**Abstract.** Sulfate geoengineering (SG) methods based on lower stratospheric tropical injection of sulfur dioxide (SO<sub>2</sub>) have been widely discussed in recent years, focusing on the direct and indirect effects they would have on the climate system. Here a potential alternative method is discussed, where sulfur emissions are located at the surface in the form of carbonyl sulfide (COS) gas. A time-dependent chemistry-climate model experiment is designed from year 2021 to 2055, assuming a 40 Tg-S/yr artificial global flux of COS, geographically distributed following the present day anthropogenic COS surface emissions. The budget of COS and sulfur species is discussed, as well as the effects of SG-COS on the stratospheric sulfate aerosol optical depth ( $\Delta\tau=0.080$  in years 2046-2055), aerosol effective radius ( $0.46 \mu\text{m}$ ), surface SO<sub>x</sub> deposition (+8.7 %) and tropopause radiative forcing (RF) ( $-2.0 \text{ W/m}^2$  for clear sky conditions and  $-1.5 \text{ W/m}^2$  including the cloud adjustment). Indirect effects on ozone, methane and stratospheric water vapor are also considered, along with the COS direct contribution (with an overall gas phase global radiative forcing of  $+0.23 \text{ W/m}^2$ ). According to our model results, the resulting net RF of this SG-COS experiment is  $-1.3 \text{ W/m}^2$  for the year 2050, and it is comparable to the corresponding RF of  $-1.7 \text{ W/m}^2$  obtained with a sustained injection of 4 Tg-S/yr in the tropical lower stratosphere in the form of SO<sub>2</sub> (SG-SO<sub>2</sub>, able to produce a comparable increase of the sulfate aerosol optical depth). Significant changes of the stratospheric ozone response are found in SG-COS with respect to SG-SO<sub>2</sub> ( $+4.9 \text{ DU}$  versus  $+1.5 \text{ DU}$ , globally). According to the model results, the resulting UVB perturbation at the surface accounts to  $-4.3\%$  as a global-annual average (versus  $-2.4\%$  in the SG-SO<sub>2</sub> case), with a springtime Antarctic decrease of  $-2.7\%$  (versus a  $+5.8\%$  increase in the SG-SO<sub>2</sub> experiment). Overall, we find that an increase in COS surface emission may be feasible, and produce a more latitudinally-uniform forcing without the need for the deployment of stratospheric aircrafts.

## 1 Introduction

Reducing part of the incoming solar radiation (known as Solar Radiation Modification, SRM) has been proposed as a short-term strategy for reducing surface temperatures and thus mitigating some of the worst side-effects of the greenhouse gases-induced global warming (Budyko, 1978; Crutzen, 2006). Various methods have been proposed to achieve this: the injection of sulfate precursors into the lower stratosphere to obtain an optically-active cloud of aerosols has been, by far, the most studied due to the observation of a similar cooling effect produced by explosive volcanic eruptions in the past (Robock, 2000). While preliminary

estimates for the cost of an eventual deployment already exist (Smith and Wagner, 2018), from an engineering perspective there are no known technologies readily available to carry SO<sub>2</sub> or any other precursors considered up to now from the ground up to the lower stratosphere in the quantities needed to obtain a noticeable effect on the surface climate (Lockley et al., 2020). Since any proposed compound would quickly react to form sulfate aerosols, they would need to be carried sealed to the desired altitude, and then released, to ensure a high enough lifetime compared to that of the same aerosols in the troposphere (Lamarque et al., 2013).

We propose here a different approach to increasing the aerosol optical depth in the stratosphere, that makes use of bottom-up emissions of a gaseous precursor of sulfate aerosols: carbonyl sulfide (COS). COS has a long atmospheric lifetime (4 to 6 years; Khalil and Rasmussen, 1984; Ulshofer et al., 1996) due to its very low reactivity in the troposphere. Because of this, it is also uniformly mixed in the atmosphere, with an average concentration of 0.5 ppbv, and therefore it easily reaches the stratosphere: in quiescent volcanic conditions, COS is the main contributor of sulfate aerosols in the Junge layer (Bruhl et al., 2012), where after photodissociation by ultraviolet light and oxidation processes, it is turned into SO<sub>2</sub> and subsequently oxidized into sulfuric acid, forming sulfate aerosols (Crutzen, 1976). It is naturally produced by various biological processes and environments, such as saline ecosystems, rainwaters (Mu et al., 2004) and biomass burning. Furthermore, it is also produced in various industrial processes (Lee and Brimblecombe, 2016) after CS<sub>2</sub> is oxidized. Its chemical life is very long (35 years; Bruhl et al., 2012) and thus its main sink is the uptake from oxic soils (Kuhn and Kesselmeier, 2000; Steinbacher et al., 2004) and vegetation (Sandoval-Soto et al., 2005). In the concentrations found in the atmosphere, it is not a toxic gas for humans or ecosystems: negative effects have been found only when concentration exceed 50 ppm (100,000 times more than the background mixing ratio (Kilburn and Warshaw, 1995; Bartholomaeus and Haritos, 2006).

For these reasons, we investigate in this work the possible use of COS as a precursor to stratospheric sulfate aerosols aimed at reducing part of the incoming solar radiation. With the use of the University of L'Aquila-Climate-Chemistry Model (ULAQ-CCM) we investigate the possible increase of COS surface fluxes to obtain a stratospheric aerosol optical depth (AOD) similar to that obtained with the injection of 8 Tg-SO<sub>2</sub> in the stratosphere. Together with assessing the resulting optically thick aerosol cloud, we also explore the eventual side-effects on key chemical components in the atmosphere, in order to determine how the side effects from COS-induced Sulfate Geoengineering (SG-COS) compare with those from SO<sub>2</sub>-induced Sulfate Geoengineering (SG-SO<sub>2</sub>). For the latter, there is ample literature assessing its effect on stratospheric ozone (Tilmes et al., 2008; Pitari et al., 2014; Xia et al., 2017a; Vattioni et al., 2019): the increase in surface area density, stratospheric heating and dynamical effect all play a part in determining the overall changes (Tilmes et al., 2018b; Richter et al., 2017) to the ozone column that, in turn, determine the changes in surface UV (Visioni et al., 2017b; Madronich et al., 2018) that would be important when considering adverse health effects (Eastham et al., 2018).

## 2 Model description and setup of numerical experiments

The simulations presented in this paper have been carried out with the University of L'Aquila Climate-Chemistry Model (ULAQ-CCM), a CCM robustly tested and used before in evaluation of the radiative, chemical and dynamical effects of

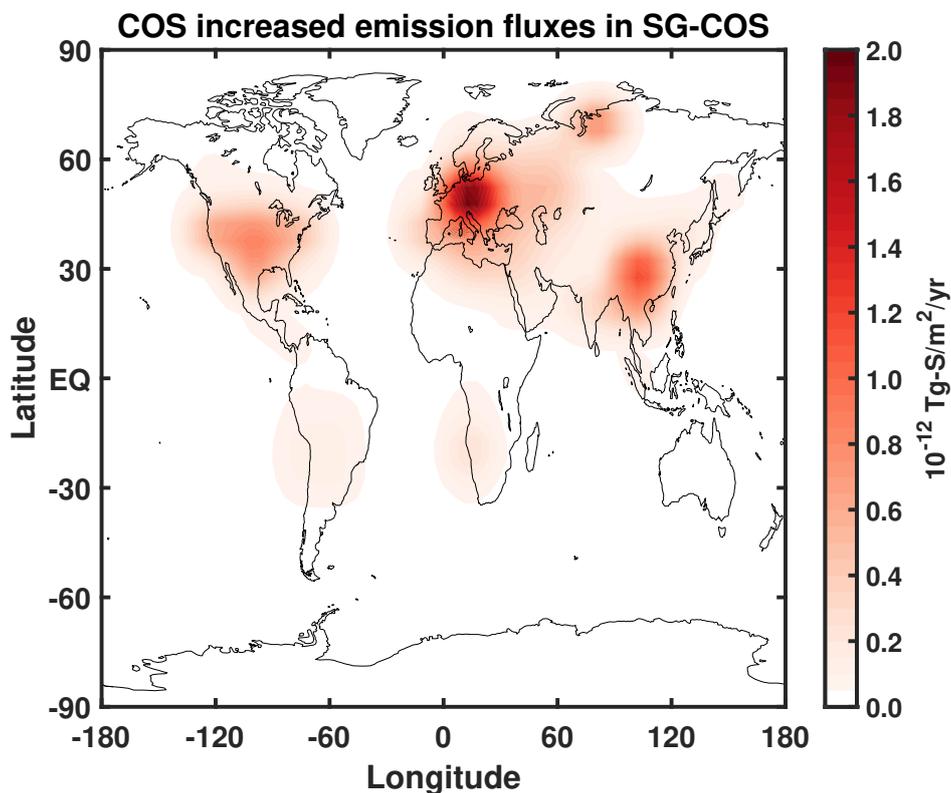

stratospheric and tropospheric aerosols (Pitari et al., 2002; Eyring et al., 2006; Morgenstern et al., 2010). It has also been used for various sulfate geoengineering simulations (Pitari et al., 2014; Vioni et al., 2018a, b) and, as part of the Climate-Chemistry Model Intercomparison project (Morgenstern et al., 2018), where it has been extensively validated with other CCMs. The high vertical resolution (127 levels) allows for a proper representation of large-scale transport of gas and aerosol species in the troposphere (Orbe et al., 2018) and in the stratosphere (Vioni et al., 2017b; Eichinger et al., 2019), and the detailed chemistry, including heterogeneous chemical reactions on sulfuric acid aerosols, polar stratospheric cloud particles, upper tropospheric ice and liquid water cloud particles allows for a full assessment of the effects of the increased sulfate burden on the atmospheric composition. ULAQ-CCM simulated COS also compares reasonably well with available measurements of seasonal COS concentrations (see Fig. S1) from Kuai et al. (2015), with an average annual error of 6.5%, albeit with peaks in some areas and months of up to 30%.

