB smoke overestimation. BB smoke becomes the dominant rival species over ABF/sulfate as summertime boreal BB activity increases. The increase in smoke AOD from spring to summer is a consistent feature across all the reanalyses (while CAMSRA, singularly, shows significantly higher BB smoke AOD and lower sulfate AOD in both seasons). All reanalyses show a June minimum in total AOD (Fig. 6). This is induced by general postspringtime ABF/sulfate, dust and sea salt AODs reductions coupled with increased July

673 and August BB activities. The spatial distributions of seasonal mean BC AOD from 674 MERRA-2 and CAMSRA greatly resemble those of smoke AOD (arguably more so for 675 JJA than MAM). This suggests a dominant role of BB sources over anthropogenic BC 676 sources over the Arctic during spring and summer seasons. This also supports McCarty 677 et al. (2021)'s BC emission estimate that wildfire emissions account for more than half 678 of all BC yearly emissions north of 60°N (the author's noted much lower wintertime BB 679 emissions when anthropogenic BC emission is at its maximum). 680 Figures 4, 5 and 6 indicate, for both seasons, that dust and sea salt are secondary 681 contributors to the total AOD in the Arctic: noticeable influences of Saharan and Asian 682 dust (c.f., for example, Stone et al., 2007; Brieder et al., 2014) as well as cyclonic-683 induced North Atlantic Greenland Sea, Norwegian Sea, and North Pacific sea salt are observable in Fig. 4. It is also noteworthy that dust AOD in CAMSRA is much lower than 684 685 the other two models (<0.02) in the spring. Monthly and latitudinally-segmented mean-AODs were found to gradually decrease 686 from lower latitudinal belts to higher latitudinal belts (Fig. 7). Total AOD for the 60°-70°N 687 688 belt increases, on average, from MAM to JJA due to the seasonality of BB activities. 689 However, the total AOD for the 80°-90°N belt decreases slightly from MAM to JJA. This means the decreasing latitudinal gradient of total AOD is characterized by a larger 690 amplitude in JJA than in MAM. This is most likely due to greater aerosol wet removal 691 during transport from source regions to the high Arctic in summer (Garrett et al., 2010, 692 693 2011). It is also noted that the CAMSRA latitudinal AOD-gradient is larger than those of 694 the two other reanalyses. This suggests stronger CAMSRA aerosol removal in the Arctic compared to MERRA-2 and NAAPS-RA. 695 696 697

**Figure 6.** Climatological (2003-2019) seasonal cycle of Arctic (60°-90°N) average total and speciated AODs at 550 nm from the three aerosol reanalyses and the MRC. The top and bottom whiskers and the symbols represent, respectively, the 25% and 75% percentiles and the medians of monthly-binned AOD distributions.

**Figure 7**. As per Figure 6, but for different latitudinal belts.

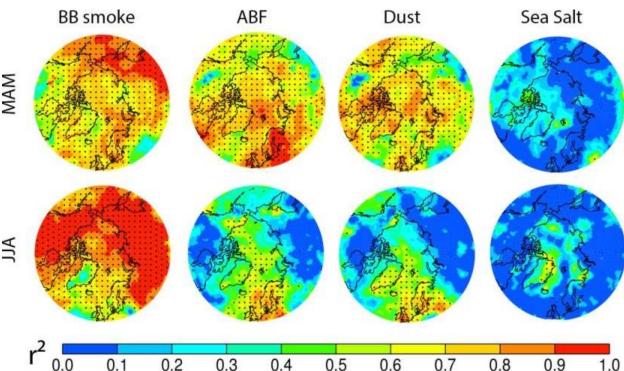

5.2 Interannual variability of AOD in the Arctic

5.2.1 General features of AOD Interannual variability

There are, as can be seen in Fig. 2 (and supported by the MAM/JJA discussion in Sec. 4), significant interannual AOD variabilities, especially for sites close to boreal fire sources. For example, the summertime peak of the total AERONET AOD at Bonanza Creek, Alaska, is around 0.6 - 0.8 in 2004, 2005, and 2019, while it is <~ 0.1-0.2 for other years. The year to year factor relating high- and low-amplitude summertime peak AOD values at Yakutsk, Siberia, can be 6 fold. The MRC shows that these large interannual variabilities are fairly consistent with AERONET FM AOD variabilities and are very likely attributable to interannual variabilities in BB smoke.

For sites far from smoke sources, such as Ittoqqortoormiit on the east coast of Greenland, Hornsund in Svalbard, and Thule on the northwest coast of Greenland, the high-amplitude peak AODs are about 2-3 times the low-amplitude peak AODs. The interannual spring/summer variability is largely associated with BB smoke as suggested by the MRC and the coherent variation of the AERONET FM AOD (c.f. Figures 6 and 7). Some of the strongest AOD events reported in previous studies have been shown to be associated with the long-range transport of BB smoke. For instance, the strong AOD peak in the summer of 2015 over Hornsund and Andenes was related to a series of

intense fires that originated in North America (Markowicz et al., 2016). The strong AOD peaks measured in August 2017 over Resolute Bay, Eureka and Thule were most probably related to intense-fire-induced pyroCB events in British Columbia and the longrange transport of high-altitude smoke (Ranjbar et al., 2019; Das et al., 2021). The high amplitude AOD peak in the spring of 2006 over Hornsund was traced to agricultural fires in Eastern Europe (Stohl et al., 2007). The summer, 2004 boreal fires in North America led to the maximum-amplitude AOD peaks (Fig. 2) for the two Alaskan sites and enhanced AOD on a pan-Arctic scale (Stohl et al., 2004). Some of the high-amplitude AOD peak events were recorded during intensive field campaigns. These included the ARCTAS/ARCPAC multi-platform campaign in the summer of 2008 (Matsui et al., 2011; Saha et al, 2010; McNaughton et al., 2011) and the NETCARE research vessel (Canadian Arctic) campaign in the spring of 2015 (Abbatt et al., 2019). Some of the BB smoke events cause short-term record-high AOD, and some lasted weeks to months, resulting in high monthly mean AOD. The statistics of extreme AOD events, and implications for the impact of regional biomass burning processes are provided in Part 2.

**Figure 8.** Percentage of interannual MRC variability of MAM (upper panel) and JJA (lower panel) seasonally-binned, total AOD at 550 nm explained by biomass-burning smoke AOD, ABF, dust, and sea salt aerosols respectively. Values in dotted area is statistically significant at the 95% level using a two-tailed Student *t* test.

745

746

747

It can be observed in Fig. 6 that the simulated interannual (60-90°N) AOD variability is mostly attributable to the large interannual variability of smoke AOD (interannual variability as measured by the size of the whisker bars). This is consistent across all the reanalysis products. For March and April, the contribution from sulfate/ABF is as important as BB smoke, if not larger. The interannual variation of dust AODs, as indicated with MERRA-2 and NAAPS-RA data, is non-negligible in MAM.

Regarding spatial distribution, Fig. 8 shows the percentage of interannual variabilities of spring and summer Arctic AOD explained by different aerosol species as computed from MRC AODs for 2003-2019. The fact that both MAM and JJA interannual variabilities are mostly explained by BB smoke (maximal r² values) is consistent with the correlation of monthly AOD time series shown in Fig. 2 and 6. The JJA r² values for BB smoke are generally larger than the MAM values and lower over the North Atlantic, the Norwegian Sea and Greenland than over North American and Eurasian sectors. Smoke explains 60%-80% of MAM and, with the exception of Greenland, about 80% of JJA AOD interannual variabilities north of 70°N. JJA values over the North American and Eurasian sectors (>60°N) represent about 100% explained variation. The second-largest contributor is ABF/sulfate and dust for MAM and to a lesser extent for JJA. Contribution from sea salt is weak and only statistically significant east of Greenland in JJA.

The explained variation by MAM ABF/sulfate is above 80% over the industry- and population-concentrated European and northeast North American sectors and their outflow regions into the North Atlantic, Greenland Sea, Norwegian Sea, and the Arctic Ocean. Values decrease to above 60% over Europe in general and the European Arctic (including water). Dust, possibly from Asian and high-latitude sources, could explain some of the interannual AOD variabilities over some regions (e.g., Greenland and the Greenland Sea in JJA as well as the North Pacific and the Arctic ocean in MAM). However, there exist large uncertainties in this evaluation based on the weaker verification scores of CM compared to FM AOD (Tables 2,3,4) and, for example, only the CAMSRA reanalyses considers high-latitude dust. Co-variability of species e.g., BB smoke, ABF/sulfate, and dust, is discernible in Fig. 8: this is likely due to the same transport pathways being employed from the mid-latitudes to the Arctic. It is also possible that these species covary because of artifacts introduced by intrinsic treatment in AOD data assimilation for low AOD situations (Zhang et al., 2008).

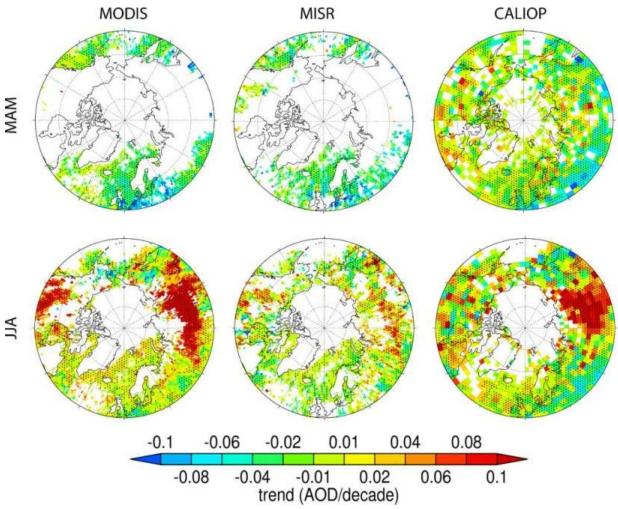

5.3 Total and speciated AOD trends over 2003-2019

The total AOD springtime and summertime trends derived from MODIS and MISR over 2003-2019 as well 2006-2019 from CALIOP are presented in Fig. 9. Valid trend analysis is, because of the scarcity of valid Arctic retrievals, mostly limited to south of 70°N and the north Atlantic region (with less MODIS and MISR coverage in MAM than in JJA and, for reasons mentioned in Sect. 5.1, less CALIOP coverage in JJA than MAM).

