16 **Abstract**

17 Volatile organic compounds (VOCs) tend to be consumed by atmospheric oxidants,  
18 resulting in substantial photochemical loss during transport. An observation-based model was  
19 used to evaluate the influence of photochemical loss of VOCs on the sensitivity regime and  
20 mechanisms of ozone formation. Our results showed that a VOC-limited regime based on  
21 observed VOC concentrations shifted to a transition regime with a photochemical initial  
22 concentration of VOCs (PIC-VOCs) in the morning. The net ozone formation rate was  
23 underestimated by  $3 \text{ ppb h}^{-1}$  ( $\sim 36 \text{ ppb day}^{-1}$ ) based on the PIC-VOCs. The relative contribution  
24 of the  $\text{RO}_2$  path to ozone production based on the PIC-VOCs accordingly increased by 13.4%;  
25 in particular, the contribution of alkene-derived  $\text{RO}_2$  increased by approximately 10.2%. In  
26 addition, the OH- $\text{HO}_2$  radical cycle was obviously accelerated by highly reactive alkenes after  
27 accounting for photochemical loss of VOCs. The contribution of local photochemistry might  
28 be underestimated for both local and regional ozone pollution if consumed VOCs are not  
29 accounted for, and policymaking on ozone pollution prevention should focus on VOCs with a  
30 high reactivity.

31

## 32 **1. Introduction**

33 Ground surface ozone ( $O_3$ ) is an important atmospheric pollutant that is harmful to human  
34 health and is connected with respiratory, cardiovascular diseases, and premature mortality  
35 (Cohen et al., 2017). It is also harmful to vegetation growth. For example, it led to annual  
36 reductions in the yields of rice and wheat by 8% and 6%, respectively, and reduced forest  
37 biomass growth by 11-13% in China (Feng et al., 2019). Surface  $O_3$  concentrations have  
38 increased by 11.9% over eastern China despite the air pollution control measures implemented  
39 in China from 2012 to 2017 (Dang and Liao, 2019). An economic loss of 0.09% of the Chinese  
40 gross domestic product (78 billion CNY) is predicted for 2030 if policies against  $O_3$  pollution  
41 are not properly implemented (Xie et al., 2019). Therefore, urgent action to minimize  $O_3$   
42 pollution in China is needed.

43 Tropospheric  $O_3$  is mainly produced from photochemical reactions between volatile  
44 organic compounds (VOCs) and nitrogen oxides ( $NO_x$ :  $NO+NO_2$ ) (Seinfeld and Pandis, 2006;  
45 Liu et al., 2021).  $O_3$  is generated from a collision of  $O_2$  and  $O(3P)$  that is produced from  
46 photolysis of  $NO_2$  in the atmosphere. Peroxyl radicals ( $HO_2$  and  $RO_2$ ), which are produced  
47 from the oxidation of VOCs by OH radical, can efficiently convert NO (from the photolysis of  
48  $NO_2$ ) to  $NO_2$ , leading to a net  $O_3$  production by compensating for the titration of  $O_3$  by NO  
49 (Monks, 2005; Zhang et al., 2021a). Over the past two decades, a number of field observations  
50 focused on  $O_3$  pollution levels and its precursors have been carried out in the Beijing-Tianjin-  
51 Hebei (BTH), Yangtze River Delta (YRD), and Pearl River Delta (PRD) regions (Wang et al.,  
52 2017; Li et al., 2019; Xue et al., 2014; Zhang et al., 2019). Due to the nonlinear relationship

53 between O<sub>3</sub> and its precursors and the variations in meteorological conditions, numerous  
54 studies have been performed to understand the sensitivity regime of O<sub>3</sub> formation (Ling and  
55 Guo, 2014; Zhang et al., 2020), the photochemical process of O<sub>3</sub> formation based on box  
56 models or observation-based models (OBM) (He et al., 2019; Tan et al., 2019), and the sources  
57 of O<sub>3</sub> using regional chemical transport models (Li et al., 2016b; Li et al., 2016c). Recently,  
58 the instantaneous production rate of the O<sub>3</sub> formation process has attracted more attention; for  
59 example, studies examining radical recycling (OH-RO<sub>2</sub>-RO-HO<sub>2</sub>-OH) related to the production  
60 of O<sub>3</sub> have been performed (Lu et al., 2017; Tan et al., 2017; Whalley et al., 2018). HCHO  
61 photolysis and alkene ozonolysis contributed approximately 85% to the primary production of  
62 HO<sub>2</sub> and HO radicals in Beijing, Shanghai and Guangzhou (Tan et al., 2019; Yang et al., 2017).  
63 The importance of HONO and HCHO photolysis for primary radical production has also been  
64 proposed in suburban and rural areas (Tan et al., 2017; Lu et al., 2012; Lu et al., 2013).

65 All of the OBM studies investigating the relationship between O<sub>3</sub> and VOCs were based  
66 on measured datasets. However, VOCs are highly reactive to atmospheric oxidants, such as  
67 OH, NO<sub>3</sub>, and O<sub>3</sub>, among which OH is dominant. The lifetimes of some highly reactive VOCs,  
68 such as isoprene, are as short as only a few tens of minutes under typical daytime atmospheric  
69 conditions. The mixing ratios of VOCs observed at a sampling site are actually the residues of  
70 VOCs from emissions due to the photochemical loss during transport from the source site to  
71 the receptor site. If photochemically consumed VOCs are not considered, the O<sub>3</sub> formation  
72 sensitivity and net O<sub>3</sub> production may be misunderstood, and subsequent policymaking on O<sub>3</sub>  
73 pollution prevention at regional or urban scales may be misguided. Thus, the photochemical