In addition to a reference historical model experiment (1960-2015), we performed three sets of simulations: a baseline unperturbed (BG) case and two geoengineering experiments (SG-COS and SG-SO<sub>2</sub>), all run between the years 2021-2055, with analyses focusing on the 2046-2055 decade; all experiments take place under the Representative Concentration Pathway 6.0 (RCP; Meinshausen et al., 2011) emissions.

The first geoengineering experiment, SG-COS, tries to produce a significant stratospheric aerosol burden by enhancing current surface emission sources of COS by up to 40 Tg-S/yr. These emissions are located at the ground, in the main regions of anthropogenic COS surface emissions (see Fig. 1). The second experiment, SG-SO<sub>2</sub>, is very similar to previous experiments discussed in the literature, primarily by Kravitz et al. (2011) in the G4 experiment, and consist of the injection of a fixed yearly amount of SO<sub>2</sub> (4 Tg-S/yr) at the equator, between 18 and 25 km of altitude.

For the geoengineering experiments, ULAQ-CCM is driven by time-dependent sea surface temperatures (SSTs) from the Community Climate System Model – Community Atmosphere Model version 4 (CCSM-CAM4; Neale et al., 2013), an atmosphere-ocean coupled model that ran similar geoengineering experiments as in SG-SO<sub>2</sub> (described by Tilmes et al., 2015); this allows for the inclusion of the cooling produced by geoengineering on the surface to the assessment of the dynamical and chemical effect as simulated by ULAQ-CCM. To include the important radiative effects produced by other atmospheric components (mainly, geoengineering-driven changes in greenhouse gases concentration and in ice clouds ; Vioni et al., 2017b, 2018a) the radiative module of ULAQ-CCM calculates at each time-step the surface temperature perturbation produced by the radiative flux changes induced by these components and includes them in the CCSM-CAM4 SSTs. This approach has been further explained and validated by Vioni et al. (2018a). While the prescribed SST setup has been shown to correctly capture dynamical changes produced by SRM (Vioni et al., 2017b), it clearly does not capture potential feedbacks that may be relevant for surface climate, such as those produced by the different latitudinal distribution of the aerosol optical depth that we will show later on. These differences may also in turn feed back onto changes in COS lifetime through precipitation changes (Whelan et al., 2016) which we can't consider here. We will therefore limit ourselves to analyzing changes in atmospheric composition and dynamics, and how those contribute to the overall radiative forcing from the aerosols. Future experiments with a more comprehensive Earth-system model will be necessary to determine the full extent of the climatic response.

**Figure 1.** Geographical distribution of COS emission fluxes per year and unit of surface area ( $10^{-12}$  Tg-S/m<sup>2</sup>/yr) in the SG-COS experiment. The annual upward flux is averaged over the period 2046-2055.

### 3 Results

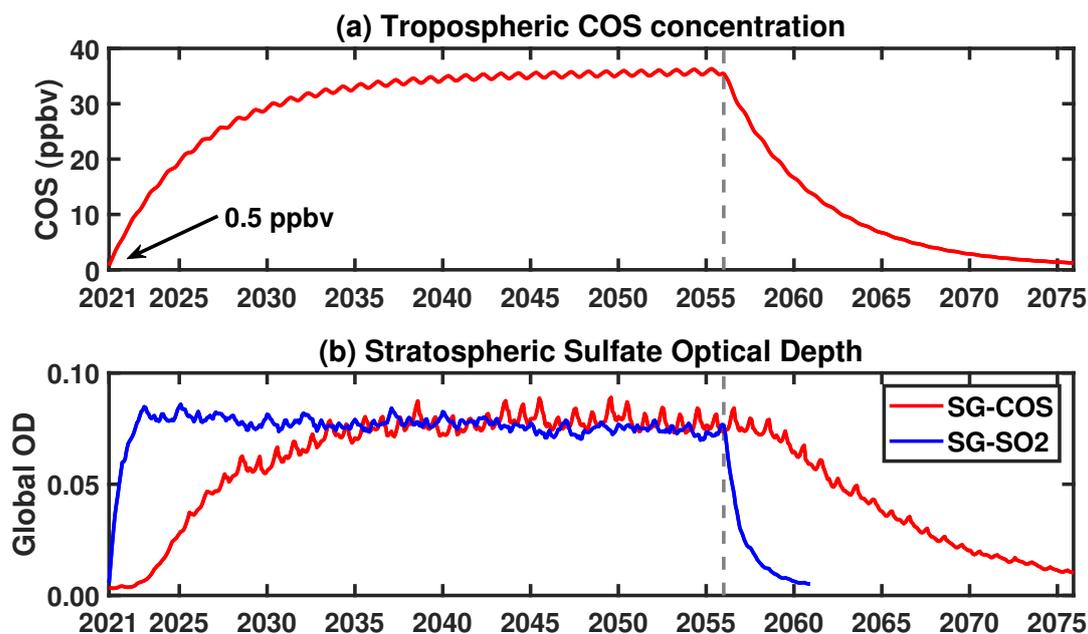

#### 3.1 Sulfate burden

COS is the most abundant sulfur-containing species in the atmosphere under quiescent conditions (i.e. not considering explosive volcanic eruptions). It is efficiently lost at the surface via dry deposition on soils and vegetation: taking this sink into account, the net global lifetime (atmospheric chemistry plus surface deposition) is approximately 4 years, depending on the assumed magnitude of the soil and vegetation sink (Sandoval-Soto et al., 2005; Van Diest and Kesselmeier, 2008). In the troposphere the COS chemical reactivity (mostly with the hydroxyl radical) is rather slow: COS is thus well mixed and is easily transported in the stratosphere through the tropical tropopause layer (TTL). In the mid-stratosphere COS becomes efficiently photolyzed by solar UV radiation, becoming an important source for stratospheric SO<sub>2</sub> and finally for sulphuric acid aerosols.

When increasing the emission fluxes in SG-COS, it takes  $\sim 15$  years before the concentration reaches a new equilibrium, from 0.5 to 35.5 ppbv (Fig. 2a). In the same timespan, the global AOD increases, reaching a value of 0.08 by 2035, similar to the global value that is reached by the direct injection of SO<sub>2</sub> in the equatorial stratosphere in SG-SO<sub>2</sub>; in that case, however,

the steady-state value is reached in only 1-2 years. At the end of 2055, the increased COS emissions and SO<sub>2</sub> injections are stopped. Average tropospheric COS concentrations follow an exponential decay guided by the tropospheric lifetime (3.8 years, 105 due to chemistry and soil deposition), reaching a value of 1.3 ppbv after 20 years (during 2075). This means an increase of 0.8 ppbv with respect to background condition, that would produce a direct RF negligible if compared to other well mixed greenhouse gases. The exponential decay of the stratospheric AOD in SG-COS is regulated by the stratospheric lifetime of COS (~10 years) mainly due to reaction with OH and photolysis, from which stratospheric SO<sub>2</sub> and finally sulphuric acid aerosols are formed. Therefore, the e-folding time for stratospheric AOD is longer with respect to the one resulting from 110 SG-SO<sub>2</sub> (Fig. 2b). In 2075, the global stratospheric AOD reaches in SG-COS a value of 0.01, with respect to 0.003 in the background case.

**Figure 2.** a) Monthly values of globally averaged tropospheric COS volume mixing ratio (ppbv) in SG-COS. The background value of 0.5 ppbv at the beginning of the simulation is highlighted. b) Globally averaged stratospheric sulfate optical depth monthly values in SG-COS (red) and SG-SO<sub>2</sub> (blue). The grey line indicates the time when emissions of COS and SO<sub>2</sub> are stopped, at the end of 2055.

### 3.2 Sulfate aerosol properties

	BG	SG-COS	SG-SO2	SG-COS - BG	SG-SO2 - BG
<b>Total Sulfate OD</b>	0.055±0.003	0.135±0.004	0.130±0.003	0.080±0.004	0.075±0.004
<b>Tropospheric Sulfate OD</b>	0.052±0.003	0.057±0.003	0.055±0.003	0.005±0.004	0.003±0.004

**Table 1.** Summary of calculated sulfate aerosol and cirrus ice globally-annually averaged quantities relevant for RF calculations (i.e., optical depth at  $\lambda=0.55 \mu\text{m}$  and effective radius). Last two columns show the calculated SG changes with respect to the BG case [years 2046-2055].

In the SG-COS experiment, surface COS fluxes are adjusted so as to have the same global aerosol optical depth (AOD)  $\approx 0.08$  (see table 1). This is done in order to more easily compare the latitudinal distribution of the aerosols, and to better quantify the differences in the radiative forcing from both direct and indirect (ozone, methane and water vapor) changes in atmospheric composition.

There is a large difference in the latitudinal distribution of stratospheric sulfate optical depth, as shown in figure 3 (a). SG-COS produces an AOD more uniformly distributed over all latitudes with respect to the SG-SO2 case, where the increase of optical depth is most prominent in the tropics; this is due to the efficient tropospheric mixing of COS before it reaches the stratosphere.

The differences in the latitudinal distribution of AOD are also observable in the differences in the particle sizes and in the surface area density (SAD). Figure 3 (b) shows that the stratospheric effective radius is smaller in the SG-COS experiment and uniform for all latitudes, with a global value of  $0.46 \mu\text{m}$ . In SG-SO2, the effective radius is higher in the tropics ( $0.63 \mu\text{m}$ ); AOD is also larger in the tropics in that case, due to a larger concentration of particles there, even if larger particles are less effective at scattering incoming solar radiation (English et al., 2012).