794 795

#### 5.3.1 AOD springtime trends

A generally negative total AOD MAM trend over the 50-60°N belt and the North Atlantic 796 797 is shown in Fig. 9. The largest-amplitude negative trend of Fig. 9 (-0.06 to -0.10) 798 AOD/decade) occurs over Europe: this is most likely due to a decrease in ABF/sulfate 799 from decreased anthropogenic emissions (as we will see in the discussion surrounding 800 the reanalyses of Fig. 10). The CALIOP trend is moderately more negative than the 801 MODIS and MISR trends. This might, again, be attributable to the shorter length of the 802 data record (where earlier and more polluted years of 2003-2006 for Europe and North America were not included) and/or the CALIOP daytime signal to noise issues. The Fig. 803 10 reanalyses all show a negative pan-Arctic total AOD trend (-0.01 to -0.02 804 805 AOD/decade) except for a near-zero CAMSRA trend over the Arctic ocean and a very slight positive trend over boreal North America. The reanalyses collectively suggest that 806 807 the strong negative trend over the southeast Siberian and East Asian outflow region is 808 associated with a decrease in BB smoke, and, perhaps, a more moderate decrease in 809 ABF/sulfate from NAAPS-RA and MERRA-2. Other consistent features shared by the 810 reanalyses include a negative ABF/sulfate trend over Europe due to decreased 811 anthropogenic emissions (Breider et al., 2017), and a weak positive North Atlantic sea 812 salt trend due possibly to an observed increase in cyclonic activities (Rinke et al., 2017; 813 Waseda et al., 2021; Valkonen et al., 2021). It is notable that NAAPS-RA (and MERRA-2 after 2008) do not incorporate an ABF emission trend. This means that their 814 815 ABF/sulfate trends are mostly driven by a negative AOD correction applied by the data 816 assimilation systems. This corroborates the negative trend in ABF/sulfate.

**Figure 9.** MODIS, MISR, and CALIOP MAM and JJA AOD trends for the time periods and AOD wavelengths given in the Figure 3 caption. Trends in the dotted areas are statistically significant.

#### 5.3.2 AOD summertime trends

The most prominent Fig. 9 JJA feature is the strong and positive total AOD trend (> 0.10 AOD/decade) that appears, to a varying, sensor-dependent, spatial extent, over vast regions of Siberia and North America. All the reanalyses indicate that this trend is attributable to a significant increase in BB smoke AOD (Fig. 11). This is coherent with the FLAMBE-derived, MODIS-hotspot-based emission inventory of Fig. 12 that shows positive regional trends in BB emissions north of 50°N (and with other BB emission inventories such as GFED and GFAS inventories shown in Fig. 2 of McCarty et al., 2021). At the same time, there are negative trends in total AOD over Alaska, northeast of Russia, and the North Pacific from the reanalyses, which is seemingly consistent with the trend in remote sensing AODs (though for some satellite datasets the coverage is spotty in these regions). These trends are driven by BB smoke and smoke emission trends as suggested by all the reanalyses and FLAMBE. In addition, there is a

continued negative trend from MAM to JJA in ABF/sulfate over Europe, which is also reflected in total AOD trend, as shown in the reanalyses. This is consistent with the discernible negative though weak trend from the three sensors. JJA AOD trends in dust and sea salt are neutral from the reanalyses.

838 839

835

836

837

# 5.3.3 High Arctic AOD trends

840 841 For the high Arctic, AOD trends will hardly be seen with the same color scale as those for the lower latitudes because of lower AOD. Thus, they are shown separately in Fig. 842 13, where time series of MAM and JJA area-mean total, smoke, and ABF/sulfate AODs 843 844 are shown individually and for all the reanalyses and the MRC over the 2003-2019 time 845 period. There is a negative trend across models in MAM total AOD with -0.017 AOD/decade (-18%/decade), and a positive trend in JJA total AOD with 0.007 846 847 AOD/decade (8%decade) based on the MRC. The largest contributor to the MAM 848 negative trend is ABF/sulfate, and the smoke AOD trend is also negative. In the 849 summertime, ABF/sulfate trend continues to be negative; however, smoke AOD trend 850 turns positive, with a high positive trend of 0.010 AOD/decade (22%/decade). BC AOD 851 trends from MERRA-2 and CAMSRA are dominantly driven by smoke AOD, and have 852 similar trends with smoke AOD in percentage per decade. The negative trend in ABF/sulfate AOD is in line with the decreasing trend in surface sulfate mass 853 854 concentrations measured over Arctic observational sites (e.g., Breider et al., 2017). The 855 negative trend in MAM and positive trend in JJA for smoke AOD are consistent with the 856 seasonally-binned and latitutude-belt-binned mean BB emission trends shown in Fig. 12 857 (e,f). The trend magnitudes of the three aerosol reanalyses are different, but the signs are the same, corroborating the trend analysis results based on the MRC. These results 858 859 are consistent with the trend analysis for lower latitude source regions as shown in Fig. 860 9-11. All these results also demonstrate that the Arctic aerosol baseline is changing 861 quickly (Schmale et al., 2021), and the estimation here could contribute to the 862 understanding and quantification of this new baseline.

874

# 5.3.4 Possible causes of BB smoke AOD trends

Besides rising surface temperature, climate phenomena such as the El Niño-Southern Oscillation (ENSO), Arctic Oscillation (AO), and Pacific Decadal Oscillation (PDO) have been reported as affecting fire activity in several key boreal fire source regions (Balzter et al., 2007; Macias Fauria and Johnson, 2007; Kim et al., 2020). However rising surface temperature, probably contributes more to the observed trend in BB emission in the high latitudes. With the rising surface temperature, lightning activity and lightningcaused wildfires in summertime high latitude regions were observed to increase in the past two decades (Zhang et al., 2021; Bieniek et al, 2020; Coogan et al., 2020). In addition, agricultural fire activity in Eastern Europe and European Russia (peaking at April to May) and central Asia and Asiatic Russian (peaking in August) (Korontzi et al,

2006; Hall et al., 2016) also affects the seasonality of total BB emissions. The MAM negative trend in BB smoke may be relevant to a strengthening of agriculture burning regulations in the later part of the time period. For example, the MAM BB emission maxima in 2003, 2006 and 2008 are all associated with wide-spread springtime agriculture burnings in high latitudes (Korontzi et al, 2006; Stohl et al., 2007; Saha et al., 2010). The aforementioned climate oscillations also modulate interannual variations of the transport of pollutants from the mid latitudes to the Arctic (e.g., Eckhardt et al., 2003; Fisher et al., 2010). Compared with the BB emission trend, trend in the atmospheric processes, e.g., transport and removals, probably plays a secondary role in the Arctic smoke AOD trend. This is illustrated by the similarity in spatial patterns of smoke AOD and BB emission trends, and the coincidence of peak years for emissions and the high Arctic area-mean smoke AODs. For example, 2012 and 2019 are associated with JJA peaks in emission and high Arctic smoke AOD, while 2003 and 2008 correspond to MAM peaks in both (Figs. 12 and 13).

**Figure 10**. Trends of MAM 550 nm total AOD and contributions from BB smoke, ABF/Sulfate, dust and sea salt from NAAPS-RA, MERRA-2 and CAMSRA and the MRC.

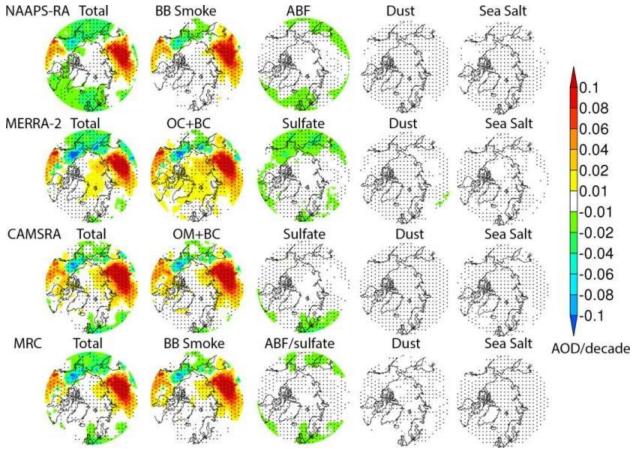

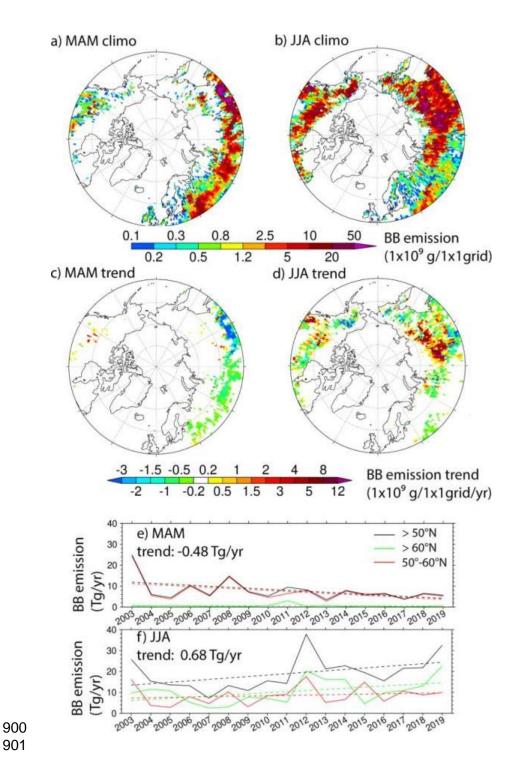

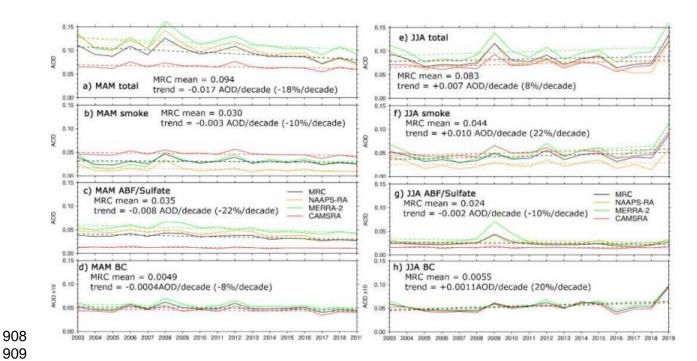

Figure 11. Same as Fig. 10, except for JJA.

**Figure 12.** MAM/JJA seasonal total BB smoke particle emission climatology and trend for 2003-2019 derived from FLAMBE (a-d). e) and f) Time series of seasonally-binned area-means (>50°N, >60°N and 50-60°N) BB smoke (PM2.5 particle) emissions for MAM and JJA respectively. Dashed lines represent linear trends, which are statistically significant with a confidence level of 95%. The trend for north of 50°N is displayed in the legends.

**Figure 13.** Time series of MAM and JJA 70°-90°N area mean total, BB smoke, ABF/sulfate and BC AODs from the reanalyses and the MRC. Solid lines are AODs, and dashed lines are linear regressions indicating trends. For easier visualization, BC AOD is multiplied by 10.