74 age-based approach has been applied to evaluate the effect of photochemical processes on VOC  
75 measurements (Shao et al., 2011). This method was used to qualitatively or semi-quantitatively  
76 estimate the O<sub>3</sub> formation process of the source-receptor (Gao et al., 2018) by calculating the  
77 O<sub>3</sub> formation potential (OFP) (Han et al., 2017), identifying the critical species for O<sub>3</sub> formation  
78 (Gao et al., 2021), or evaluating the VOC emissions ratio (Yuan et al., 2013). In evaluating the  
79 importance of initial VOCs to ozone production, Xie et al. (2008) found that the OFP at a  
80 Peking University site increased by 70% after accounting for the photochemical loss of VOCs.  
81 Li et al. (2015) also showed that the OFPs of total NMHCs (excluding isoprene) increased by  
82 16.1% (from 59.6 to 69.2 ppb O<sub>3</sub>), 12.1% (from 33.5 to 37.5 ppb O<sub>3</sub>), and 3.4% (from 68.9 to  
83 71.2 ppb O<sub>3</sub>) after correcting for photochemical loss in Gucheng, Quzhou, and Beijing,  
84 respectively. Gao et al. (2018) reported that the OFP could be underestimated by 23.4% (62.4  
85 ppb O<sub>3</sub>) in Beijing if the photochemical loss of VOCs is not considered. Zhan et al. (2021)  
86 found that based on measured VOCs, the OFP increased from 57.8 ppb to 103.9 ppb using the  
87 initial VOCs. All the previous work was based on the maximum incremental reactivities (MIR)  
88 method. However, the application of such calculations using the MIR method is restricted to  
89 areas or episodes in which O<sub>3</sub> formation is VOC-sensitive (Carter, 1994). In the troposphere,  
90 the sensitivity of ozone formation to NO<sub>x</sub> and VOCs varies greatly, as evidenced by the wide  
91 range of OFP underestimations from ~3% to 70% in previous work. Thus, the nonlinear  
92 relationship between ozone and VOCs/NO<sub>x</sub> cannot be well described using the MIR method,  
93 and a quantitative analysis is necessary to explicitly understand the ozone formation process  
94 and its mechanisms in the atmosphere.

95 In this study, an OBM was used to evaluate the local O<sub>3</sub> formation process in summer in  
96 Beijing based on concentrations of observed and photochemical initial concentrations of VOCs  
97 (PIC-VOCs). The O<sub>3</sub>-NO<sub>x</sub>-VOC sensitivity, instantaneous O<sub>3</sub> formation rate and in situ O<sub>3</sub>  
98 formation process were discussed. The aim of this study was to understand the possible  
99 influence of photochemical loss of VOCs on the formation sensitivity regime of O<sub>3</sub> and how  
100 the photochemical loss of VOCs affects O<sub>3</sub> formation. This study can provide new insight for  
101 better understanding atmospheric O<sub>3</sub> pollution.

## 102 **2. Methodology**

### 103 **2.1 Experimental section**

104 Field observations were carried out on the Qingyuan campus of the Beijing Institute of  
105 Petrochemical Technology (BIPT, 39.73°N and 116.33°E) (Figure S1). Details on the  
106 observation site have been described in our previous work (Zhan et al., 2021). In short, the site  
107 is a typical suburban site in the Daxing District between 5<sup>th</sup> Ring Road and 6<sup>th</sup> Ring Road. The  
108 field campaign was carried out during August 1-28, 2019, when photochemistry was the most  
109 active and rainfall was rare in Beijing.

110 The concentrations of nonmethane hydrocarbons (NMHCs) were detected by both a gas  
111 chromatography-flame ionization detector (GC/FID) and a single photon ionization (SPI) TOF-  
112 MS (SPI-MS 3000, Guangzhou Hexin Instrument Co., Ltd., China). A detailed description of  
113 the instrumentation can be found in previous publications (Zhan et al., 2021; Chen et al., 2020).  
114 The SPI-MS was also used to detect halohydrocarbons. More details on this instrument and its  
115 parameter settings have been described in previous studies (Zhang et al., 2019; Liu et al.,

116 2020a). In short, a 0.002 int thick polydimethylsiloxane (PDMS) membrane (Technical  
117 Products Inc., USA) was used to collect VOCs and diffuse them from the sample site to the  
118 detector under high vacuum conditions. Vacuum ultraviolet (VUV) light generated by a  
119 commercial D2 lamp (Hamamatsu, Japan) was utilized for ionization at 10.8 eV. For ion  
120 detection, two microchannel plates (MCPs, Hamamatsu, Japan) assembled with a chevron-type  
121 configuration were employed. This TOF-MS has an LOD varying from 50 ppt to 1 ppb with a  
122 1-minute time resolution for most trace gases without any preconcentration procedure. To  
123 verify the data compatibility of the SPIMS and GC/FID, we compared the concentrations of  
124 toluene measured using these two different instruments (Figure S2). The correlation coefficient  
125 was 0.9 (with a slope of 0.7), indicating that the concentrations of NMHCs were comparable  
126 using these two measurement techniques.

127 Oxygenated VOCs (OVOCs) were collected using 2,4-dinitrophenylhydrazine (DNPH)-  
128 coated silica gel cartridges (Sep-Pak, Waters) by an automatic sampling device with a sampling  
129 flow rate of  $1.2 \text{ L min}^{-1}$  and a duration of 2 h for each sample. Then, the OVOCs were analysed  
130 using high-performance liquid chromatography (HPLC, Inertsil ODS-P  $5 \mu\text{m}$   $4.6 \times 250 \text{ mm}$   
131 column, GL Sciences) with an acetonitrile-water binary mobile phase (Ma et al., 2019). To  
132 avoid possible contamination or desorption after sampling, cartridges were capped, placed into  
133 tightly closed plastic bags and kept in a refrigerator before analysis. The sampled cartridges  
134 were eluted with 5 mL acetonitrile and analysed by HPLC as soon as possible after they were  
135 shipped back to the laboratory. This system was calibrated with 8-gradient standard solutions  
136 (TO11/IP-6A Aldehyde/Ketone-DNPH Mix, SUPELCO). The correlation coefficients were all

137 greater than 0.999. The LOD for most OVOCs was approximately 10 ppt.