Figure 4 shows a comparison of the effective radius (a) and SAD (b) between the BG, SG-COS and SG-SO2 cases, separating the tropics, mid-latitudes and polar regions. As  $\text{SO}_2$  is injected at the equator, all oxidation and nucleation happens in the tropics in SG-SO2. This is reflected in the vertical distribution which has a maximum in the lowermost stratosphere. On the other hand in SG-COS, the effective radius increase is reached at higher altitudes, between 18-30 km, which is consistent with COS reaching higher altitudes through deep tropical convection before it is photochemically destroyed (Barkley et al., 2008). The same explanation is valid for the tropical SAD in panel (b).

As the size of the particles is determined by nucleation in the tropical region, where  $\text{SO}_2$  oxidation occurs, mid-latitude and polar behaviour of the aerosols depends on the polewards transport by the Brewer-Dobson Circulation (BDC).

In SG-SO<sub>2</sub>, aerosols grow rapidly in the tropical region due to the high concentration of SO<sub>2</sub>, and their larger size affects  
135 sedimentation rates, thus decreasing their lifetime. Consequently, the amount of aerosols transported to higher latitudes is  
lower; in SG-COS, smaller particles with a higher lifetime are either easily transported towards the poles or directly formed  
there. Smaller particles at a higher concentration, and larger particles at a lower concentration may then result in a SAD which  
looks similar at mid-latitudes and polar region, but for different reasons.

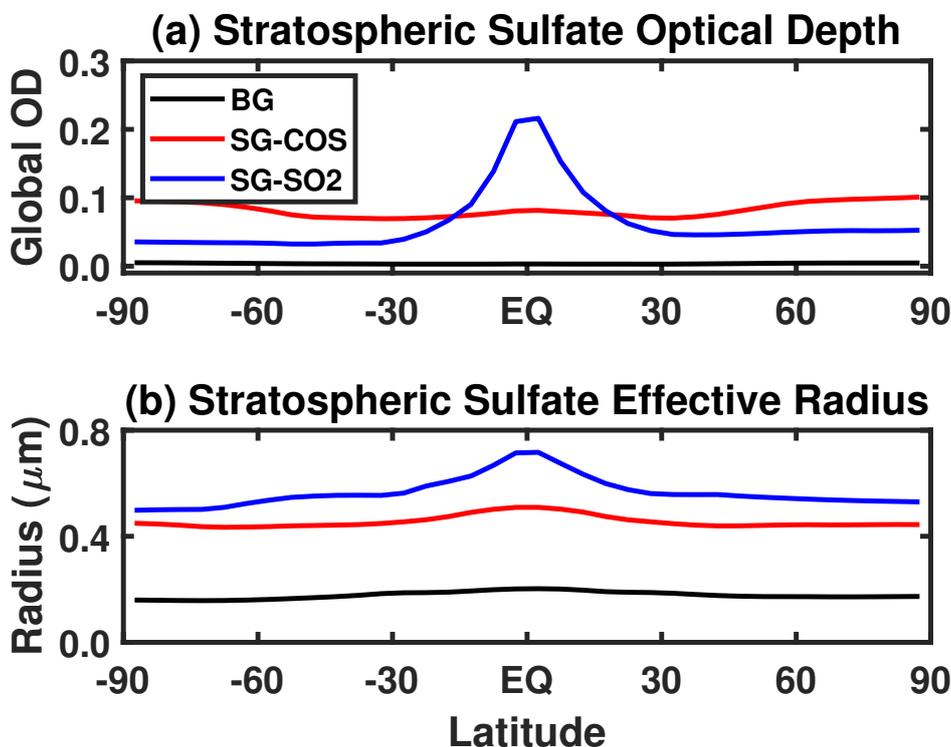

The vertical distribution of particles and their optical properties are shown in Figure 5 (see Fig. S2 for COS, SO<sub>2</sub> and  
140 SO<sub>4</sub> concentration changes). The vertical distribution of the SAD is fundamental to understand the role of the heterogeneous  
reaction and their effect on stratospheric ozone. The baseline case in panels (a) and (b) are a reference for understanding their  
changes in SG-COS (panels (c) and (d)). The particles transported via the BDC to the poles are large enough to efficiently  
scatter solar radiation so that the SAD and extinction changes show a similar behaviour, with a global increase of stratospheric  
values with maxima at higher latitudes between 15-25 km.

145 Panels (f) and (d) show the extinction and SAD changes between the two SG experiments, to underline that in SG-SO<sub>2</sub>  
extinction of the radiation is confined in the tropical stratosphere between 15-25 km, meaning a negative change in SG-COS.  
As discussed before, the formation of larger particles in SG-SO<sub>2</sub> in the tropical region reduces the amount of aerosol transported  
to the poles compared to the SG-COS case, where a larger number of smaller particles produces a positive change in SAD and,  
consequently, in extinction.

### 150 3.3 Deposition

Experiment	MSA	SO <sub>2</sub>	SO <sub>4</sub>	COS	CS <sub>2</sub>	H <sub>2</sub> S	Total
<b>BG</b>	1.0±0.1	35.2±1.4	9.4±0.4	0.39±0.01	0.47±0.03	1.5±0.1	48.0±1.8
<b>SG-SO<sub>2</sub></b>	1.0±0.1	35.6±1.5	9.5±0.4	0.39±0.01	0.47±0.03	1.5±0.1	48.5±1.8
<b>SG-COS</b>	1.0±0.1	36.4±1.5	9.9±0.4	31.6±0.1	0.47±0.03	1.5±0.1	80.9±1.7

**Table 2.** Globally-annually averaged dry deposition rates of sulfur species (Tg-S/yr) [years 2046-2055].

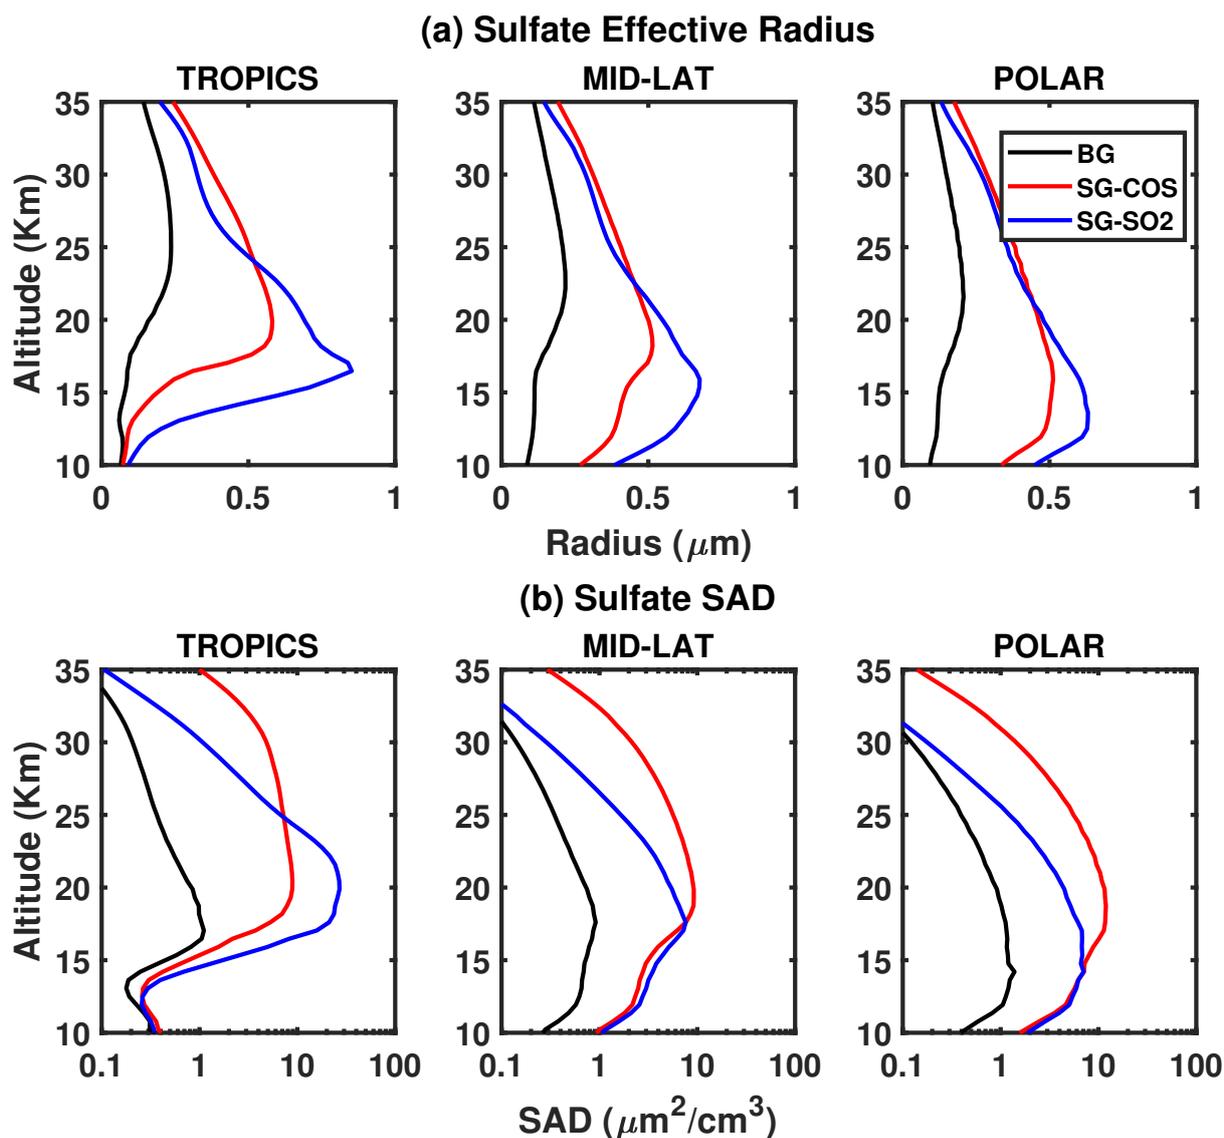

**Figure 3.** a) Latitudinal distribution of zonal mean values of stratospheric sulfate optical depth for the BG (black), SG-COS (red) and SG-SO<sub>2</sub> (blue) cases. b) Stratospheric effective radius (in  $\mu\text{m}$ ) (from tropopause to 6hPa). All quantities are annually averaged over the years 2046-2055.