The quality control processes applied on the AOD retrievals from MODIS, MISR, and CALIOP help to generate a consistent AOD climatology and trend near the Arctic. The cloud-clearing process on the MISR data and QA processes on the MODIS data removed a good volume of data (about 40% for MISR and MODIS). However, these QA processes help to retain only the best-quality data, which yield a closer magnitude of AOD for MODIS and MISR to AERONET AODs near the 70°N latitude circle (around or less than 0.1), compared to ~0.2 using regular level 3 MODIS and MISR data in Figs 20 and 23 of Tomasi et al., 2015, especially for springtime. The manual QA process on the AERONET AOD data also reveals more frequent cloud contamination in springtime than in summertime. Often artificial AOD values of zero are observed over the Arctic in CALIOP V4.2 L2 and L3 data, resulted partially from algorithmically setting altitude bins with retrieval filled values in the aerosol profile to zero, as these represent undetectable levels of faint aerosol (i.e., Toth et al., 2016; 2018). With AOD=0 values retained in the CALIOP V4.2 L2 data analysis (same processing in CALIOP V4.2 L3), the climatological seasonal mean AOD magnitude is much smaller (about half) than that shown in Fig. 3 and the AOD trends are slightly smaller than those in Fig. 9, although the spatial patterns of the seasonal AOD and trends are similar to those obtained with AOD data after removing the AOD=0 values (Fig. S2). After removing the pixels with filled and

zero values, CALIOP AOD seasonal spatial AOD distributions are similar to those from MODIS and MISR.

The total AOD at 550 nm from the three aerosol reanalyses are much more convergent in spatial distribution, magnitude, and seasonality in the Arctic compared to the climate models, and are similar to those from the remote sensors near the Arctic. For example, for AEROCOM models in Sand et al., 2017, MAM AODs averaged over nine Arctic AERONET sites (all included in this study) are an order of magnitude different for the highest and lowest AOD models, and peak AOD season varies among winter, spring and summer: In the CMIP5 models in Glantz et al., 2014, spring and summertime AODs over the Svalbard area also show an order of magnitude difference and there are different seasonality for some of the models. The possible reasons for the convergence of AOD in the reanalyses include 1) the hourly/daily resolved satellite-hotspot-based BB emissions used by these reanalyses apply fine-temporal and interannual-variabilityresolved emission constraints; 2) despite that the commonly assimilated satellite AOD (e.g., MODIS AOD in all three reanalyses) has limited coverage in the Arctic due to retrieval challenges of dealing with bright surfaces and high cloud coverage, the observational constraint of model fields through assimilation of AOD in the lower latitudes is effective in constraining Arctic AOD to a good extent through transport; 3) more accurate meteorology representations. It is reasonable that the AOD spread among the three reanalyses increases with latitude, and into the early months (e.g., March) when retrieval coverage for lower latitudes is less than summer months.

 Except for the chemical processes relevant to conversion of SO<sub>2</sub> to sulfate, the aerosol reanalysis products (or their underlying aerosol models) don't include other new particle formation processes that may be important over the Arctic open water/leads in Springtime or over packed ice during transitional summer to Autumn season (Abbatt et al., 2019; Baccarini et al., 2021). High latitude dust sources, e.g., glacier dust, which are present for some areas in the Arctic (Bullard et al., 2016), are only included in CAMSRA, despite that Arctic dust AOD in CAMSRA is much lower than those in the other two models (Fig. 6e).

To show the contribution of biomass burning on total AOD in the Arctic, we approximated BB smoke with the sum of BC and OC/OA from MERRA-2 and CAMSRA. This approximation is arguable: it is better suited for JJA than MAM, as the climatological seasonally-binned mean of Arctic AOD is dominated by BB smoke in JJA, which means that BC and OC/OC are mostly from BB sources, while the contribution of BC and OC/OA from anthropogenic sources is relatively higher in early spring (Figs. 4, 5). So smoke AOD is overestimated from MERRA-2 and CAMSRA and more so for MAM. This explains the larger difference in smoke AOD (ratio to total AOD) in MAM

than in JJA between the two reanalyses and NAAPS-RA, which explicitly tracks aerosol mass from BB sources (Figs. 4, 5, 6). While NAAPS-RA includes BC and OA from anthropogenic sources and sulfate into ABF, which is an arguably reasonable configuration for pollution species, as observational studies show a strong correlation between sulfate and elemental BC surface concentrations at pan-Arctic sites away from BB sources, indicating the sources contributing to sulfate and BC are similar and that the aerosols are internally mixed and undergo similar removal (Eckhardt et al., 2015). BB smoke is expected to have different vertical distributions from anthropogenic pollution if smoke is emitted above the boundary layer. Some estimates based on satellite observations near local noon have suggested that the fraction of smoke escaping the boundary layer is only ~10% (Val Martin et al., 2010), but taking account of the diurnal cycle of fire activity and potential for pyroconvection, the actual fraction of elevated smoke could be much larger (Fromm et al., 2010; Peterson et al., 2015; Peterson et al., 2017).

> Stratospheric aerosols from volcanic eruptions can contribute to the total AOD in the Arctic, especially for the four years after the Mount Pinatubo eruption in 1991 (Herber 2002). For our study period, the eruptions of Kasatochi, Redoubt, Sarychev, and Eyjafjallajökull in August 2008, March 2009, July 2009, and March 2010, respectively, would have affected the stratospheric AOD and thus total column AOD. However, these eruptions are at least one order of magnitude smaller than that of Pinatubo. The stratospheric AOD contribution to the Arctic background AOD is estimated to be relatively small at ~0.01 (from Fig. 16 of Thomason et al., 2018; non-Pinatubo affected years in Fig. 5 of Herber 2002), despite that locally and over a short period the AOD contribution can be large (e.g., O'Neill et al., 2012). All the reanalyses have some sort of SO<sub>2</sub> and sulfate representation from volcanic degassing emissions, but a full representation for explosive volcanic sources is lacking (except that MERRA-2 has time-varying explosive and degassing volcanic SO<sub>2</sub> before December 31, 2010). The volcanic influence on Arctic AOD, if detectable, would be reflected in the ABF/sulfate AOD in the reanalyses, but its contribution would be much smaller than the anthropogenic counterpart for our study period. It is also worth noting that volcanic activities are not the only influence on the stratospheric aerosol budget: pyroCB-injected BB smoke can also contribute to stratospheric AOD, as discussed earlier. Stratospheric BB smoke was also detected over the Arctic with lidar measurements during the MOSAiC campaign (Engelmann et al., 2021). Stratospheric injection of BB smoke associated with pyroCB events are not represented in the reanalyses, despite that BB emission associated with these pyroCB events are included in the emission inventories with possible large bias in emission amount and height.

Arctic shipping is often brought up as a potentially important source of BC for the Arctic in the future. All of the reanalyses include shipping emissions, although little interannual trend is considered especially for the late period in 2003-2019. However "Arctic shipping is currently only a minor source of black carbon emissions overall" according to the recent Arctic Monitoring and Assessment Programme (AMAP) report (2021).

## 7. Conclusions

Using remote sensing AOD retrievals from MODIS, MISR and CALIOP, and AODs from three aerosol reanalyses, including NAAPS-RA, MERRA-2, and CAMSRA, and ground-based AERONET data, we have reported the Arctic/High-Arctic AOD climatology, and trend for spring and summer seasons during 2003-2019.

1) Arctic AOD climatology: The total AODs from space-borne remote sensing and the aerosol reanalyses show quite consistent climatological spatial patterns and interannual trends for both spring and summer seasons for the lower-Arctic, where remote sensing data is available. AOD trends for the high Arctic from the reanalyses have consistent signs too. Climatologically, FM AOD dominates CM AOD in the Arctic. Based on the reanalyses, BB smoke AOD increases from March to August associated with seasonality of BB activities in the boreal region (>50°N); ABF AOD is slightly higher in MAM than in JJA; sea salt AOD is highest in March and decreases with time into later spring and summer; contribution of dust AOD to total AOD is non-negligible in April and May. The latitudinal gradient of AOD is larger in JJA than in MAM, consistent with observed more efficient removal in summertime (Garrett et al., 2011). Among aerosol species, BC is a very efficient light absorber, and climate forcing agent (e.g., Bond et al., 2013). We show that over the Arctic, the contribution of BC AOD from BB source overwhelms anthropogenic sources in both MAM and JJA, and more so in JJA during 2003-2019.

2) *Interannual AOD trend*: Total AOD exhibits a general negative trend in the Arctic in MAM, and strong positive trends in North Americas, Eurasia boreal regions (except Alaska and northeast Siberia) in JJA. For the high Arctic, the total AOD trend is -0.017/decade (-18%/decade) for MAM and 0.007/decade (8%/decade) for JJA based on the MRC. The total AOD trends are driven by an overall decrease in sulfate/ABF AOD in both seasons (-0.008/decade, or -22%/decade for MAM and -0.002/decade or -10%/decade for JJA), and a negative trend in MAM (-0.003/decade or -10%/decade) and a strong positive trend in JJA (0.01/decade or 22%/decade) from biomass burning smoke AOD. The decreasing trend in sulfate in the Arctic in recent decades is in line with other

studies using surface concentration measurement (e.g., Eckhardt et al., 2015). The smoke AOD trends are consistent with MODIS fire-hotspot-based BB emission trends over the boreal continents.

- 3) Impact of BB smoke on AOD interannual variability: The interannual variability of total AOD in the Arctic is substantial and predominantly driven by fine-mode, and specifically BB smoke AOD in both seasons and more so in JJA than in MAM. For AERONET sites close to BB emission sources, the difference in monthly total AOD can be 6-fold for high versus low AOD years. For remote regions away from BB sources, the interannual variability of total AOD can also be explained mostly by smoke AOD.
- 4) Overall performance of the aerosol reanalyses: The aerosol reanalyses yield much more convergent AOD results than the climate models (e.g., AeroCOM models in Sand et al., 2017; CMIP5 models in Glantz et al., 2014) and verify with AERONET to some good extent, which corroborates the climatology and trend analysis. Speciated AODs appear more diverse than the total AOD among the three reanalyses, and a little more so for MAM than for JJA. NAAPS-RA and MERRA-2 total and FM AODs verify better in the Arctic than CAMSRA, which tends to have a high bias in FM overall. The reanalyses generally perform better in FM than CM. The three reanalyses exhibit different latitudinal AOD gradients, especially in summertime, indicating different removal efficiencies. The emerging capability of assimilating OMI Aerosol Index (AI) to constrain absorptive aerosol amount, could potentially fill in the observational gaps for aerosol data assimilation in reanalyses over the Arctic (Zhang et al., 2021). With more advanced retrieval algorithms on the current space-borne sensors for over snow/ice, new sensors on future satellites, improvements on the underlying meteorology and aerosol representations in models, improvements in aerosol reanalysis are expected.