138 Trace gases, including NO<sub>x</sub>, SO<sub>2</sub>, CO, and O<sub>3</sub>, were measured using corresponding  
139 analysers (Thermo Scientific, 42i, 43i, 48i, and 49i, respectively). The HONO concentration  
140 was measured using a homemade long path absorption photometer (LOPAP) (Liu et al., 2020c).  
141 The meteorological parameters, including temperature (T), pressure (P), relative humidity  
142 (RH), wind speed, and wind direction, were measured by a weather station (AWS310, Vaisala).  
143 The photolysis rate ( $J_{NO_2}$ ) was measured via continuous measurement of the actinic flux in the  
144 wavelength range of 285-375 nm using a  $J_{NO_2}$  filter radiometer ( $J_{NO_2}$  radiometer, Metcon).

## 145 **2.2 Calculation of photochemical loss of VOCs**

146 The photochemical loss of VOCs was calculated using the ratio method (Wiedinmyer et  
147 al., 2001; Yuan et al., 2013). The initial mixing ratio of a specific VOC was calculated using  
148 the following equations (Mckeen et al., 1996):

$$149 \quad [VOC_i]_t = [VOC_i]_{t0} \times \exp(-k_i \times [OH] \times \Delta t) \quad (1)$$

$$150 \quad \Delta t = \frac{1}{[OH] \times (k_X - k_E)} \times \left\{ \ln \left( \frac{X_0}{E_0} \right) - \ln \left( \frac{X_t}{E_t} \right) \right\} \quad (2)$$

151 where  $[VOC_i]_t$  and  $[VOC_i]_{t0}$  are the observed and initial concentrations of  $VOC_i$ , respectively;  
152  $k_i$  is the second-order reaction rate between compound  $i$  and OH radical; and  $[OH]$  and  $\Delta t$  are  
153 the concentration of OH radical and the photochemical ageing time, respectively.  $k_X$  and  $k_E$  are  
154 rate constants for the reaction between OH radicals and xylene ( $7.00 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ )  
155 and ethylbenzene ( $1.87 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ ) (Atkinson and Arey, 2003), respectively.  
156 ( $X_0/E_0$ ) is the initial mixing ratio between xylene and ethylbenzene, and ( $X_t/E_t$ ) is the mixing  
157 ratio between xylene and ethylbenzene at the observation time. In this study, we chose the mean

158 concentrations of xylene and ethylbenzene at 05:00-06:00 as their initial concentrations before  
159 sunrise according to the ambient  $J_{NO_2}$  (Figure S3) to calculate the photochemical loss of OH  
160 exposure. In previous work (Shao et al., 2011; Zhan et al., 2021), the selection of ethylbenzene  
161 and xylene as tracers was justified for calculating ambient OH exposure under the following  
162 conditions: 1) the concentrations of xylene and ethylbenzene were well correlated (Figure S4),  
163 which indicated that they were simultaneously emitted; 2) they had different degradation rates  
164 in the atmosphere; and 3) the calculated PICs were in good agreement with those calculated  
165 using other tracers, such as i-butene/propene (Zhan et al., 2021). To test the relative constant  
166 emission ratio from different sources, we chose benzene vs. acetylene and n-hexane vs. toluene  
167 as references, and the result is shown in Figure S5. These ambient ratios could directly reflect  
168 their relative emission rates from sources (Goldan et al., 2000; Jobson et al., 2004). The linear  
169 correlation coefficients ( $R^2$ ) were generally higher than 0.7, which were equal to that reported  
170 by Shao et al. (2011). To further test the assumption that the emissions of xylene and  
171 ethylbenzene were constant throughout the day, their potential sources were calculated using a  
172 source-receptor model (the potential source contribution function, PSCF). As shown in Figure  
173 S6, xylene and ethylbenzene showed similar distributions. In addition, the ratio of  
174 ethylbenzene/xylene at 5:00 and 6:00 was similar to that during the daytime. These results  
175 indicated that the emissions of xylene and ethylbenzene were constant throughout the day. The  
176 ratio of xylene to ethylbenzene and the OH exposure concentration are shown in Figure S7.  
177 The results showed that the ratio of xylene to ethylbenzene increased gradually (07:00~12:00),  
178 which is consistent with the trend of xylene and ethylbenzene. The OH exposure was from 0.82

179 to  $8.1 \times 10^6$  molecule  $\text{cm}^{-3}$  h, with a mean daytime value of  $4.3 \pm 1.9 \times 10^6$  molecules  $\text{cm}^{-3}$  h.  
180 Accordingly, the mean photochemical ages were  $1.7 \pm 0.9$  h using the mean daytime (8:00-17:00  
181 LT) OH concentrations ( $4.3 \pm 3.1 \times 10^6$  molecules  $\text{cm}^{-3}$ ) calculated based on JO1D using the  
182 method reported in our previous work (Liu et al., 2020b; Liu et al., 2020c). This meant that  
183 VOCs would undergo obvious degradation even during a short range of transport in the  
184 atmosphere.

185 It should be noted that the  $k_{OH}$  of isoprene is  $9.98 \times 10^{-11}$   $\text{cm}^3$  molecule $^{-1}$  s $^{-1}$  at 298.15 K  
186 (Atkinson and Arey, 2003), almost two orders of magnitude greater than other VOCs. The ratio  
187 method assumes constant emissions for VOCs. However, the emission of isoprene greatly  
188 depends on temperature and solar irradiation intensity (Zhang et al., 2021b). In addition to  
189 accounting for photochemical loss, additional correction of daytime isoprene concentrations  
190 was performed using the average diurnal flux of isoprene emissions (Figure S8) (Zhang et al.,  
191 2021b). The emission of isoprene showed a clear unimodal curve, and the volume  
192 concentration of isoprene was calculated based on the daily emission curve using Eq. (S1).