Experiment	MSA	SO <sub>2</sub>	SO <sub>4</sub>	Total	Net [sources-sinks]
<b>BG</b>	1.5±0.1	3.0±0.1	43.2±1.5	47.7±1.6	+0.3±0.1
<b>SG-SO<sub>2</sub></b>	1.5±0.1	3.2±0.1	46.5±1.5	51.2±1.6	+0.5±0.1
<b>SG-COS</b>	1.5±0.1	3.4±0.1	49.4±1.5	54.3±1.6	+0.8±0.1

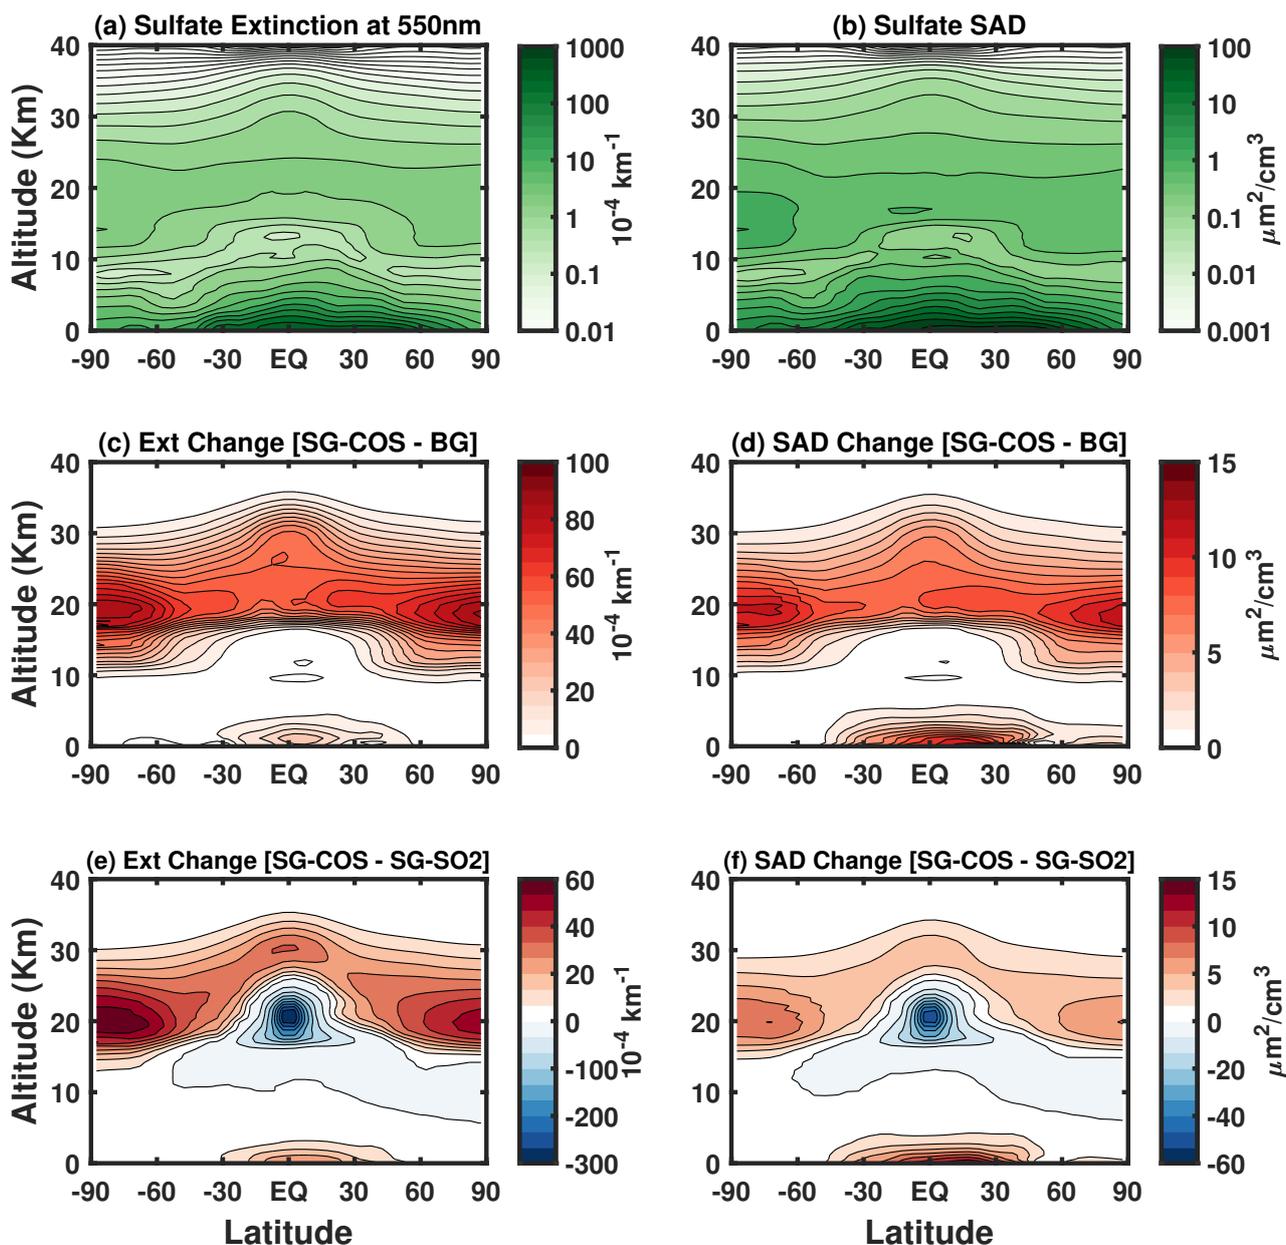

**Table 3.** Globally-annually averaged wet deposition rates of sulfur species (Tg-S/yr) [years 2046-2055]. The last column shows the net balance of total sulfur sources and sinks (Tg-S/yr).

The enhancement of the stratospheric sulfate burden would produce an increase in sulfur deposition, in dry form through acid gas deposition and in wet form through rain, fog and aerosol particles.

Acid deposition may damage human health when high concentrations of particles with a diameter below certain thresholds (PM<sub>2.5</sub> and PM<sub>10</sub>) are inhaled. The acidification of soils and water may damage plants, microorganisms and aquatic animals,

**Figure 4.** Vertical profiles of sulfate effective radius (in  $\mu\text{m}$ , a) and surface area density (in  $\mu\text{m}^2/\text{cm}^3$ , b) at different latitudinal bands (20N-20S for the Tropics, 30-50 at both N and S for the Mid-lat and 60-90 at both N and S for the Polar plots). All quantities are annually averaged over the years 2046-2055.

**Figure 5.** Zonal mean values of sulfate extinction (in  $10^{-4} \text{ km}^{-1}$ ) and SAD (in  $\mu\text{m}^2/\text{cm}^3$ ) in BG (panels a and b, respectively) and their change in the case of the SG-COS experiment (panels c and d). Panels e) and f) show extinction and SAD changes between SG-COS and SG-SO2. All quantities are annually averaged over the years 2046-2055.

155 but the impact on the ecosystem depends on the rate at which acidifying compounds are deposited from the atmosphere, compared with the rate at which acid neutralizing capacity (ANC) is generated within the ecosystem (Driscoll et al., 2001).