The results presented here provide a baseline of AOD spatiotemporal distribution, magnitude, and speciation over the Arctic during spring and summer seasons for the recent two decades. This will help improve aerosol model evaluations and better constrain aerosol radiative and potentially indirect forcing calculation to evaluate aerosol impact in the Arctic amplification. For example, the contribution of reduction in sulfate to Arctic surface warming in recent decades (e.g., Shindell and Faluvegi, 2009; Breider et al., 2017) could potentially be better quantified, with the caveat that speciated AOD have larger uncertainties than total AOD in the reanalyses. The AOD statistics could also provide background information for field campaign data analysis and future field campaign planning in a larger climate context. It is also recommended that climate

1092 models should take into account BB emissions besides anthropogenic climate forcers 1093

and BB interannual variabilities and trends in Arctic climate change studies.

## Appendix A. Summary of data used in the study

Products	Data	resolution	time
MODIS (Moderate Resolution Imaging Spectroradiometer) C6.1L3	550nm AOD	1°x1° monthly	2003-2019
MISR (Multi-angle Imaging SpectroRadiometer) V23	558nm AOD	1°x1°, monthly	2003-2019
CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarisation) V4.2L2	532nm AOD	2°x5°, monthly	2006-2019
AERONET (AErosol RObotic NETwork) V2L3	SDA total, FM, CM AOD at 550nm	6hrly, monthly	2003-2019
MAN (Marine Aerosol Network) Level2	SDA total, FM, CM AOD at 550nm	6hrly	2003-2019
MERRA-2 (Modern-Era Retrospective Analysis for Research and Applications, v2)	Total and speciated AOD at 550nm	0.5°lat x0.63°lon, monthly	2003-2019
CAMSRA (Copernicus Atmosphere Monitoring Service Reanalysis)	Total and speciated AOD at 550nm	0.7°x0.7°, monthly	2003-2019
NAAPS-RA v1 (Navy Aerosol Analysis and Prediction System reanalysis v1)	Total and speciated AOD at 550nm	1°x1°, 6hrly, monthly	2003-2019
MRC (Multi-Reanalysis-Consensus)	Total and speciated AOD at 550nm	1°x1°, monthly	2003-2019
FLAMBE (Fire Locating and Modeling of Burning Emissions) v1.0	BB smoke emission flux	1°x1°, monthly	2003-2019

1096 1097 1098

Note: These are final form of data used in the result section. Some pre-processing and quality-control were applied to remote sensing data as described in the data section.

#### Abstract

16

17 In a companion paper (Part I of the study), we present an Arctic aerosol optical depth (AOD) climatology and trend analysis for 2003-2019 spring and summertime periods 18 derived from a combination of aerosol reanalyses, remote sensing retrievals, and 19 20 ground observations. Continued from the previous discussion and as the second part of 21 the study, we report the statistics and trends of Arctic AOD extreme events using the 22 U.S. Navy Aerosol Analysis and Prediction System ReAnalysis version 1 (NAAPS-RA 23 v1), the sun photometer data from the Aerosol Robotic Network (AERONET) sites, and 24 the oceanic Maritime Aerosol Network (MAN) measurements. Here, extreme AOD 25 events are defined as events with AOD exceeding the 95th percentile (denoted 26 "AOD<sub>95</sub>") of AOD distributions for given locations using 6 hourly or daily AOD data. 27 While AERONET and MAN data estimate that the Arctic median 550 nm AOD value to 28 be 0.07, the 95th percentile value is 0.23. Such extreme events are dominant by finemode aerosol particles, largely attributable to biomass burning (BB) smoke events for 29 30 the North American Arctic, the Asian Arctic, and most areas of the Arctic Ocean. 31 However, extreme AOD events for the lower European Arctic is more attributable to 32 anthropogenic/biogenic particles. The extreme-event occurrence dominance of sea salt is largely limited to the North Atlantic and Norwegian Seas. The extreme AOD 33 34 amplitudes of anthropogenic and biogenic fine mode and sea-salt AOD are, however, 35 significantly lower than those regions where extreme smoke AOD is dominant. Even for 36 sites distant from BB source regions, BB smoke is the principle driver of AOD variation 37 above the AOD<sub>95</sub> threshold. 38

Maximum AOD values in the high Arctic in 2010-2019 have increased compared to 2003-2009, indicating stronger extreme BB smoke influence in more recent years. The occurrence of extreme smoke events tended to be more equally distributed over all months (April-August) during the 2003-2009 period while being more concentrated in the late season (July-August) during the 2010-2019 period. The temporal shift of the occurrence of AOD extreme events is likely due to improved control of early-season agriculture burning, climate change related increases in summertime lightning frequencies, and a reduction in anthropogenic pollution over the 2010-2019 period.

### 1. Introduction

- Warming faster than the rest of the world, the Arctic is a focal point for global warming
- 49 (Serreze and Francis 2006; Serreze and Barry 2011). Interactions between the
- atmosphere, ocean, land surface, and sea ice, compounded by numerous human
- 51 factors make the Arctic climate system challenging to predict, with large diversity
- 52 between current numerical model outcomes (IPCC 2021). Aerosol particles from
- anthropogenic and natural sources affect regional energy balance through direct
- radiative processes and indirect cloud processes (Quinn et al., 2008; Engvall et al.,
- 55 2009; Flanner, 2013; Sand et al., 2013; Markowicz et al., 2021; Yang et al., 2018).
- When deposited on the surface of snow and ice, light-absorbing aerosol particles,
- 57 including dust and black/brown carbon from biomass burning and anthropogenic
- emissions, can trigger albedo feedbacks and accelerate melting (Hansen & Nazarenko,
- 59 2004; Jacobson, 2004; Flanner et al., 2007; Skiles et al., 2018; Dang et al., 2017; Kang
- 60 et al., 2020).
- Arctic aerosol concentrations are in general relatively low, with spring and summertime
- median/mean 550 nm aerosol optical depths (AOD) of 0.06 0.07 (e.g., Tomasi et al.,
- 2007; Saha et al., 2010; AboEl-Fetouh et al., 2020) as compared to a global mean of
- roughly 0.20 over land and 0.12 over water (e.g., Levy et al., 2010; Lynch et al., 2016;
- Shutgers et al., 2020; Sogacheva et al., 2020). Extreme AOD events do occur within the
- Arctic, mostly associated with large-scale transport from lower latitudes. Biomass
- burning (BB) smoke from boreal wildfires, for example, can episodically result in record-
- 68 high Arctic AOD (Myhre et al. 2007; Stohl et al., 2007; Markowicz et al., 2016; Ranjbar
- 69 et al., 2019). Some strong smoke events were recorded during intensive field
- 70 campaigns, including the ARCTAS/ARCPAC campaign in the summer of 2008 (Matsui
- et al., 2011; Saha et al, 2010; McNaughton et al., 2011) and the NETCARE research
- vessel (Canadian Arctic) campaign in the spring of 2015 (Abbatt et al., 2019). More
- 73 extreme BB smoke cases in the Arctic can be found in Sec. 3.3.
- 74 Extreme AOD events cause large perturbations in regional energy balance (e.g., Myhre
- et al., 2007; Stone et al., 2008; Lisok et al., 2018). For example, a BB smoke transport
- 76 event from North America to the High Arctic region of Svalbard in early July 2015 led to
- 500 nm AOD exceeding 1.2 at Spitsbergen (Markowicz et al., 2016). The two-day mean
- aerosol direct radiative forcing was estimated to cause overall cooling (-79 W/m<sup>2</sup> at the
- 79 surface and -47 W/m<sup>2</sup> at the top of the atmosphere). However, a corresponding
- atmospheric heating rate profile was solved of up to 1.8 K/day within the BB plume
- 81 (Lisok et al., 2018). Over bright snow and ice surfaces, or above clouds, top of the
- atmosphere BB smoke forcing can turn from negative to positive (i.e., warming) by
- reducing columnar albedo (Yoon et al., 2019; Markowicz et al., 2021).

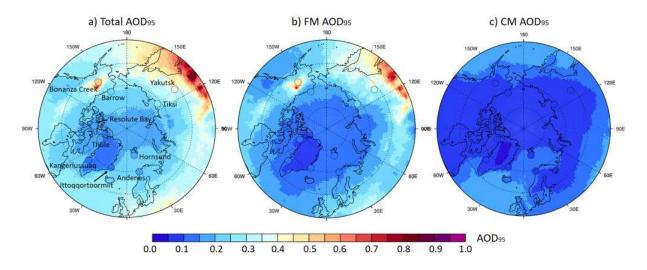

- 84 Although the microphysical impacts of aerosol particles on Arctic clouds and
- precipitation processes are generally more difficult to measure and quantify, Arctic
- 86 clouds are generally believed more sensitive to changes in the relatively low
- 87 concentration of aerosols compared with the lower latitudes (Prenni et al., 2007;
- 88 Mauritsen et al. 2011; Birch et al., 2012; Coopman et al., 2018; Wex et al., 2019).
- 89 Extreme aerosol events correspond with an influx of relatively large concentrations of
- 90 potential cloud condensation nuclei (CCN) and/or ice nucleating particles (INP), in what
- 91 is otherwise a comparatively pristine background environment (Mauritsen et al. 2011;
- Leck et al., 2015). Such extreme events will accordingly have observable impacts on
- cloud albedo, lifetime, phase, and probability of precipitation (e.g., Lance et al., 2011;
- 24 Zhao and Garrett 2015; Zamora et al., 2016; Bossioli et al., 2021) and further influence
- 95 the regional energy budget. Dry deposition (and blowing snow processes), as well as
- 96 wet deposition of BB smoke particles, can also trigger sustained surface radiative
- 97 forcing by inducing surface snow discoloration and attendant surface albedo reduction
- 98 (Warren and Wiscombe, 1980; Stohl et al., 2007; Hadley and Kirchstetter, 2012).
- 99 Extreme aerosol events, especially BB smoke events, often modulate the interannual
- variability of Arctic AOD (Part 1 of this study; Xian et al., 2022), as well as to the total
- annual aerosol budget in the Arctic. The modeling study by DeRepentigny et al. (2021)
- shows, in comparison with BB emissions characterized by a fixed annual cycle, that the
- inclusion of interannually varying BB emissions leads to larger Arctic climate variability
- and enhanced sea-ice loss. Their finding illustrates the unique sensitivity of climate-
- relevant processes to regional aerosol interannual variability, and further suggests that
- extreme aerosol events play an important Arctic climate role. It is accordingly important
- to understand how extreme aerosol-event statistics change with the changing Arctic
- 108 climate to better inform climate simulations and our baseline understanding of how the
- 109 region is poised to evolve.
- 110 This is the second of two papers examining spring and summertime Arctic AOD
- climatologies and their trends. In Part 1 (Xian et al., 2022), we report a baseline Arctic
- AOD climatology from AERONET, MAN, and satellite AOD data for those two seasons
- and the skill of three reanalysis AOD products in simulating those climatologies. The
- 114 reanalyses and space-borne retrievals show consistent climatological spatial patterns
- and trends. Overall, AOD exhibits a multi-year negative trend for springtime and a
- positive trend for summertime during 2003-2019, due to an overall decrease in
- 117 sulfate/anthropogenic pollution and a significant summertime increase in BB smoke.
- This second paper focuses on the statistics and trends of extreme Arctic AOD events.
- The data and methods we employ are described in Sec. 2, while results are provided in
- 120 Sec. 3. Conclusions are presented in Sec. 4.
  - 2. Data and Methods