### 193 **2.3 Observation-based model simulation**

194 A box model based on the Master Chemical Mechanism (MCM3.3.1) and the Regional  
195 Atmospheric Chemical Mechanism (RACM2) was used in this study. The MCM3.3.1 was used  
196 to understand the instantaneous ozone formation process, and the RACM2 was used to depict  
197 the ozone isopleth due to its high computational efficiency (Sect. 2.4). Table S1 shows the  
198 model inputs. The model calculations were constrained with the measured meteorological  
199 parameters (RH, T, P, and  $J_{NO_2}$ ) and the concentrations of trace gases, including inorganic

200 species (NO, NO<sub>2</sub>, CO, SO<sub>2</sub>, and HONO) and 61 organic species (NMHCs (46), OVOCs (8),  
 201 and halohydrocarbons (7)). The model was validated using the observed and simulated O<sub>3</sub>  
 202 concentrations, which showed good consistency, as shown in Figure S9. The slope and  
 203 correlation coefficients were 0.9 and 0.8, respectively (Figure S10), respectively, indicating the  
 204 validity of the model simulation. It is worth mentioning that the results of model simulation  
 205 can sometimes be overestimated or underestimated to some extent, which has also been  
 206 reported by previous studies (Zong et al., 2018; Zhang et al., 2020), but this did not affect our  
 207 simulations of the ozone formation process and mechanisms because we constrained the ozone  
 208 concentration during our simulations.

209 The ozone formation rate P(O<sub>3</sub>) can be quantified by the oxidation rate of NO to NO<sub>2</sub> by  
 210 peroxy radicals (Tan et al., 2019), as expressed in Eq. (3). In this study, the modelled peroxy  
 211 radical concentrations were used to calculate the ozone production rate.

$$212 \quad P(O_3) = k_{HO_2+NO}[HO_2][NO] + k_{RO_2+NO}[RO_2][NO] \quad (3)$$

213 where  $P(O_3)$  is the ozone formation rate;  $[HO_2]$  and  $[RO_2]$  are the number concentrations of  
 214  $HO_2$  and  $RO_2$  radicals;  $k_{HO_2+NO}$  is the second reaction rate between  $HO_2$  and  $NO$ ; and  $k_{RO_2+NO}$   
 215 is the second reaction rate for the reaction of  $RO_2$  and  $NO$ , which only produces  $RO$  and  $NO_2$ .  
 216 Once ozone forms, it will be consumed by  $OH$ ,  $HO_2$ , and alkenes. Additionally, some  $NO_2$  can  
 217 react with  $OH$ , resulting in the formation of nitrate before photolysis. The chemical loss of both  
 218  $O_3$  and  $NO_2$  is considered in the calculation of the net ozone production rate (Tan et al., 2019),

$$219 \quad L(O_3) = (k_{O_3+OH}[OH] + k_{O_3+HO_2}[HO_2] + k_{O_3+alkenes}[alkenes])[O_3] +$$

$$220 \quad k_{NO_2+OH}[NO_2][OH] \quad (4)$$

221 where  $L(O_3)$  is the ozone chemical loss rate;  $[OH]$  is the number concentration of  $OH$  radical;  
222  $k_{O_3+OH}$ ,  $k_{O_3+HO_2}$ , and  $k_{O_3+alkenes}$  are the second reaction rates between  $O_3$  and  $OH$ ,  $HO_2$  and  
223 alkenes, respectively; and  $k_{NO_2+OH}$  is the second reaction rate between  $NO_2$  and  $OH$ . Finally,  
224  $F(O_3)$  is the net ozone formation rate calculated by the difference between  $P(O_3)$  and  $L(O_3)$ , as  
225 expressed in Eq. (5),

$$226 \quad F(O_3) = P(O_3) - L(O_3) \quad (5)$$

## 227 **2.4 Empirical Kinetic Modelling Approach**

228 The empirical kinetic modelling approach (EKMA) used in this work is a set of imaginary  
229 tests to reveal the dependence of photochemical oxidation products on the change in precursors.  
230 We set up  $30 \times 30$  matrices by reducing or increasing the measured VOCs and  $NO_x$   
231 concentrations in the model input. The resulting radical concentrations and ozone production  
232 rates were calculated correspondingly.

233 At this stage, the observed VOCs were grouped into different lumped species according  
234 to their RACM2 classification; more details can be found in a previous publication (Tan et al.,  
235 2017). The chemical model simulated photochemical reactions with input species for a time  
236 interval of 60 minutes, which was enough for  $NO_x$ ,  $OH$ ,  $HO_2$ , and  $RO_2$  to reach a steady state  
237 because the typical relaxation time of the chemical system is 5-10 minutes in summer (Tan et  
238 al., 2018). However, all the species and parameters were input at a 5 min interval by data  
239 interpolation to reduce simulation inconsistencies and large distortions of meteorological  
240 parameters at longer time intervals (Tan et al., 2018). The ozone production rate was calculated  
241 as described in Sect. 2.3. It is worth mentioning that the average survey data were selected as