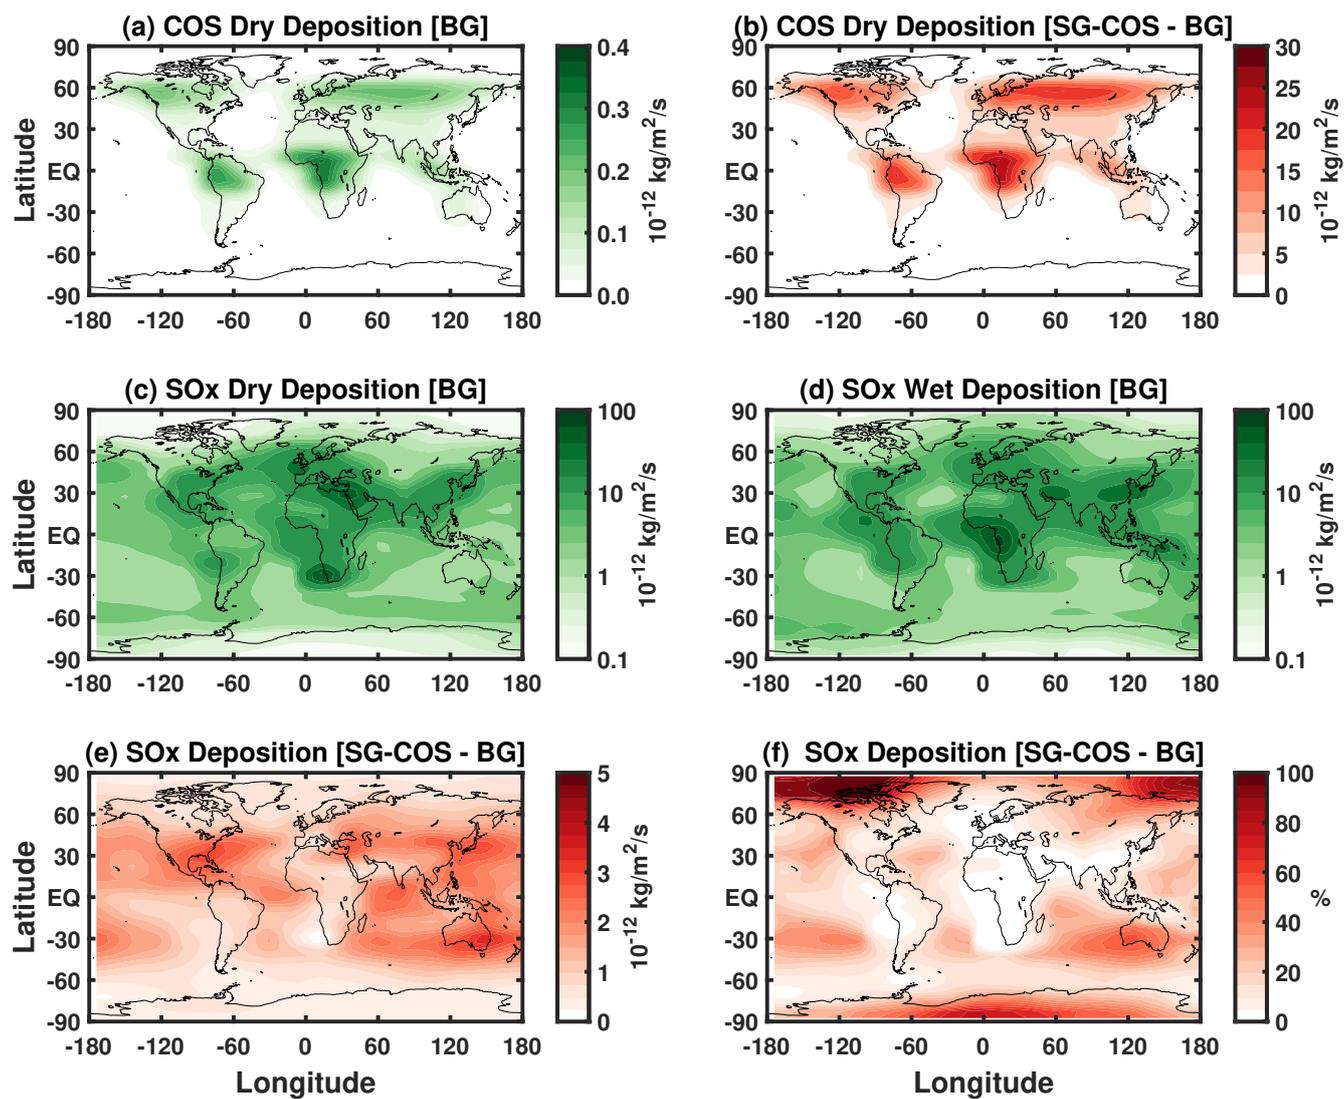

Here we analyse how dry and wet deposition of sulfur species are distributed globally as a result of the two SG interventions. Table 2 and 3 summarize wet and dry deposition rates for the SG-COS and BG experiments, respectively, and they include the contribution of each species to the total deposition. In particular, in SG-COS the increase in COS fluxes produces both an  
160 increase in sulfuric deposition, after its photolysis and oxidation to sulfuric acid, and in dry deposition of COS itself, as it is removed to the ground through uptake by vegetation and soils (Kettle et al., 2002).

The global distribution of COS deposition for the baseline case is shown in figure 6(a) while the increase in deposition from the SG-COS experiment is shown in figure 6(b). COS uptake by plants is concentrated mainly in the tropical rainforests of South America, Africa, and southeast Asia and boreal coniferous forests across North America, northern Europe, and northern  
165 Asia. Uptake by soils occurs mainly in arid and semiarid regions, such as savanna regions in the northern and southern Africa and in the southwestern regions of North America, in the pampas of Argentina, in Australia, and in the steppes of central Asia (Kettle et al., 2002). Dry deposition of COS doesn't contribute to acid deposition and, currently, there is no information available on how different soils or ecosystems would be affected by higher local COS concentrations; therefore, we assumed that their uptake efficiency does not change. The robustness of this assumption will need to be studied.

170 The global distribution of  $\text{SO}_x$  deposition is also shown in figure 6. Panels (c) and (d) show dry and wet deposition, respectively, for the background case. Dry deposition maxima are localized in urban areas close to the source where the emitted sulfur dioxide is immediately oxidized, while wet deposition distribution depends both on sulfate concentration and precipitation.

Panels (e) and (f) show the total  $\text{SO}_x$  deposition change in SG-COS with respect to the baseline case, in absolute terms and as a percentage of the baseline case, and most of its increase is due to wet deposition (see tables 2 and 3, and see Tables S1-4  
175 for a breakdown of global sources and sinks of sulfur species). In both figures, the distribution of deposition is more uniform over the globe with respect to the tropical injection of  $\text{SO}_2$ , except for the polar regions, because of the reduced precipitation rates. Consequently, figure 6 (f) shows a large increase in percent deposition in the polar region (17% in the Arctic, 8% in Antarctic) because of very low values in the baseline case. On the other hand, deposition change is close to zero in polluted regions.

180 Globally, the annual differences in deposition fluxes for all species compared to the background case amount to  $8.3 \pm 0.2$  Tg-S/yr for SG-COS and  $3.9 \pm 0.2$  Tg-S/yr for SG-SO<sub>2</sub>, which equates to an increase of  $8.9 \pm 0.3$  % and  $4.2 \pm 0.3$  %, respectively.

**Figure 6.** a) Surface dry deposition fluxes ( $10^{-12}\text{kg/m}^2/\text{s}$ ) of COS in the background case. b) Change in COS dry deposition fluxes in SG-COS compared to a). c) SO<sub>x</sub> dry deposition fluxes ( $10^{-12}\text{kg/m}^2/\text{s}$ ) in the background case. d) SO<sub>x</sub> dry deposition fluxes ( $10^{-12}\text{kg/m}^2/\text{s}$ ) in the background case. e) Change in SO<sub>x</sub> total deposition fluxes in SG-COS compared to the background. f) as e) but in % of the background values.

#### 4 Indirect effects

**Table 5.** Summary of calculated globally-annually averaged quantities of UVB and UVA at surface. Last two columns show the calculated SG percentage changes with respect to the BG case [years 2046-2055].

The simulated enhancement in the stratospheric aerosol layer would produce two main effects: an increased scattering of solar radiation, that in turn would reduce surface temperatures, and the local absorption of more near-infrared solar and terrestrial radiation, that would warm the stratospheric layer where the aerosols reside (as observed for volcanic eruptions, see Lacis et al., 1992; Labitzke and McCormick, 1992). Furthermore, the increase in the surface area density of the aerosols would affect the heterogeneous chemistry of ClO<sub>x</sub> and NO<sub>x</sub> with implications for ozone concentration and UV radiation at the surface (Tilmes et al., 2009, 2018b, 2021).

For SO<sub>2</sub>, it has been shown that the combination of surface cooling, perturbation of stratospheric temperatures and changes in tropospheric ozone and in UV at the surface also affects methane lifetime (Visioni et al., 2017a). In this section we analyse the differences in these changes also for the SG-COS experiment.

Figure 7 shows the ozone changes in the two SG experiments with respect to the BG case. Panels (a) and (b) show the monthly total ozone column changes as a function of latitude. Close to the equator there is a small reduction in the overall

195 column, mostly due to a reduction in tropospheric ozone, as visible in panels (c) and (d), as a direct consequence of the surface cooling (Nowack et al., 2016). On the other hand, at higher latitudes an overall increase in the total column is observable due to an increase in stratospheric ozone. This is particularly evident closer to the poles.

During springtime months, there is some Antarctic ozone depletion, while in the Arctic a recovery of ozone is observable. In the Antarctic spring, the polar vortex is strengthened by the stratospheric heating in the tropics that affects the equator-to-  
200 pole thermal wind balance (Visioni et al., 2020), resulting in greater confinement of cold air, that, in turn, enhances the ozone depletion by the polar stratospheric clouds (PSC). The tropical stratospheric heating is higher in SG-SO<sub>2</sub> with respect to SG-COS as the aerosols are less confined (fig. S4). Consequently, the strengthening of polar vortex in SG-SO<sub>2</sub> produces a higher ozone depletion. In the Arctic, on the other hand, PSC-related ozone loss is lower (Tilmes et al., 2018a), and the predominant effect is that from an acceleration of the BDC transporting ozone-rich air from lower latitudes.

205 Panels (c) and (d) show the annual mean of ozone mixing ratio percentage change as a function of altitude and latitude. In both SG experiments, negative changes below the tropopause are governed by the decrease in solar radiation which comes into play in the photo-dissociation reaction of NO<sub>x</sub> as an ozone precursor ( $\text{NO}_2 + h\nu \ (\lambda < 420 \text{ nm}) \rightarrow \text{NO} + {}^3\text{O}$ ). Sunlight reduction also affects the O<sub>3</sub> photolysis, decreasing the ozone loss. Positive changes are due to the balance of the previous reactions and the increase of methane (see table 4) as a source of ozone in its oxidation chain, and mainly due to the decrease  
210 of the tropospheric water vapour in a clean air environment (low NO<sub>x</sub>), such as the tropics (Nowack et al., 2016; Xia et al., 2017b).