## 122 2.1 AERONET

- 123 The AErosol RObotic NETwork (AERONET) is a federated ground-based sun
- 124 photometer network with over 600 active sites across the globe. AERONET's Cimel
- 125 photometers measure sun and sky radiance at several wavelengths, ranging from the
- near-ultraviolet to the near-infrared. While the exact set of bands depend on the model,
- all Cimel configurations include 440, 670, 870 and 1020 nm bands. All the sites used
- here also included 380 and 500 nm bands. The network has been providing high-
- accuracy daytime measurements of aerosol optical properties since the 1990s (Holben
- et al., 1998; Holben et al., 2001). Cloud-screened and quality-assured Version 3 Level 2
- 131 AERONET data (Giles et al., 2019) are used in this study.
- Fine mode (FM) and Coarse mode (CM) AOD at 550 nm are derived based on the
- Spectral Deconvolution Method (SDA) of O'Neill et al. (2003) and averaged over 6 hr
- time bins. The same ten AERONET sites employed in Part 1, were selected (Fig. 1) for
- this study. Those sites had been chosen based on their regional representativeness as
- well as the availability of data records between Jan 2003 and Dec 2019 period of study.
- Optically thin clouds, mostly cirrus, occasionally contaminate CM aerosol retrievals in
- Level 2, Version 3 AERONET data (Ranibar et al., 2022). Data were manually
- inspected, and retrievals screened, using MODIS imagery at visible wavelengths from
- NASA Worldview (https://worldview.earthdata.nasa.gov/ last accessed 15 May 2022)
- and by comparing 6-hrly NAAPS-RA with AERONET AODs. This step is likely an
- incomplete one, given the likely lesser sensitivity of MODIS imagers to thin clouds
- (Marguis et al., 2017). As such, CM AODs that deviate by more than the 3-sigma level
- from the background climatological mean were also removed (as per AboEl-Fetouh et
- 145 al., 2020).
- 146 2.2 AERONET Marine Aerosol Network AOD Datasets
- 147 The Marine Aerosol Network (MAN) is part of the broader AERONET global network: in
- this case however, it is limited to AODs collected over open water. Hand-held
- Microtops sun photometers are deployed during research cruises of opportunity
- (Smirnov et al., 2009, 2011). Data processing is similar to that of AERONET with
- product nomenclature similar to AERONET. Level 2 data acquired above 70°N in the
- 152 2003-2019 period are used in this study. FM and CM AOD at 550 nm are derived using
- the SDA and averaged over 6 hr time bins.
- 154 2.3 NAAPS AOD reanalysis v1
- 155 The Navy Aerosol Analysis and Prediction System (NAAPS) AOD reanalysis (NAAPS-
- 156 RA) v1 was developed at the U.S. Naval Research Laboratory. It provides speciated

- AOD and concentrations at a global scale with 1°x1° degree latitude/longitude and 6 hr
- resolution for 2003-2019 (Lynch et al., 2016). NAAPS-RA is driven by the Navy
- Operational Global Analysis and Prediction System (NOGAPS; Hogan and Rosmond,
- 160 1991), with satellite precipitation applied within the tropics to mitigate model
- precipitation errors (Xian et al., 2009). NAAPS-RA features assimilation of quality-
- 162 controlled AOD retrievals from MODIS and MISR (Zhang et al., 2006; Hyer et al., 2011;
- Shi et al., 2011). A first-order approximation of secondary organic aerosol (SOA)
- processes is adopted. Production of SOA from its precursors is assumed to be
- instantaneous and is included with the original anthropogenic species to form a
- 166 combined anthropogenic and biogenic fine (ABF) species. In other words, ABF is a
- mixture of sulfate, BC, organic aerosols and secondary organic aerosols from non-BB
- sources. Monthly anthropogenic emissions come from a 2000-2010 average of the
- 169 ECMWF MACC inventory (e.g., Granier et al., 2011). BB smoke is derived from Fire
- Locating and Modeling of Burning Emissions inventory (FLAMBE, Reid et al., 2009).
- 171 This version of FLAMBE uses MODIS, near-real-time satellite-based thermal anomaly
- data to initialize the smoke source where corrections that minimize the impact of inter-
- orbit variations are applied to the MODIS data (Lynch et al., 2016). FLAMBE processing
- is applied consistently through the reanalysis time period while a smoke-particle
- emission climatology and its spring and summertime trends (both north of 50°N and
- 176 60°N) are provided in Fig. 12 of Part 1. Dust is emitted dynamically and is a function of
- modeled friction velocity to the fourth power, surface wetness, and surface erodibility. In
- this model run, erodibility is adopted from Ginoux, et al., (2001) with regional tuning.
- 179 Sea-salt modeling is the same as Witek et al. (2007) and sea-salt emission is driven
- 180 dynamically by sea surface wind.
- Verification of monthly-binned NAAPS-RA total AODs at 550 nm using monthly-binned
- AERONET data from 10 Arctic sites (Table 1 and Fig. 2 of Part 1) shows that NAAPS-
- 183 RA is able to capture the AOD interannual variability. The spatial distributions and
- magnitudes of climatological and seasonal AOD averages and their trends for 2003-
- 185 2019 are also consistent with those derived from MODIS, MISR, and CALIOP (Part 1).
- 186 2.4 Data analysis methods
- Our study period is Jan 2003 to Dec 2019, the same principal study period as used in
- Part 1. We define extreme events as those corresponding to AOD exceeding the 95<sup>th</sup>
- percentile mark in 6 hr or daily AOD data at a specific location or across a given region
- 190 (the region north of 70°N for example). We employ 6 hr AERONET AODs as well as
- speciated daily and 6 hr NAAPS-RA AOD to depict the frequency and magnitude of the
- large FM AOD events. Pair-wised data are used for verification. "Pairwise" refers to
- those NAAPS-RA AODs that correspond to a resampled AERONET or MAN AOD
- whose  $\pm$  3hr bin contains at least one AERONET/MAN retrieval. Three independent

- aerosol reanalysis products were used in the Part 1 of the study. For this study, the
- NAAPS-RA reanalysis was chosen given its slightly better performance in terms of FM
- and total AOD bias, RMSE, and r<sup>2</sup> scores (Part 1), as well as its capability of separating
- 198 BB smoke from other aerosol species. To simplify some of the discussion below, we
- 199 frequently employed the symbol "AOD<sub>n</sub>" to represent the AOD associated with the n%
- 200 percentile of its cumulative (histogram) distribution. One important application of this
- 201 AOD<sub>n</sub> formulation is to employ a particular value (AOD<sub>95</sub>) as a threshold for the
- definition of extreme events (see Section 3.1 below). AOD<sub>75</sub>, AOD<sub>90</sub>, AOD<sub>99</sub>, AOD<sub>99.5</sub>
- 203 and maximum AOD are also calculated to show AOD gradients for high AODs. A local
- 204 extreme total AOD event for the NAAPS-RA means AOD > AOD<sub>95</sub> for the model grid
- cell of 1° x 1° (Latitude/Longitude). Again, we define the Arctic and the high-Arctic as
- regions north of 60°N and 70°N respectively. To reference source influences from
- 207 lower-latitude, the area of 50°N-90°N is included for context.
- 208 3. Results
- 209 Regional statistics and trends of extreme AOD events are presented in this section: 6-hr
- 210 AERONET AOD as well as speciated daily and 6-hr NAAPS-RA AOD are employed to
- 211 characterize the frequency and magnitude of strong FM AOD events.
- 212 3.1 Verification of NAAPS-RA AOD over the Arctic
- 213 The reanalysis performance for 6-hr time bins was evaluated in order to study extreme
- events. Our choice of AOD<sub>95</sub> as an extreme event threshold was influenced by the fact
- 215 that it was an upper-limit cumulative probability indicator that was robust. We reasoned,
- 216 at the same time, that it should be comparable with the analog parameter derived from
- 217 NAAPS-RA. Figure 1 displays NAAPS-RA AOD<sub>95</sub> overplotted with those from the ten
- 218 selected AERONET sites for spring and summertime 2003-2019. NAAPS-RA appears
- 219 to successfully capture the AOD<sub>95</sub> amplitude and spatial pattern, as well as those of FM
- AOD<sub>95</sub> and CM AOD<sub>95</sub>. It also shows that FM is the main contributor to AOD<sub>95</sub> in the
- 221 Arctic.

**Figure 1.** Total, FM and CM AOD at the 95th percentile (AOD<sub>95</sub>) for the March-August time frame from the NAAPS-RA and the ten AERONET sites based on 6hrly data between 2003-2019.

Detailed geographical coordinates of the ten AERONET sites employed in our study are included in Table 1, as well as the simulation performance indicators of NAAPS-RA 550 nm total, FM and CM AOD. These AERONET parameters are an analogue to parameters used in the first part of the study and its Table 1 statistics, except that the averaging period extends across both the spring and summer seasons, as the averaging period is mostly confined to the April-August time frame. NAAPS-RA performance indicators relative to MAN data are shown in Fig. S1 and S2.