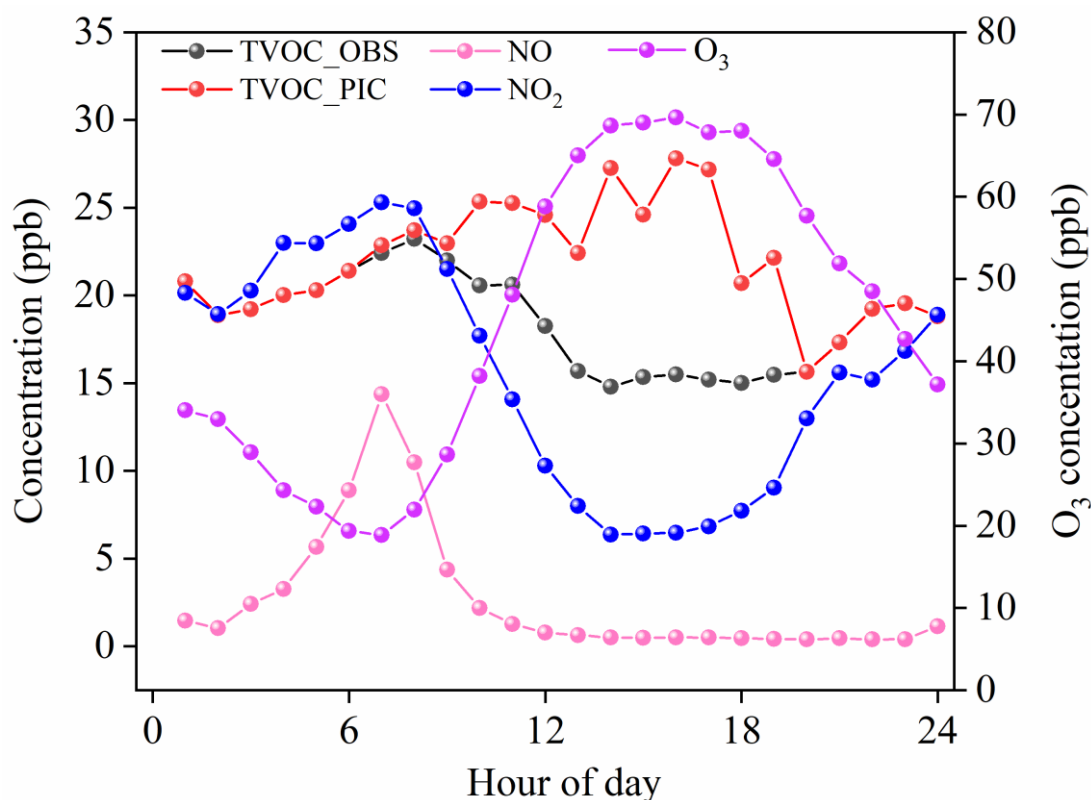

242 the baseline scenario in simulating the EKMA curve in this study.

### 243 **3. Results and discussion**

#### 244 **3.1 Overview of diurnal variation in O<sub>3</sub>, NO<sub>x</sub>, and TVOC**

245 Figure 1 shows the average diurnal variation of concentrations in O<sub>3</sub>, NO<sub>x</sub>, and TVOC  
246 (including alkanes, alkenes, OVOCs, and halohydrocarbons) driven by emissions,  
247 photochemical reactions and the evolution of the mixing layer height (MLH). The ozone  
248 concentration during the observation period was  $44.8 \pm 27.2$  ppb with a maximum of 119.1 ppb,  
249 as reported in our previous study (Zhan et al., 2021), which was generally comparable with the  
250 O<sub>3</sub> concentrations during 2014-2018 (Ma et al., 2020). The O<sub>3</sub> followed a unimodal curve with  
251 a minimum value ( $18.8 \pm 15.4$  ppb) at 07:00 and then it increased to a maximum value ( $69.6$   
252 ppb) at 15:00 as photochemical ozone formed. In contrast, NO<sub>x</sub> reached its maximum  
253 concentration ( $39.7 \pm 14.2$  ppb) at 07:00 and then decreased. After 07:00, the mixing ratio of  
254 NO continuously dropped, while the concentration of NO<sub>2</sub> decreased at first and then started  
255 to increase at 14:00. The diurnal variations in the observed TVOCs were generally consistent  
256 with those of NO<sub>2</sub>. The observed TVOCs concentrations ranged from 2.2 to 23.2 ppb, with a  
257 mean value of  $18.6 \pm 2.6$  ppb. Compared to the concentrations ( $45.4 \pm 15.2$  ppb) in the same  
258 period in August 2015 (Li et al., 2016a), the concentration of VOCs in Beijing was effectively  
259 reduced. However, the photochemical initial concentrations (PICs) of TVOCs, which varied  
260 from 2.2 to 27.8 ppb with a mean value of  $24.5 \pm 2.1$  ppb, showed a different diurnal curve  
261 compared with the observed concentrations. It slightly increased from 07:00 to 14:00, which  
262 was similar to the diurnal variation of VOCs in previous work (Zhan et al., 2021). The average

263 PIC-VOCs was  $6.9 \pm 0.5$  ppb higher than the observed concentration of TVOCs, indicating an  
 264 underestimated contribution of the local photochemistry of VOCs to O<sub>3</sub> and organic aerosol  
 265 formation.

266  
 267 **Figure 1.** Overview of average diurnal variations in O<sub>3</sub>, NO<sub>x</sub>, and TVOC. The data represent  
 268 measured results, except for those of the TVOC\_PIC, which are calculated based on OH radical  
 269 exposure. The data range is August 1-28, 2019.

### 270 3.2 Influence of photochemical loss of VOCs on the O<sub>3</sub> formation sensitivity regime

271 The sensitivity of O<sub>3</sub> formation is analysed using the isopleth diagram generated from the  
 272 EKMA model, which is widely used to qualitatively study O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity. As  
 273 described in Sect. 2.4, the concentrations of NO<sub>2</sub> and VOCs were artificially scaled to  $\pm 75\%$   
 274 of the observed values to calculate the response of O<sub>3</sub> concentration to an imaginary change in  
 275 the concentrations of NO<sub>2</sub> and VOC, with other constrained conditions remaining unchanged.