Above the tropopause, there is a negative ozone change in the lower stratosphere in both SG experiments, except for the Arctic region where we observe a small increase in the Arctic lowermost stratosphere in both cases. The key drivers of stratospheric ozone change are the increase in heterogeneous reactions, as a result of the enhancement of stratospheric aerosols, and  
215 the perturbation of the dynamics governing ozone transport.

Negative ozone changes correspond to the region where the SAD reaches its maximum values (fig. 5 (d) and (f)): between 10-20 km in the polar regions for SG-COS and mainly between 15-25 km at tropics for SG-SO<sub>2</sub>. The increase of the SAD enhances heterogeneous chemistry and results in denitrification via hydrolysis of dinitrogen pentoxide ( $\text{N}_2\text{O}_5 + \text{H}_2\text{O} \xrightarrow{\text{M}} 2\text{HNO}_3$ ). The loss of NO<sub>x</sub> decreases the rate of ozone depletion through its catalytic cycle. Whereas in the mid-stratosphere,  
220 where the cycles of chlorine (ClO<sub>x</sub>) and bromine (BrO<sub>x</sub>) are dominant, there is an increase in ozone loss since reduction of NO<sub>x</sub>, that normally bounds chlorine (ClONO<sub>2</sub>), allows ClO to destroy more ozone (Tilmes et al., 2018b; Grant et al., 1992).

At low latitudes, stratospheric ozone concentration is also driven by change of tropical upwelling (Visioni et al., 2021): the reduction of tropical upwelling of ozone-poor air coming from the lowermost stratosphere leads to higher ozone concentration at altitudes of about 20-22 km (Tilmes et al., 2018b).

225 Figure S5 (e) shows the change of tropical upwelling in relation to change of the residual vertical velocity ( $w^*$ ) with respect to the baseline case. Negative  $w^*$  anomalies in SG-COS mean weaker tropical upwelling as consequence of tropospheric cooling. In SG-SO<sub>2</sub>, the highest concentration of absorbing aerosols leads to positive  $w^*$  above 20 km due to the local warming but this doesn't affect the transport of ozone-poor air from the lower layers.

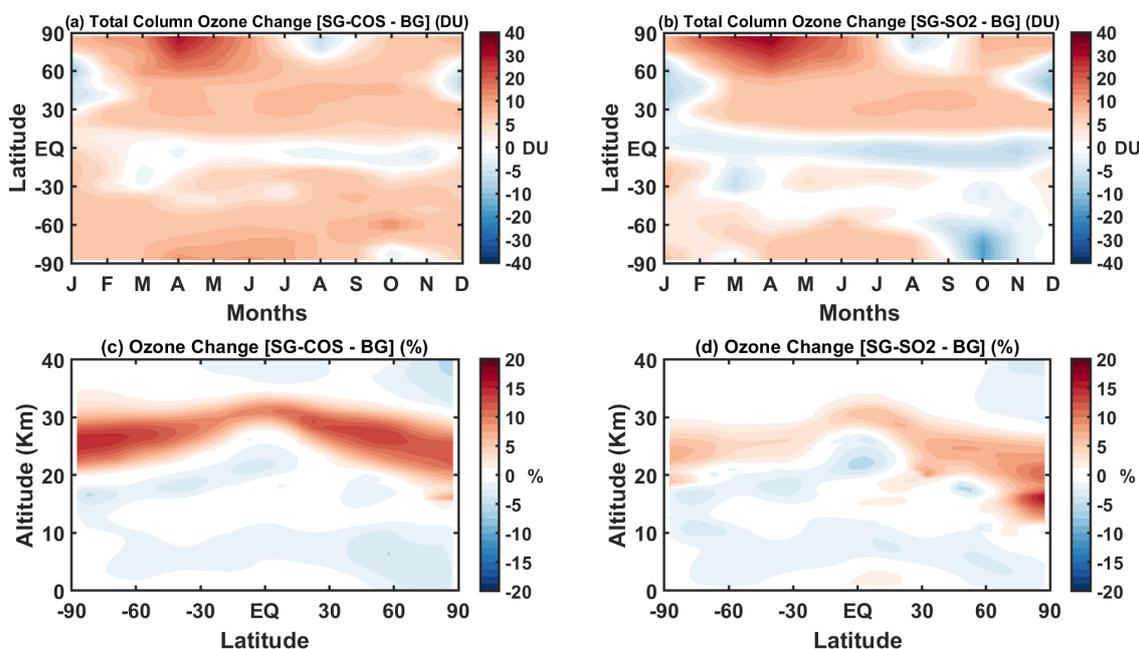

Above the discussed altitudes, there is a net ozone production in both SG experiments, with an higher increase of ozone  
230 mixing ration in SG-COS experiment with respect to SG-SO<sub>2</sub>, especially in the extra-tropical region. Ozone depletion at these  
altitudes is mainly controlled by the catalytic cycle of NO<sub>x</sub>, that is inhibited by the denitrification process due to heterogeneous  
reactions on aerosols.

Globally, the annually-averaged ozone column increases of 4.9 and 1.5 DU for SG-COS and SG-SO<sub>2</sub>, respectively (table 4).  
The stratospheric ozone increase affects UVB at the surface due to its photodissociation, while aerosol could affect UVA  
235 radiation by scattering processes: the projected changes are shown in figure 8 for both UVA and UVB. We estimated these  
changes using TUV (from <https://www2.acom.ucar.edu/modeling/tropospheric-ultraviolet-and-visible-tuv-radiation-model>),  
using in input our model latitudinal and monthly values for the period (2046-2055) for aerosol optical depth, total ozone  
column, climatological cloud cover and surface albedo.

In both SG experiments, the negative changes of UVB radiation at surface, except in the Antarctic region, are related to the  
240 variation in stratospheric ozone. as well as the interannual variation that increase towards the poles, due to the seasonal variation  
of ozone, as discussed before. UVA decrease is everywhere negative in both SG experiments. In particular, the correlation  
between UVA change and particles scattering is evident if we compare this latitudinal distribution with the stratospheric AOD  
of figure 3(a). The globally averaged UVB and UVA changes at surface are summarized in table 5.

Methane is an indirect source of tropospheric ozone (West and Fiore, 2005), and it is also a greenhouse gas. Knowing its  
245 variation is fundamental to understand the final contribution to the radiative forcing that one would wish to achieve with this  
geoengineering method. From table 4, we measure a global increase in methane lifetime of 12.7% in SG-COS and 12.2% in  
SG-SO<sub>2</sub>, which we can identify in the increase in methane itself. The reason for the increase in methane is to be found in  
the behaviour of the hydroxyl radical (OH), as the main sink of methane is the oxidation reaction with OH: decrease of OH  
means an increase of methane lifetime. As discussed by Visionsi et al. (2017b), mechanisms that cause an increase in OH are  
250 as follows: (a) surface cooling lessens the amount of tropospheric water vapor and inhibits the temperature-dependent reaction  
of NO + O<sub>3</sub>; (b) decrease of tropospheric UV, due to enhancement of ozone and scattering radiation, reduce O(<sup>1</sup>D) that takes  
part of the reaction O(<sup>1</sup>D) + H<sub>2</sub>O → 2 OH; (c) increase of SAD enhances heterogeneous chemistry reducing the amount of  
NO<sub>x</sub> (NO + HO<sub>2</sub>, NO + RO<sub>2</sub>); (d) increase of tropical lower stratosphere temperature (TTL) that regulates the stratosphere-  
troposphere exchange, which can be positive or negative depending on the net result of the superimposed species (CH<sub>4</sub>, NO<sub>y</sub>,  
255 O<sub>3</sub>, SO<sub>4</sub>) in the extratropical upper troposphere-lower stratosphere (UTLS).

The warming of the TTL is shown in figure S5 (d): in SG-SO<sub>2</sub>, larger particles confined in the tropical region produce a  
greater warming of the TTL with respect to smaller ones distributed all over the globe in SG-COS. The role of dimensions and  
distributions of aerosols in stratospheric warming is confirmed by the heating rates, as shown in figure S4.

**Figure 7.** a,b) Monthly mean zonal values of SG ozone total column changes (DU) with respect to the BG case for SG-COS and SG-SO<sub>2</sub> respectively. c, d) ozone mixing ratio percent changes with respect to the BG case. All quantities are annually averaged over the years 2046-2055.