NAAPS-RA performance for this large averaging period is reasonable for FM and total AOD, though it is less skillful at predicting CM AOD. The FM AOD exhibits an average (Table 1) bias over all stations of -0.01, a root mean square error (RMSE) of 0.08 and a coefficient of determination (r²) of 0.66. RMSE values for total and FM AOD are generally large for sites vulnerable to strong smoke influence, e.g. Bonanza Creek, Barrow, Tiksi and Yakutsk. Total AOD r² values are mostly between 0.5-0.7, except for Hornsund, Kangerlussuaq and Ittoqqortoormiit. FM AOD r² values exceed those of the total AOD for all sites except Kangerlussuaq. The 6-hr-binned Table 1 total AOD bias is similar to the monthly-binned NAAPS-RA bias results of Table 2, Part 1. This is due to the numerous 6-hr samples included in the AERONET bias averaging. In contrast, the Table 1 RMSE values are roughly doubled, and the r² values drop by about 30% relative to those of Tables 3 and 4 of Part 1. This suggests Table 1 model shortcomings in capturing finer temporal-scale AERONET-AOD variations. This is also consistent with model performance for regions other than the Arctic, and is generally a common result for numerical aerosol models (Lynch et al., 2016; Yumimoto et al., 2017)

The lesser CM vs FM skill of the NAAPS-RA might be a reflection of AERONET limitations as one approaches typical instrumental errors ~ 0.01 in total AOD or they could be a reflection of simulation and / or reanalysis limitations as one approaches very small values of CM AOD. The lack of model representation of CM smoke and possible soil particles associated with severe burning events may also contribute. At the same time, it must be recognized that residual cloud contamination in AERONET and MAN data cannot be ruled out as a "false" indicator of poor simulation skill. Cloud screening issues aside, a lesser CM vs FM correlation skill is a common feature of both the Table 1 and Table 4 (Part 1) reanalyses. However, modeled monthly CM AOD correlation is slightly more skillful than the averages derived from 6 hr data (Table 4 in Part 1 vs Table 1) inasmuch as the seasonal CM signal associated with dust and sea salt aerosols are apparently better resolved in the former case. The better model skill in seasonal CM simulation is likely due to the relative insensitivity of the model to the higher frequency components of the reference data in the latter case. It is also noted that the NAAPS-RA is generally less skillful in the Arctic region relative to global reanalyses (c.f. Fig. 7 in Lynch et al., 2016). This is understandable given that there is little satellite-based AOD data available to constrain the model through assimilation in the Arctic compared to lower latitudes. We note however that Zhang et al. (2021) attempted to address this problem with assimilation of Ozone Monitoring Instrument (OMI) Aerosol Index. To date, no remedy for aerosol data assimilation has yet been implemented in a larger RAquality study.

**Table 1.** Geographical coordinates along with the total, FM and CM AOD statistics (2003-2019 depending on availability) for AERONET and 6-hrly NAAPS-RA 550 nm performance indicators versus AERONET. The last row shows the same statistics for MAN AODs acquired north of 70°N as the bias reference. These numbers are given as information: as indicated above the table statistics in Part 1 were explicitly computed using monthly binned data (which were, in turn, derived from the 6 hr data).

277 Shown in Figure 1 and Table 2 are NAAPS-RA and AERONET AOD<sub>95</sub> values for the 278 March-August time frame and the 2003-2019 period. The values of AOD<sub>95</sub> are high 279 (0.4~0.55) over Siberia and Alaska (and over the Yakutsk and Bonanza Creek AERONET stations) due to strong BB smoke influence. North of 70°N, the values are 280 281 mostly between 0.15 to 0.25, with the exception of Greenland where they are largely below 0.15 (weak values that are attributable to the high terrain). It is also shown that 282 283 (FM AOD)<sub>95</sub> has similar spatial distribution and magnitude as AOD<sub>95</sub>, suggesting the dominant contribution of FM to AOD<sub>95</sub>. Contribution of CM is relatively larger over the 284 North Atlantic and European Arctic, though (CM AOD)<sub>95</sub> and (FM AOD)<sub>95</sub> are 285

The site-by-site, total, and FM AOD ranges are also shown in Fig. 2 from the 6-hr
AERONET data for all 550 nm retrievals acquired between 2003-2019. In general, the

comparable in these regions.

286

297

NAAPS-RA largely captures the AERONET FM and total AOD range. This includes, for example, the AERONET AOD $_5$  to AOD $_{95}$  values (0.02 to > 0.10 for most sites), and the

example, the AERONET AOD $_5$  to AOD $_{95}$  values (0.02 to > 0.10 for most sites), and the larger 0.02 to 0.4-0.6 range of sites with known strong BB influence (notably Bonanza

292 Creek, Tiksi, and Yakutsk). Mean and median AODs are also comparable to AERONET

values. Maximum AERONET FM AODs vary between 0.5 (Ittoqqortoormiit) to < 2.0 for

294 most sites and around 3.0 for sites with strong BB smoke influence (see also Table 2).

295 Maximum NAAPS-RA AOD values are often biased low, which is a common challenge

for global aerosol models (e.g. Sessions et al., 2015; Xian et al., 2019).

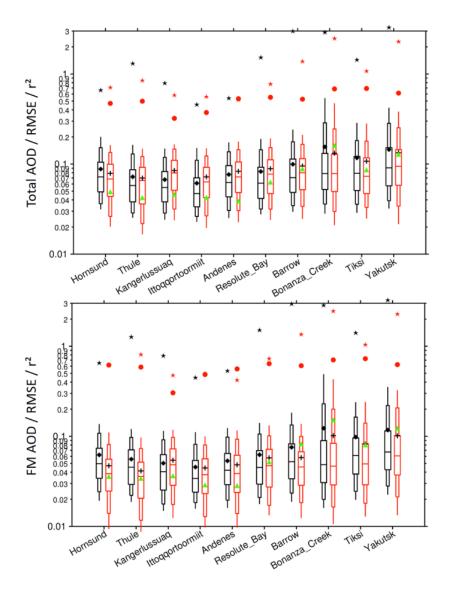

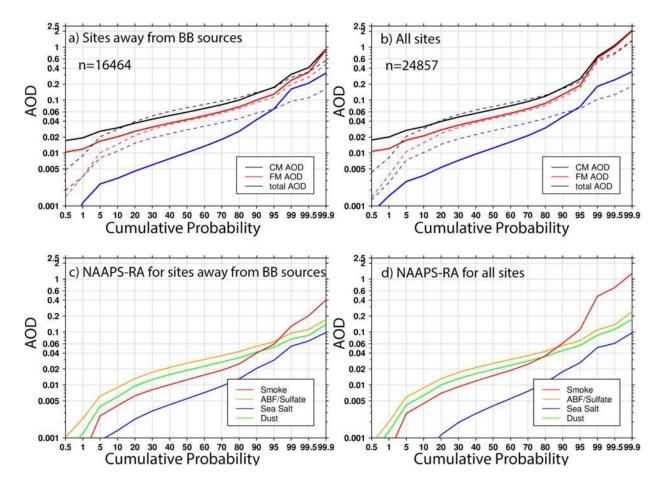

Figure 2. Comparison of the 6-hrly 550 nm total (top) and FM AOD (bottom) of the NAAPS-RA (red) at 95, 90, 75, 50, 25, 10, and 5% percentiles (respective, sequential features of the doubled spear-like symbols from the top tip to the bottom tip) with pairwise AERONET V3L2 data (black) for the ten AERONET sites of Table 1 and Fig. 1 for the 2003-2019 time period. Also shown are the site means of the NAAPS-RA and AERONET AODs ("+" and "♠" symbols respectively) and the NAAPS-RA RMSE ("♠"), the coefficient of determination (r²) between the NAAPS-RA and AERONET ("♠") and the maximum AERONET and NAAPS-RA AODs ("★" and "★" respectively). Note that values greater than 3.0 are not shown.

**Figure 3.** Upper panes (a, b): cumulative probability distributions of 2003-2019, 6-hr total, FM and CM AOD at 550 nm for AERONET V3 L2 data (solid curves) and pair-wise NAAPS-RA (dashed curves). Lower panes (c,d): cumulative probability distributions for the corresponding speciated AOD from the NAAPS-RA. Left hand panes (a,c): AOD for sites that are distant from BB source regions, including Barrow, Resolute Bay, Kangerlussuaq, Thule, Andenes, Hornsund and Ittoqqootoormiit (see the discussion of Table 2 for emission considerations with respect to the particular site of Barrow). Right-hand panels (b,d) are all sites. "n" represents the total number of 6-hrly data points over the 2003-2019 period, including a small amount of AERONET data from September besides the March-August time frame.

The cumulative probability distributions of 6-hr total, FM and CM AODs are shown in Fig. 3 for AERONET and pair-wise NAAPS-RA total and modal AODs and speciated AODs. The median AOD for all AERONET sites in the Arctic (all sites north of 60°N) for 2003-2019 is 0.07, while the AOD<sub>95</sub> extreme-event threshold is 0.23 with a dominant FM contribution. The CM AOD median for all measurements is 0.01, with a (CM AOD)<sub>95</sub> threshold of only 0.07. NAAPS-RA total AOD bias is, due to a relatively large positive bias in CM AOD of 0.01 below the 95% threshold, slightly positive (<0.01) for all sites

north of 60°N, and for the 20%-80% cumulative probability range (a positive bias that is generally evident in Table 1).

The negative bias found at the largest CM AOD values could conceivably be associated with an underestimation of the CM AOD generated by sea-salt aerosols in the presence of strong winds or CM smoke and soil particles associated with severe burnings. We should, however, reemphasize this caveat: despite the quality-control measures taken to filter out cloud-contaminated AERONET data, the impact of CM residual clouds may still influence estimates of CM AOD.

It worth noting that BB smoke plays a dominant role compared to other aerosol species above our AOD<sub>95</sub> extreme-event threshold (see Fig. 3c, d in particular and note that Fig. 3a, b shows the expected dominance of FM AOD). Even for sites distant from BB source regions, including Resolute Bay, Kangerlussuaq, Thule, Andenes, Hornsund, Ittoqqortoormiit, BB smoke is the principal driver of AOD variations above the AOD<sub>95</sub> threshold. To some extent, Barrow can be categorized as being a site that is distant from BB emissions. However, it is also relatively close to the region of Alaska fires, depending on dominant upstream winds and trajectories (see Eck et al., 2009 for details).

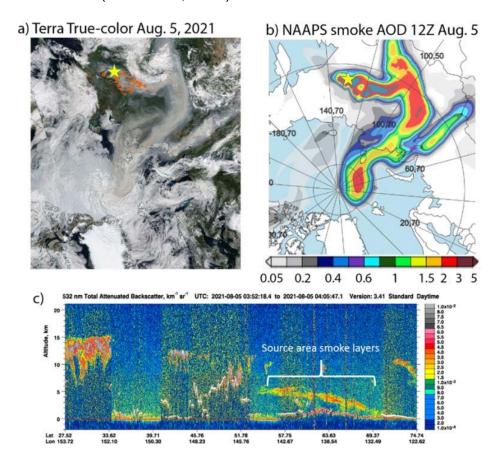

**Table 2.** AERONET V2L3 FM, CM, and total AOD at 550nm at different percentiles for the listed Arctic sites along with maximum AOD values in the third last column. "N" represents the total number of 6-hr AODs for 2003-2019. The percentage of extreme FM events relative to the number of extreme total AOD events (using our AOD<sub>95</sub> extreme-event threshold) is also shown in the last column. The 2<sup>nd</sup> to last row shows MAN statistics for data acquired north of 70°N.