276 Figure 2 shows the typical EKMA curves during our observations. The black stars and  
277 pentagons denote the observed concentrations of NO<sub>x</sub> and VOCs in the morning (09:00-10:00)  
278 and at noon (14:00-15:00), respectively, while the blue symbols are the corresponding values  
279 of PICs. Based on the measured data, O<sub>3</sub> formation was in a VOC-limited regime in the  
280 morning and a NO<sub>x</sub>-limited regime in the afternoon. The black arrow indicates a linearly  
281 decreasing trend of NO<sub>x</sub> and VOCs from 09:00 to 15:00 in the chemical coordinate system,  
282 and ozone production shifted from VOC-limited to NO<sub>x</sub>-limited conditions from morning to  
283 afternoon, which was consistent with the mean diurnal profiles (Figure 1). This was similar to  
284 the data reported in Wangdu (Tan et al., 2018). As expected, ozone production shifted from a  
285 VOC-limited regime (the observed VOCs) to a transition regime based on the PIC-VOCs in  
286 the morning. Ozone production clearly moved further to a NO<sub>x</sub>-limited regime in the afternoon  
287 after the photochemically consumed NO<sub>x</sub> and VOCs had been accounted for (Figure 2).  
288 Because the average photochemical ageing time was only  $1.7 \pm 0.9$  h, these results indicated  
289 that the O<sub>3</sub> formation mechanism might typically be misdiagnosed, which misleads mitigation  
290 measures for O<sub>3</sub> prevention if the consumed VOCs under real atmospheric conditions are not  
291 considered.

292

293 **Figure 2.** Isopleth diagram of the ozone concentration as a function of the concentration of  
 294 NO<sub>x</sub> and VOCs derived from an empirical kinetic modelling approach. The pentagons and stars  
 295 indicate the status in the morning (09:00-10:00) and at noon (14:00-15:00), respectively. The  
 296 black and blue colours represent the observed and corrected statuses, respectively.

### 297 3.3 Contribution of VOC species to O<sub>3</sub> production

298 The time series of simulated OH, HO<sub>2</sub>, and RO<sub>2</sub> concentrations were used to calculate the  
 299  $P(O_3)$  and  $L(O_3)$ . The diurnally averaged  $P(O_3)$  and  $L(O_3)$  are shown in Figure 3. Ozone  
 300 formation can be divided into processes related to RO<sub>2</sub>+NO and HO<sub>2</sub>+NO (Sect. 2.3).  
 301 According to their VOC precursors, peroxy radical groups were divided into alkane-derived  
 302 (ALKAP), alkene-derived (ALKEP), aromatic-derived (AROMP), isoprene-derived (ISOP),  
 303 oxygenated-VOC-derived (OVOCP), and halohydrocarbon-derived (HALOP) RO<sub>2</sub> and HO<sub>2</sub>P.

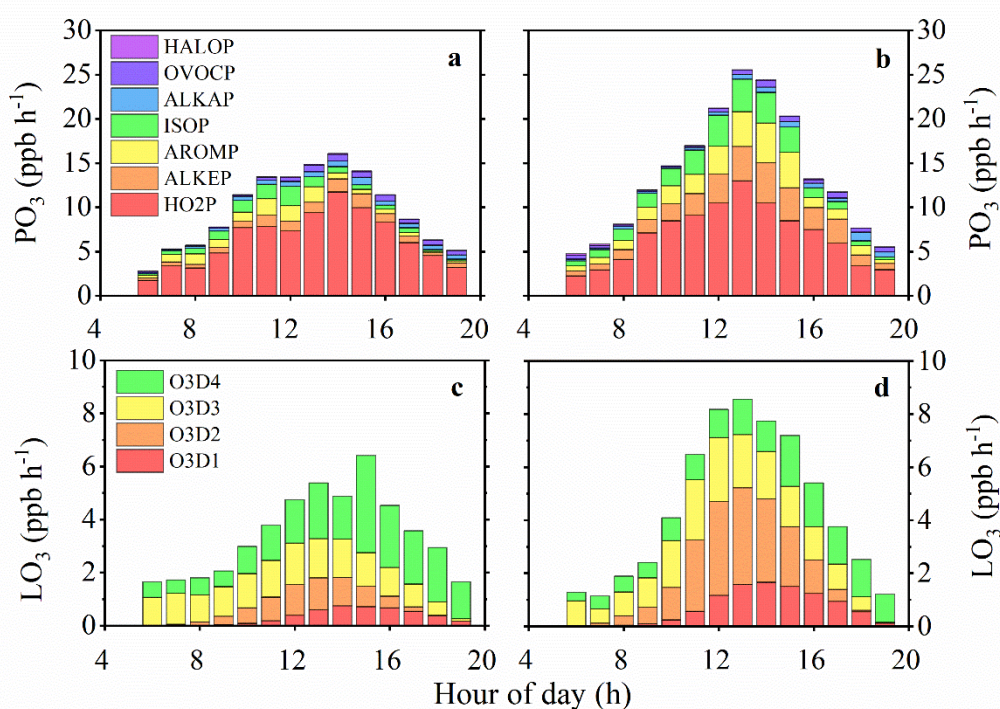

304 The ozone destruction processes included the reaction between  $O_3$  and  $HO_x$  (O3D1), the  
305 reaction between  $O_1D$  and  $H_2O$  (O3D2), the reaction between  $O_3$  and alkenes (O3D3), and the  
306 reaction between  $NO_2$  and  $OH$  (O3D4).