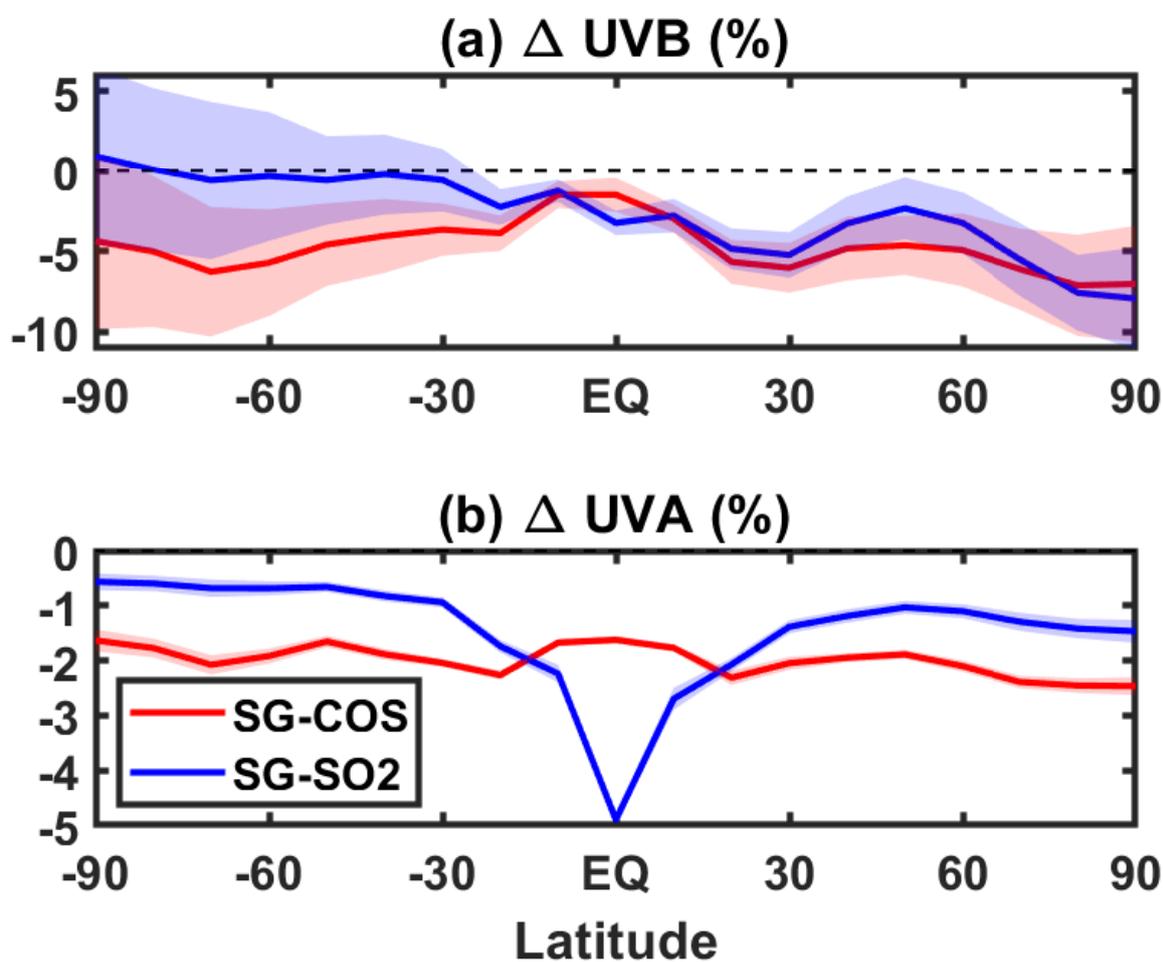

## 5 Radiative forcing

Total RF (W/m <sup>2</sup> )	SW	LW	NET
<b>SG-COS</b>	-1.47±0.12	+0.18±0.25	-1.29±0.13
<b>SG-SO<sub>2</sub></b>	-1.57±0.10	-0.13±0.23	-1.70±0.13

**Table 6.** Globally-annually averaged total RF of sulfate aerosols and greenhouse gases for the two SG experiments with respect to BG (shortwave, longwave and net) (W/m<sup>2</sup>) [years 2046-2055].

260 The ULAQ-CCM radiative transfer module calculates online the radiative forcing due to aerosols, greenhouse gases (GHGs), and low and high clouds. The effects of single components have been estimated offline for both shortwave (SW) and longwave (LW) with the same radiative transfer core, for sulfate aerosols, clouds, COS, CH<sub>4</sub>, stratospheric H<sub>2</sub>O, stratospheric and tropospheric O<sub>3</sub> in order to properly separate the contributions.

Tables S7 and S8 summarise the individual contributions of GHGs changes for SG-COS and SG-SO<sub>2</sub>, respectively. Similar  
 265 increases of methane in both SG experiments produce the same positive LW RF; the TTL warming (which results in an

**Figure 8.** Mean zonal UVB and UVA percent changes at surface with respect to BG case (panels a and b, respectively) in SG-COS (red) and SG-SO<sub>2</sub> (blue). All quantities are annually averaged over the years 2046-2055.

increase in stratospheric water vapor), results in a small but positive contribution from H<sub>2</sub>O in SG-SO<sub>2</sub>. Contributions from both stratospheric and tropospheric O<sub>3</sub> changes have also been estimated, but are negligible.

In SG-COS, obviously, the increase of COS concentration, which is a GHG, must be taken into account. We estimated its contribution to RF based on the definition of global warming potential (GWP) on a mass/mass basis as in Bruhl et al. (2012) for a time horizons of 30 years (2021-2050). GWP can be approximated as follows by the expression of Roehl et al. (1995), assuming that the perturbation of the radiation balance of the Earth by greenhouse gases COS and CO<sub>2</sub> decays exponentially after a pulse emission for a time horizon  $\Delta T$ .

$$GWP_{\Delta t} \simeq \frac{RF_{COS}}{RF_{CO_2}} \times \frac{\tau_{COS}}{\tau_{CO_2}} \times \frac{1 - \exp\left(-\frac{\Delta t}{\tau_{COS}}\right)}{1 - \exp\left(-\frac{\Delta t}{\tau_{CO_2}}\right)} \quad (1)$$

We assumed an overall lifetime of  $\tau_{COS}=3.8$  yr and  $\tau_{CO_2}=75$  yr, and the radiative forcing of 1 kg of COS relative to 1 kg of CO<sub>2</sub> added to the present atmosphere ( $RF_{COS}/RF_{CO_2}$ ) is 724 (Brühl and Crutzen, 1988). This results in a GWP of 111. For our time period, the mass of COS and CO<sub>2</sub> added to the atmosphere ( $\Delta m$ ) is  $1.97 \cdot 10^{12}$  kg of COS and  $1.23 \cdot 10^{15}$  kg of CO<sub>2</sub>. Therefore, the COS radiative forcing can be calculated as:

$$RF_{COS} = GWP_{\Delta t} \times RF_{CO_2} \times \frac{\Delta m_{COS}}{\Delta m_{CO_2}} \quad (2)$$

where  $RF_{CO_2}$  in RCP6.0 is estimated to be 0.83 W/m<sup>2</sup> considering an increase of 68.5 ppm from a baseline of 409.2 ppm. Overall, this results in a radiative forcing from the COS increase of 0.17 W/m<sup>2</sup>.

The main contributions of sulfate aerosols and clouds are summarised in tables S5 and S6 for SG-COS and SG-SO<sub>2</sub>, respectively. Globally, the estimated values are similar for the Clear-Sky SW and LW forcing from the sulfate aerosols: in terms of the latitudinal distribution, however, SG-SO<sub>2</sub> presents a peak in the tropics whereas the forcing from SG-COS is much more latitudinally even.

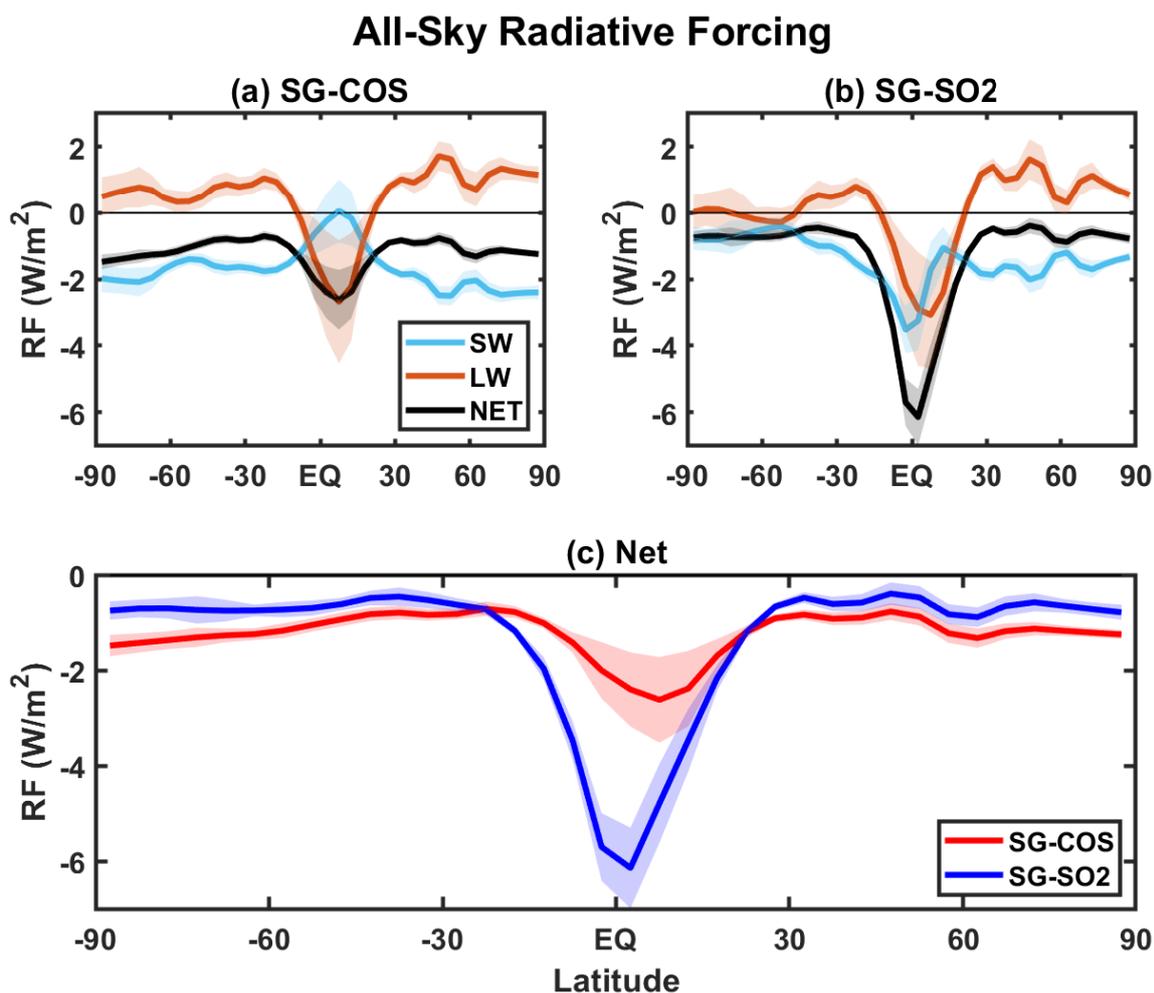

The reduction in optical depth from cirrus clouds (see table 1) produced by the aerosols (Kuebbeler et al., 2012; Visioni et al., 2018a) results in a net negative radiative forcing given by the balance between the reduction of reflected solar radiation, resulting in a positive RF in the shortwave (SW) and the decrease of trapped planetary radiation, which reduces the contribution to the greenhouse effect with a negative RF in the longwave (LW). In the SG-COS case, at the equator the positive RF from the thinning locally cancels out the direct forcing from the aerosol (9 and fig. S6).