	Total   FM   CM AOD at 550nm							FM

The modal and total AOD values at different percentile levels for the AERONET sites and MAN data collected north of 70° N are provided in Table 2. For sites closer to BB sources, including Bonanza Creek, Yakutsk, and Tiksi, the AOD<sub>99</sub> and (FM AOD)<sub>99</sub> values are larger than 1.0 while the maximum values are between 1.4-3.3. For the more distant sites, the AOD<sub>99</sub> and (FM AOD)<sub>99</sub> values vary between 0.23-0.46 while the maximum values are between 0.45-3.0 (1.5 for Resolute Bay and 3.0 for Barrow). FM event occurrences for the extreme total AOD events, range from 60-99%, with an

- average of 86%, and accordingly dominate CM events statistically. Sites closer to the
- 359 BB source regions show relative occurrences over 95%.
- Large particles like ash and soil components emitted from vigorous burning during
- extreme BB smoke events (Reid et al., 2005; Schlosser et al., 2017) can likely be
- detected as AERONET CM AOD (see, for example, the correlation between the FM and
- "weak" CM particle size distributions for Bonanza Creek in Fig. 9a of Eck et al. [2009]).
- The extreme AOD events described above are likely dominated by smoke. For
- example, (FM AOD)<sub>99</sub> is 1.64 at Bonanza Creek and 0.94 at Tiksi in Table 2. For events
- with FM AOD greater than (FM AOD)<sub>99</sub>, the associated CM AOD means at the two sites
- showed significantly larger values of 0.05 and 0.03, respectively (significantly larger
- relative to, for example, the CM AOD means in Table 1). The coherency of the
- associated CM AOD mean increase with the FM AOD mean increase suggests the
- 370 presence of detectable CM smoke and/or soil particles induced by severe burning. The
- inability of the model to simulate potential CM smoke or soil components associated
- with severe burning could be a contributing reason as to why it performs less well in
- 373 predicting CM AOD near BB sites.
- 3.3. Extreme biomass burning smoke AOD cases
- 375 A distinct class of extreme smoke cases comes from pyrocumulonimbus (pyroCb)
- events induced by intense biomass burning sources: these events inject smoke high
- into the troposphere or even well into the stratosphere (Fromm et al., 2010; Peterson et
- 378 al., 2017). A significant pyroCb smoke event that occurred over British Columbia (BC) in
- 379 August 2017 led to substantial increases in various optical measures of aerosol
- 380 concentration in the lower Canadian and European Arctic (Peterson et al., 2018; Torres
- 381 et al., 2020; Das et al., 2021). Ranjbar et al. (2019) showed that a specific Aug. 19,
- 382 2017 smoke event over the high Arctic PEARL observatory at Eureka, Nunavut was
- induced by the BC pyroCb fires and that it was a statistically significant extreme FM
- AOD event. More recent eastern Siberian fires in June August 2021, induced more
- than a dozen cases of elevated smoke intrusion into the high Arctic with some smoke
- plumes reaching the North Pole and/or its vicinity. For example, on the 5<sup>th</sup> of August,
- 387 2021, operational NAAPS (common chemistry, physics, and BB emission sources with
- the NAAPS-RA) resolved a smoke plume north of 80°N (Fig. 4) with AOD values of 2-3.
- 389 Smoke AOD over the source region was also 2 to >3 with a similar amplitude to AODs
- measured at Yakutsk. CALIOP data suggested a 1-6 km high smoke layer in the source
- 391 region.
- 392 Other extreme or near-extreme smoke events in the Arctic have been reported. A series
- of intense fires originating in North America led to strong AOD peaks in the summer of
- 394 2015 over Svalbard (Markowicz et al., 2016; Lisok et al., 2018). Agricultural fires in

Eastern Europe in the spring of 2006 caused record-high AODs and pollution levels in the European Arctic (Stohl et al., 2007). The North American boreal fires in the summer of 2004 led to large-amplitude AOD peaks in Alaska and enhanced AODs on a pan-Arctic scale (Stohl et al., 2004).

**Figure 4.** An August 5, 2021 example of BB smoke intrusion into the high Arctic from fires originating in eastern Siberia. a) Composite true-color Terra satellite imagery. The red dots represent satellite-detected fire hotspots. b) Operational NAAPS smoke AOD analysis at 12Z. c) CALIOP 532 nm attenuated backscatter coefficient showing the smoke layers around the source area. The yellow stars on a) and b) represent the location of Yakutsk, which experienced a daily mean total AOD (500 nm) of 2.0 (FM AOD ~1.9) and an intra-day peak around 2.5 based on AERONET V3L1.5 data. Sources: MODIS-Terra true-color satellite imagery and CALIOP-CALIPSO 532 nm attenuated backscatter coefficient profile (respectively https://worldview.earthdata.nasa.gov/ and https://www-calipso.larc.nasa.gov/).

#### 3.4 Geographic distribution of extreme AODs

The NAAPS-RA total-AOD map at different percentile levels locally for March-August 2003-2019 is shown in Fig. 5. We separated the study period into early (2003-2009) and

late (2010-2019) subperiods. The end-year of the first period was chosen as 2009 given the drop in ABF/sulfate emissions due to the civil Clean Air Acts enacted across the U.S. (e.g., Tosca et al., 2017; Kaku et al., 2018) as well as Europe and China, and the attendant decrease in ABF/sulfate AOD in these countries/regions (Lynch et al., 2016; Zhang et al., 2017). This ABF/sulfate AOD decrease was also observed in the Arctic, as shown in Fig. 13 of Part 1. The median Arctic AOD (less than 0.1 as compared with 0.07 for the AERONET sites from Fig. 3 and Table 2) are an order of magnitude smaller than the maximum AODs. Clear BB smoke features in the North American and Asian boreal burning regions start to emerge in the AOD<sub>95</sub> maps (see also Fig. 1). The maximum AOD is high (greater than 2.0) while being relatively low over the Arctic Ocean (~ 0.3 - 1.0) and the North Atlantic, with the lowest values over the generally high-elevation Greenland landmass. The maximum AOD is associated with peak burning activities and generally occurs in July and August. The exception is the Norwegian Sea area, where the maximum AODs occurs in March-May. This is possibly associated with a combined high AOD level from anthropogenic pollutions, marine aerosols and springtime agriculture fires.

**Figure 5.** NAAPS-RA daily (550 nm) total-AOD maps at different percentile levels for the March-August time frame, the maximum AOD and (rightmost column) the month that the maximum AOD occurred. The three rows represent respectively, the sampling periods of 2003-2019, 2003-2009, and 2010-2019. The AOD<sub>95</sub> value for 2003-2019 is the same as that of Fig. 1 despite of different color scales.

The occurrence of different aerosol species relative to the occurrence of total AOD for total AOD extreme events (March-August time frame) are shown in Fig. 6. The occurrence maps accordingly indicate which aerosol species are numerically dominant for extreme AOD events. As expected, BB smoke is the prevailing extreme event contributor over the North American and Asian Arctic, especially near the boreal source regions and associated transport pathways, as well as most of the Arctic ocean (except the Barents Sea and the Norwegian Sea). ABF occurrence dominates the low European Arctic. Sea-salt particles and, to a lesser extent, ABF are the most significant occurrence contributors, in the North Atlantic and the Norwegian Sea. Dust occurrences to extreme AOD events are very small (0-10%) except over the predominantly high-elevation region of Greenland where the relative occurrence of high-altitude African dust dominates the relative occurrence of the other species.

In terms of AOD amplitudes for total AOD extreme events (Fig. 7), BB smoke AOD shows dominant contributions, especially in the areas near the boreal source regions and transport pathways, including most areas of the high Arctic. ABF and sea salt show slightly higher extreme-event AODs than BB smoke over the North Atlantic and European Arctic. The regional extreme AODs are not, however, as large as the extreme AODs in the BB smoke-dominant regions.

**Figure 6.** Occurrence of different aerosol species (expressed as a percent) relative to the occurrence of total AOD extreme events (daily total AOD > AOD<sub>95</sub> locally) for the March-August time frame. The sampling periods are the same as in Fig. 5.

## 3.5 Seasonality of extreme AOD events

The NAAPS-RA seasonal cycle of total and speciated AOD are shown in Figure 8 for daily averages across the area north of 70° N (a latitude limit which largely excludes BB source regions). The seasonal cycle of monthly mean total AOD shows relatively higher values in Mar-Apr-May (MAM) compared with the lower AODs in Jun-Jul-Aug (JJA), and a minimum in June. The spread of the ABF AOD seasonal values is moderately stable, with a relatively higher mean/median in MAM than JJA (see the Figure 9 caption for a definition of spread). Sea-salt AOD and its spread are relatively higher in the earlier months (March and April). Dust AOD and spread are generally stable through the season, with a visibly higher mean/median in April and May. Smoke AOD amplitude and spread exhibit the greatest inter-species seasonal variations with the lowest mean and spread in March, increased means and spreads in April, and significantly higher mean and spread in later months. July and August appear to have the largest mean, spread and maximum smoke AODs (a smoke importance statement that is generally consistent with the results of Fig.6). These smoke features significantly contribute to the seasonality of total AOD extremes. It is also noted that the MAM total and smoke AOD means approximately equal their medians, but that the JJA means are greater than their

medians (and that this is especially true for August). The greater number of smoke AOD extremes in the later season and the attendant consequence of greater positive histogram skewness would explain those relative increases in the mean.

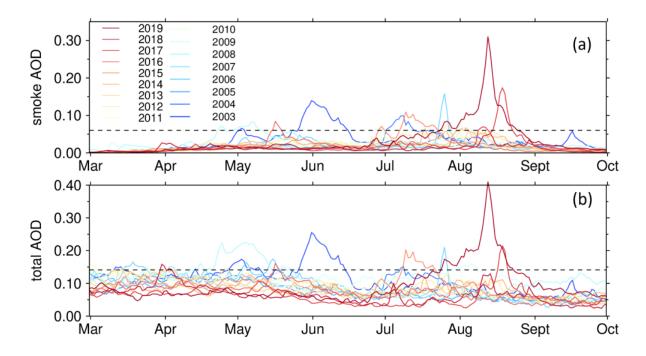

**Figure 8.** Box and whisker plot of daily and area-averaged (70°N-90°N) speciated AOD at 550 nm from NAAPS-RA (2003-2019) for different months. The box and whiskers represent AOD at 95, 90, 75, 50, 25, 10, and 5 percentiles. Mean total AODs are shown as solid black circles and maximum AODs as stars. Maximum AOD values appear as appropriately colored numerical values if they extend beyond the 0.2 plot maximum.