307 Based on the observed VOCs (or PIC-VOCs), a fast  $O_3$  production rate was observed at  
308 14:00 (or 13:00), with a diurnal maximum value of 16.1 (or 25.6)  $ppb\ h^{-1}$  (Figure 3a and 3b),  
309 while the peak destruction rate was 6.4 (or 8.6)  $ppb\ h^{-1}$  at 15:00 (or 13:00) (Figure 3c and 3d).  
310 The average daytime  $P(O_3)$  from 07:00 to 19:00 based on the initial concentrations of VOCs  
311 was  $4.0 \pm 3.1\ ppb\ h^{-1}$  higher than that based on the measured VOCs concentrations (Figure 3b).  
312 At the same time, the  $F(O_3)$  from 07:00 to 19:00 based on the initial concentrations of VOCs  
313 was also  $3.0 \pm 2.1\ ppb\ h^{-1}$  higher than the measured counterpart (Figure S11). Thus, the net  $O_3$   
314 production could be accumulatively underestimated by  $\sim 36\ ppb\ day^{-1}$  from 07:00 to 19:00 if  
315 the consumption of VOCs was not considered. This meant that the contribution of the local  
316 formation of  $O_3$  could be underestimated using the directly measured VOCs concentrations. It  
317 should be pointed out that it is better to compare  $O_3$  production with the true metric for  $O_3$   
318 production. However, it is impossible to directly measure the true metric for  $O_3$  production in  
319 the atmosphere at the present time to know how well the method presented here corrects for  
320 that underestimation. In addition, the ozone concentrations must be constrained when  
321 simulating the ozone formation process (Lu et al., 2013; Tan et al., 2017). Thus, it is impossible  
322 to directly compare the ozone production based on PIC-VOCs with that using measured VOCs  
323 concentrations. Therefore, we alternatively compared the integrated net ozone production rates  
324 rather than ozone production or concentrations between the two scenarios. An upwind  $O_3$  and

325 VOCs measurement combined with a trajectory analysis might provide an approach for  
326 checking the accuracy of our results. Alternatively, conducting a transient O<sub>3</sub> production rate  
327 analysis after subtracting the transport of O<sub>3</sub> with a regional model and/or satellite observation  
328 might be another option. Unfortunately, neither the upwind measurement nor the regional  
329 model simulation was available at the time of our study. To further check the accuracy of our  
330 results, we chose August 4<sup>th</sup> as a test case to explore the influence of the transport of ozone on  
331 a downwind site based on the trajectory analysis. As shown in Figure S12, the mean ozone  
332 concentration of the downwind site (national monitoring station, NMS) was 27.6±21.9 ppb  
333 day<sup>-1</sup> higher than that of the observation site (OS), which was slightly less than the difference  
334 (~36 ppb day<sup>-1</sup>) between PIC-VOCs and observed VOCs and indirectly rationalized our results.

335 The HO<sub>2</sub> path contributed 64.8% to the total ozone formation on average, which was  
336 slightly higher than the reported value (57.0%) in Wangdu (Tan et al., 2018), whereas the RO<sub>2</sub>  
337 path, in which aromatics (9.4%), alkenes (8.4%), isoprene (7.8%), alkanes (4.7%), OVOCs  
338 (4.3%) and halohydrocarbons (0.6%) were the main contributors, contributed to the remaining  
339 part. For the PIC-VOCs, the dominant path of O<sub>3</sub> production (51.7%) was still the HO<sub>2</sub> path,  
340 followed by the RO<sub>2</sub> path related to alkenes (14.7%), aromatics (12.8%), and isoprene (11.7%).  
341 The relative contribution of the RO<sub>2</sub> path to P(O<sub>3</sub>) increased by 13.4% compared with the  
342 measured VOCs, particularly alkene-derived RO<sub>2</sub>, which increased by 10.2%. As shown in  
343 Figure 3c and 3d, the destruction of total oxidants was dominated by the reaction between O<sub>3</sub>  
344 and alkenes (O3D3) in the morning. It gradually shifted to the reaction between NO<sub>2</sub> and OH  
345 (O3D4) from 11:00 to 16:00 and the photolysis of O<sub>3</sub> followed by a reaction with water (O3D2)

346 from 12:00 to 15:00 because O<sub>3</sub> concentration increased while NO<sub>2</sub> decreased (Figure 3c).  
 347 Figure S13 shows the percentages of the different paths of P(O<sub>3</sub>) and L(O<sub>3</sub>). The relative  
 348 contributions of the reactions between O<sub>3</sub> and alkenes (O1D3) and between NO<sub>2</sub> and OH  
 349 (O1D4) to the O<sub>3</sub> sinks decreased when calculated based on PIC-VOCs compared with those  
 350 of the measured VOCs, while they obviously increased for the other two paths, i.e., O3D1 and  
 351 O3O2. The O<sub>3</sub> destruction of the HO<sub>x</sub> and O<sub>3</sub> reaction (O3D1) gradually increased with the  
 352 continuous photochemical reaction. In addition, the maximum O<sub>3</sub> formation rates of the RO<sub>2</sub>  
 353 derived from OVOCs and halohydrocarbons were 0.75 and 0.18 ppb h<sup>-1</sup>, respectively. These  
 354 values could be underestimated due to the incomplete gas reaction mechanism of OVOCs and  
 355 halohydrocarbons in MCM3.3.1. In general, the measured VOCs as model inputs could fail to  
 356 truly reflect the oxidation capacity and underestimate the local formation of O<sub>3</sub> and organic  
 357 aerosols (Zhan et al., 2021).