Table 6 summarises the total contribution of sulfate aerosols and greenhouse gases under All-Sky conditions.

## 6 Technical feasibility of SG through COS emissions

We briefly discuss here the technical feasibility of the approach described in this paper, as related to the increase of surface COS emissions (for SO<sub>2</sub> injections, see for instance Smith and Wagner, 2018).

Patent number 3,409,399 (1968) has developed a method for high yield synthesis of COS (93.2-96.6%):

**Figure 9.** a-b) Mean zonal shortwave (cyan), longwave (orange), and net (black) radiative forcing (in  $\text{W/m}^2$ ) in SG-COS and SG-SO<sub>2</sub> respectively. c) Comparison of the net radiative forcings from SG-COS (red) and SG-SO<sub>2</sub> (blue). All quantities are annually averaged over the years 2046-2055. Shadings in all panels represent 1 standard deviation in the interannual variability.

$\text{CO}_2$  is abundant even in concentrated (90%+) streams, from various natural and industrial sources, particularly with co-  
operation from states or industries. For example, capturing flue gas from coal-fired power plants is an established technology  
and may yield over 90%  $\text{CO}_2$  (Wang et al., 2013).  $\text{CS}_2$  is produced via numerous means, perhaps the easiest being from coke  
300 (carbon) and molten sulfur:

Approximately 1 million tons of  $\text{CS}_2$  is produced per year (Madon and Strickland-Constable, 1958), with China consuming  
approximately half of the global production of  $\text{CS}_2$  for rayon manufacturing.  $\text{CS}_2$  is highly unstable and is flammable in air. It  
305 is also toxic at low concentrations (10 ppm).

Given the reactions above, about 0.5 Tg of S will produce 0.94 Tg of COS: this amounts to 0.16 Tg of C (coke) and 0.55  
Tg of molten sulfur. In the last decade, approximately 70 Tg of sulfur were produced worldwide, so this would constitute an  
increase in S production of 0.8%. The price varied between \$50 and \$200 per ton, leading to an annual cost of approximately  
\$25-100 million. Worldwide production of coke was around 640 Tg, so this increase in production is negligible. The price of  
310 coke varies between \$50 and \$100 per ton, leading to an annual cost of approximately \$8-16 million.

To this we would have to add the cost of  $\text{CO}_2$ , as well as the production and energy costs. Considering an estimate of \$400  
million per year for each Tg of S between  $\text{CO}_2$  and production and energy cost, and assuming an effort shared between 1000  
locations, this would add up to \$400.000 per location per year per each Tg of S. The overall cost is roughly of the same order  
of magnitude as that in Smith and Wagner (2018) for a stratospheric aerosol deployment at  $\sim 20$  km of injection (so different  
315 from the injection set-up in our study for SG-SO<sub>2</sub>), but without the need to develop a new aircraft-based delivery system.

## 7 Conclusions

We have presented here the results of a modeling experiment with the aim of producing an optically thick cloud of sulfate  
aerosols in the stratosphere without the injection of sulfate precursors directly in the stratosphere, but rather using increased  
surface emissions of carbonyl sulfide (COS). The low reactivity of COS in the troposphere, where it is not reactive and where  
320 it is predominantly absorbed by some soils and by plants, allows for a large portion of its emissions to reach the stratosphere,  
where it is turned into sulfate aerosols by photo-dissociation and oxidation.

We compare the results obtained with an increased emission of 40 Tg-S/yr (roughly 400 times more than the background  
emissions) with those from a 4 Tg-S/yr injection of  $\text{SO}_2$  in the stratosphere as prescribed in previous experiments (Kravitz

et al., 2011; Visioni et al., 2017a). Both experiments result in a similar global optical depth from the produced stratospheric  
325 aerosols ( $\sim 0.07$ ), but with different latitudinal distributions: for  $\text{SO}_2$ , as previously observed in various modeling experiments,  
equatorial injections result in an increased concentration of aerosols in the tropical stratosphere that tends to overcool the tropics  
and undercool the high latitudes (Kravitz et al., 2018; Jiang et al., 2019), while also reducing the efficacy of the back-scattering  
from the aerosols due to the increased size of the particles (Visioni et al., 2018c). On the other hand, with COS emissions the  
uniform mixing of the gas allows for a more uniform distribution of the produced aerosols in the stratosphere, resulting in  
330 increased optical depth also at very high latitude.

The differences in distribution and size of the particles result in different changes to the composition of the atmosphere:  
smaller particles absorb and heat the stratosphere less, thus resulting in fewer dynamical changes. From a chemical perspec-  
tive, stratospheric ozone would be impacted differently from the two geoengineering schemes. For  $\text{SO}_2$  injections, previous  
studies have shown that the overall effect is the result of a combination of various dynamical and chemical factors that behave  
335 differently depending on the latitude and altitude of the aerosols.

At low latitudes the increase in lower stratospheric water vapor produced by the warming of the tropopause layer enhances  
the halogen-driven destruction of ozone in the lower stratosphere (Tilmes et al., 2018b) due to  $\text{NO}_x$  depletion. This effect is  
balanced by reduced ozone destruction in the middle stratosphere due to the slowing down of the  $\text{NO}_x$  cycle produced by  
enhanced heterogeneous chemistry (Pitari et al., 2014; Richter et al., 2017; Franke et al., 2020).

340 Overall, in the case of COS emissions the further increase in SAD produced by smaller particles increases the inhibition of  
the ozone cycles in the middle stratosphere, resulting in a net increase in stratospheric ozone and thus in a larger decrease of  
UV radiation at the surface. Similarly, the larger sulfate burden at high latitudes produces further ozone recovery and thus less  
UV radiation also at the poles for the COS case.

Our results point to the feasibility of surface emissions of COS as a possible substitute to stratospheric  $\text{SO}_2$  (or other sulfate  
345 precursors) injections to produce stratospheric sulfate aerosols. This would sidestep the problem of deploying methods not  
already available to bring the sulfate at those altitudes, including development of novel aircraft (Bingaman et al., 2020).

Since COS is already a byproduct of human activities, it might be possible to devise methods of mass-production of the  
required quantities that may be cheaper than the known proposed methods (Smith et al., 2020).

Overall, there are some weak points in a geoengineering strategy using COS compared to  $\text{SO}_2$  that need to be addressed.  
350 First, it necessitates a larger amount of emissions to achieve the same global stratospheric AOD, resulting in larger amounts of  
deposition. It would be less easily scalable, and both deployment and phase-out, as we have shown, would require a much longer  
time-frame compared to the almost instantaneous effect produced by  $\text{SO}_2$  injections. Considering the dangers to ecosystems  
presented by a too fast deployment or termination of sulfate geoengineering (Trisos et al., 2018), this might not actually be a  
large drawback, but it does remove the possibility of rapidly “regulating” the necessary amount of stratospheric sulfate in case  
355 of changes in strategy or external conditions (such as a Pinatubo-like volcanic eruption; Laakso et al., 2016). Furthermore, the  
mixing happening in the troposphere would not allow any control in the latitudinal or seasonal distribution of the resulting  
aerosols, as proposed elsewhere (MacMartin et al., 2017; Dai et al., 2018; Visioni et al., 2019).

Clearly, this study is intended to be just a pilot study of this newly proposed method, and further simulations with other climate models, possibly with a coupled ocean and interactive land model, to determine the surface response, are needed. The agreement between the baseline results presented here and the information present in the literature point to a robustness of our results, but further studies are required to understand different aspects of the climate response: for instance, studies would need to investigate the possible response of vegetation and soils to the increased concentration of COS in the troposphere, and if the efficacy of the sinks would change due to shifts in temperature and precipitation produced by both climate change and the intervention.

While toxic levels of COS concentrations are many orders of magnitude larger than the one achieved in our simulations (Kilburn and Warshaw, 1995; Bartholomaeus and Haritos, 2006), the effects of prolonged exposure to lower concentrations will have to be assessed. Estimations of the tropospheric radiative effect would also need to be refined to make sure that it is not larger than previously estimated, reducing the efficacy of the aerosol-induced cooling. Overall, however, the results obtained in this work show that, as a geoengineering technique, the surface emission of carbonyl sulfide should be further studied and considered by the scientific community as a possible alternative to the others already studied in the literature.

*Data availability.* Data used in this work will be made available through the Cornell eCommons platform before publication.

*Author contributions.* DV and GP devised the study. IQ ran the simulations, analysed the results, produced the figures and wrote the manuscript with the assistance of DV. BK wrote Section 6 and contributed to the final draft of the manuscript.