## 3.6 Trends of extreme AOD events

There is, as shown in Part 1 of the study, a multi-year decreasing MAM trend and an increasing JJA trend for total AOD in the Arctic over the 2003-2019 sampling period. This was attributed to an overall decrease in MAM and JJA sulfate/ABF AOD coupled with a negative trend in MAM, and a strong positive trend in JJA for biomass-burning smoke AOD. In terms of extreme event trends, AOD<sub>95</sub> (Fig. 5) and the average AOD above AOD<sub>95</sub> (Fig. 6) generally increased over the boreal continents from the 2003-2009 to 2010-2019 period (with the notable exception of Alaska and northeastern Siberia in 2010-2019). This is consistent with the positive BB emission trends in JJA north of 50°N and 60°N (for which the JJA trend dominated the MAM trend inasmuch as JJA was associated with much higher BB emissions; Part 1).

The negligible or slight decrease in high Arctic AOD<sub>50</sub>, AOD<sub>75</sub> and AOD<sub>95</sub> values from the 2003-2009 to the 2010-2019 period (Figure 5), is likely associated with the generally weak ABF decrease seen in Figure 7. However, the increase in the maximum AOD value (Fig. 5) and the contribution of BB smoke to AOD extreme events (Fig. 7) in the latter period is an indication of stronger extreme BB smoke influence in more recent years. It is also noted that the maximum high-Arctic AOD occurred later in the season (mostly August) in 2010-2019 compared with the more balanced variation occurring in March through August in 2003-2009. This is likely attributable to overall lower ABF levels in the 2010-2019 period (especially in MAM), and a shift in extreme smoke events to

later in the season (Fig. 9). Specific counts of extreme BB smoke days for different months and years and yearly cumulative extreme AODs also support the seasonal shift of extreme smoke events (Table S1).

**Figure 9.** Seasonal (March to September) time series of daily-mean AODs averaged over the (70°N-90°N) high-Arctic area for each individual year of the 2003-2019 period: (a) BB smoke AOD, and (b) total AOD. The years before 2010 are shown as cold colors, and years after 2010 are shown as warm colors. The dashed horizontal lines show the smoke AOD<sub>95</sub> value of 0.06 and the total AOD<sub>95</sub> value of 0.14 respectively during the study period.

The time series of high-Arctic-averaged daily-mean BB smoke and total AOD from March to September for all years between 2003-2019 is shown in Fig. 9. The extreme total AOD variation is largely dictated by BB smoke. There is also a discernible 2003-2009 to 2010-2019 springtime reduction in extreme total AOD: this, as discussed in the previous paragraph, is likely due to an overall reduction in ABF AOD. The occurrence of extreme smoke events tended to be more equally distributed over all months (April-August) during the 2003-2009 period while being more concentrated in the late season (July-August) during the 2010-2019 period. The extreme smoke and total AOD trends resembled the extreme-smoke occurrence trends: more seasonally balanced during the 2003-2009 period and summertime dominance during the 2010-2019 period.

The occurrence of extreme high-Arctic smoke events thus demonstrates a clear smoke and total AOD shift from a more balanced spring and summer to the late season

- (notably the months of July and August; see also Table S1). This is consistent with the
- temporal shift of fire activity to a later time in Siberia over 2003-2018 (Liu et al., 2020),
- and the projection of emerging pan-Arctic fire regimes marked by increases in the
- likelihood of extreme fires later in the growing season (McCarty et al., 2021). An earlier
- fire season in the boreal region normally suggests a better-managed forest/land with
- fewer large and destructive fires, while a later fire season indicates the opposite.
- 537 The shift of boreal fire activity, and the resulting BB smoke AOD extremes in the Arctic
- from early season to late season, is probably related to early-season strengthening of
- agriculture burning regulations and increased summertime lightning frequencies with
- 540 climate change in the latter decade. For example, the springtime BB smoke AOD peak
- values in 2003, 2006 and 2008 are all associated with agricultural activity (resulting in
- fires burning out of control) and widespread high-latitude burning (Korontzi et al, 2006;
- 543 Stohl et al., 2007; Saha et al., 2010). At the same time, with climate change, lightning
- activity and lightning-caused wildfires in summertime high-latitude regions were
- observed to increase in the past two decades (Zhang et al., 2021; Bieniek et al, 2020;
- Coogan et al., 2020). Also noted is a lengthening of growing season in boreal regions,
- which infers lengthening of fire season as well (Park et al., 2016). These factors aside,
- 548 climate oscillations, including the Arctic Oscillation, ENSO and Pacific Decadal
- Oscillation, also affect boreal fire activities (Balzter et al., 2007; Macias Fauria and
- Johnson, 2007; Kim et al., 2020). These climate factors modulate interannual variations
- and possibly the transport dynamics of pollutants from the mid-latitudes to the Arctic
- region (e.g. Eckhardt et al., 2003; Fisher et al., 2010).
- 553 The dominant contributor, ABF, to regional extreme AOD occurrence and magnitude in
- the lower European Arctic decreased slightly from 2003-2009 to 2010-2019 (Fig. 6 and
- 555 7): This observation is generally coherent with the Part 1 results showing a pan-Arctic
- ABF AOD decrease in the 2003-2019 period and Fig. 9. Extreme total-AOD events
- dominated by sea-salt contributions in the North Atlantic and Norwegian Sea increased
- slightly in 2010-2019. This was possibly due to the observed increase in cyclonic
- activities (Rinke et al., 2017; Waseda et al., 2021; Valkonen et al., 2021). Although the
- model simulation of CM AOD is not as skillful as that of FM, trend analysis of CM AOD
- which is based on relative change is arguably significant.

## 4. Summary

- AOD data from the NAAPS-RA, the ground-based AERONET, and MAN were
- employed in analyzing the 2003-2019 statistics and trends of extreme Arctic-AOD
- events for spring and summer seasons. Extreme AODs are defined as any AOD greater
- than the 95th percentile (AOD<sub>95</sub>) for any given distribution of AODs, whether that
- distribution is generated by the ensemble of AODs representing the time series of a

specific location or of a regional average. Total, FM and CM AODs at 550 nm from 6-hr

resolution NAAPS-RA were first validated against AERONET and MAN AOD data.

NAAPS-RA was shown to be capable of largely capturing FM and total AOD ranges and

variability. The NAAPS-RA performance in simulating CM AOD was significantly better if

the temporal resolution of the all-season statistics was less sensitive to high frequency

573 dust and sea-salt events (i.e. the use of temporal resolution bins of a month rather than

6 hr). Statistics of the 6-hr Arctic AOD and extreme AOD events were analyzed. Finally,

575 trends of extreme AOD in the Arctic were presented and analyzed.

- 576 Baseline statistics for 6hrly AOD: The median of 6-hr total AODs at 550 nm for all
- 577 Arctic AERONET sites and MAN retrievals over the 2003-2019 period is 0.07 while
- 578 AOD<sub>95</sub> is 0.23. Both the median and AOD<sub>95</sub> values show a dominant FM AOD
- 579 contribution. The CM AOD median is 0.01 while AOD<sub>95</sub> is 0.07. The maximum AOD
- over the 2003-2019 period varies between 0.5-3.0 for measurements made away from
- BB source regions, and 1.5 to greater than 3.0 for measurements made closer to BB
- source regions. The seasonal NAAPS-RA spread of smoke AOD is much higher than
- other speciated AODs, including ABF, dust, and sea salt AODs, for all months between
- May and August: the spread is especially large in July and August. These late-season
- smoke features significantly contribute to the seasonality and interannual variabilities of
- 586 extremes in total AOD.
- 587 Extreme AOD events: Extreme AOD events using the Arctic spring and summer data
- are largely attributable to FM AOD events, and notably BB smoke transport events in
- 589 general. Extreme Arctic AOD events show large seasonal and interannual variability,
- 590 with the interannual AOD variability largely modulated by BB smoke. Extreme AOD
- occurrences in the North American Arctic, the Asian Arctic, and the high Arctic are
- dominated by BB smoke events. The occurrence of regionally extreme AOD events is
- attributed more to ABF in the lower European Arctic. The extreme-event occurrence
- dominance of sea salt aerosols is largely limited to the North Atlantic and Norwegian
- Seas. The extreme AOD amplitudes of ABF and sea-salt AOD are, however,
- significantly lower than those regions where extreme-AOD smoke AOD is dominant.
- 597 Even for sites distant from BB source regions, BB smoke is the principal driver of AOD
- 598 variation above the AOD<sub>95</sub> threshold.
- 599 **Shift of extreme AOD events from spring-summer to summer season:** There is an
- overall increase in the maximum AOD values in the high Arctic in 2010-2019 compared
- to 2003-2009, suggesting stronger extreme BB smoke influence for more recent years.
- 602 Extreme AOD events are observed to occur in a more balanced fashion over the entire
- April-August season during 2003-2009 while being more concentrated in the latter part
- of the season (i.e., July and August) during 2010-2019. The seasonal shift in extreme
- smoke AOD events is consistent with the multi-year negative MAM trend and positive

- JJA trend in BB emissions (north of 50°N, Part 1). These trends are likely attributable to
- early season agricultural burning controls, and increased lightning activity and lightning-
- caused wildfires in summertime in the boreal high-latitude regions on top of the overall
- lower level, especially in spring, of 2010-2019 vs 2003-2009 anthropogenic aerosols.
- The shift in extreme smoke events is consistent with a general multi-year decreasing
- springtime trend and an increasing summertime trend of BB emissions north of 50°N
- 612 (Part 1).
- 613 Global warming is expected to continue generating drier conditions and increased
- wildfire activities in the high latitudes (McCarty et al., 2021) and thus render the Arctic
- 615 more susceptible to extreme smoke events. These events can significantly change the
- regional aerosol budget by bringing large amounts of smoke aerosols into the Arctic.
- These extreme smoke events will likely play an increasingly important Arctic aerosol
- budget role given the decreasing (Part 1) baseline in anthropogenic pollution aerosols
- over the 2003-2019 period. Smoke aerosols are, notably, much more light-absorbing
- 620 than anthropogenic sulfate. As well, their different physical and chemical properties
- relative to anthropogenic aerosols will translate into different efficiencies in their role as
- 622 CCN and INP. When deposited on surface snow and ice, they impact the surface
- 623 radiative forcing budget by reducing surface albedo. The climate impacts of BB smoke
- would, accordingly, differ and possibly counteract the dynamics of anthropogenic
- aerosols. Therefore, the baseline AOD trends reported in Part 1 and the trends in
- extreme AOD events reported here are important in terms of implications for the
- 627 changing Arctic climate. The greater sensitivity of Arctic climate to aerosol forcings
- relative to other regions of the globe (e.g. Wang et al., 2018), the impact of the extreme
- BB smoke events and their interannual variability and trends on Arctic climate warrants
- 630 further exploration. The statistics of extreme AODs reported here are expected to help
- in the formulation of climate sensitivity experiments and improve our knowledge of the
- relative importance of aerosol processes compared to other factors of the changing
- 633 Arctic climate.