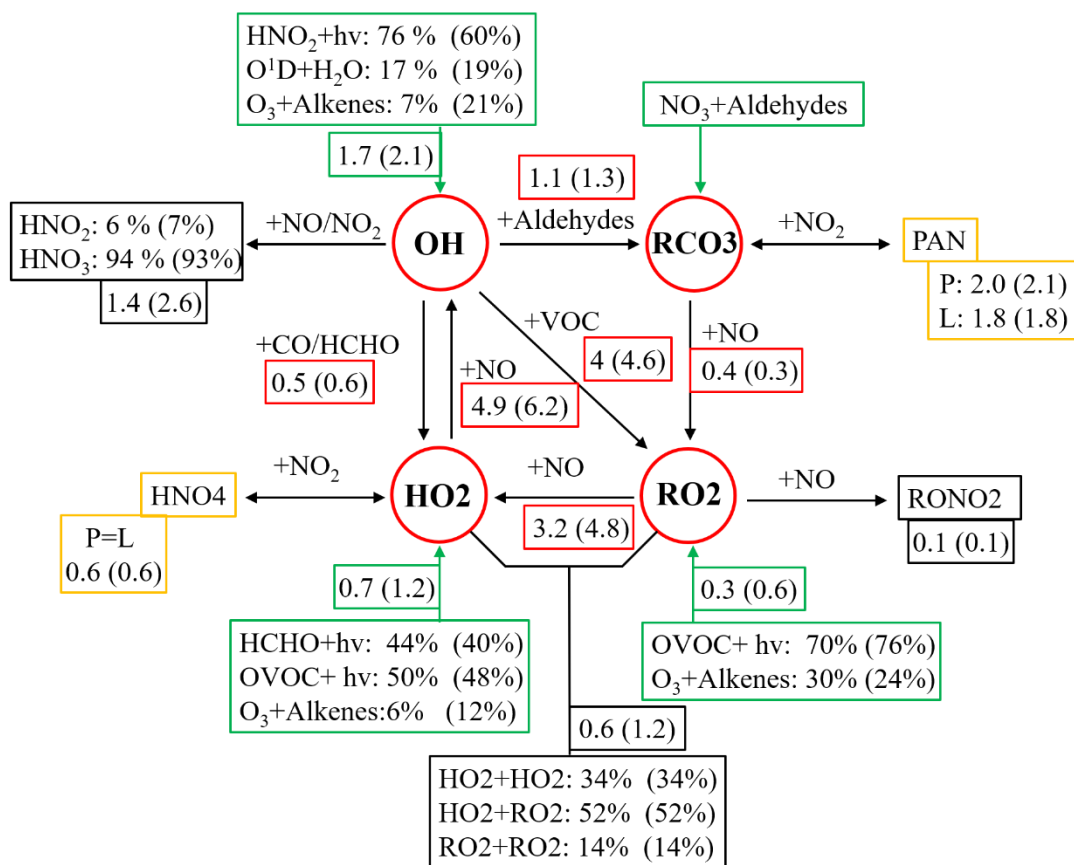

358

359 **Figure 3.** Mean diurnal profile of the instantaneous ozone production and destruction rate  
360 calculated from the MCM-OBM model (instantaneous ozone rate derived from observed VOCs  
361 in a and c and from PIC-VOCs in b and d). The upper panel presents the speciation of the ozone  
362 formation rate. The lower panel presents the speciation of the ozone destruction rate. The data  
363 range is August 1-28, 2019.

364  
365 The budget of OH-HO<sub>2</sub>-RO<sub>2</sub> radicals was further analysed to understand the  
366 photochemical O<sub>3</sub> formation process. The comparison of the radical budget derived from the  
367 observed and PIC-VOCs is shown in Figure 4. The radical cycles are divided into radical  
368 sources (green boxes), radical sinks (black boxes), radical propagations (red circles) and  
369 equilibria between radical and reservoir species (yellow boxes). The numbers or percentages  
370 are the average formation rates (ppb h<sup>-1</sup>) or relative contributions of the corresponding reaction  
371 path based on the observed VOCs (outside the brackets) and the PIC-VOCs (inside the brackets)  
372 to a certain radical. The relative contributions of different radical paths based on the observed  
373 VOCs (outside the brackets) were comparable with those reported in Beijing, Shanghai, and  
374 Guangzhou (Tan et al., 2019), while variations were observed for some reaction paths based  
375 on the PIC-VOCs. For example, the reaction between ozone and alkenes based on initial VOC  
376 concentrations (percentages inside the brackets) contributed more to OH (from 7% to 21%)  
377 and HO<sub>2</sub> radical production (from 6% to 12%), while photolysis of HONO and HCHO  
378 contributed less to the production of OH (from 76% to 60%) and HO<sub>2</sub> radicals (from 44% to  
379 40%), respectively. Other radical sources were consistent between the two scenarios.  
380 Interestingly, the average formation rates of OH, HO<sub>2</sub> and RO<sub>2</sub> radicals derived from the PIC-

381 VOCs were obviously higher than those from the observed VOCs. In particular, the oxidation  
 382 of NO by RO<sub>2</sub> and HO<sub>2</sub> increased by 1.6 and 1.3 ppb h<sup>-1</sup>, respectively. The enhanced oxidation  
 383 rate of NO was equal to the increase in the average F(O<sub>3</sub>) in the analysis process above. This  
 384 meant that the radical propagation of OH-RO<sub>2</sub>-HO<sub>2</sub> sped up in the case of PIC-VOCs,  
 385 subsequently accelerating the chemical loop of NO-NO<sub>2</sub>-O<sub>3</sub>. For the radical sinks and equilibria  
 386 related to HNO<sub>4</sub>, RONO<sub>2</sub> and PAN, the values were basically comparable between the two  
 387 scenarios. In addition, the O<sub>3</sub> formation from the RO<sub>2</sub> path increased by 4.1% (from 39.5% to  
 388 43.6%) in the simulation using the PIC-VOCs compared with the observed VOCs. The above  
 389 budget analysis explained the observed increases in F(O<sub>3</sub>) (~3 ppb h<sup>-1</sup>), which were mainly  
 390 driven by the reaction of missed reactive VOCs, such as alkenes, with O<sub>3</sub>.

391  
 392 **Figure 4.** Comparison of the OH-HO<sub>2</sub>-RO<sub>2</sub> radical budget derived from the observed and PIC-

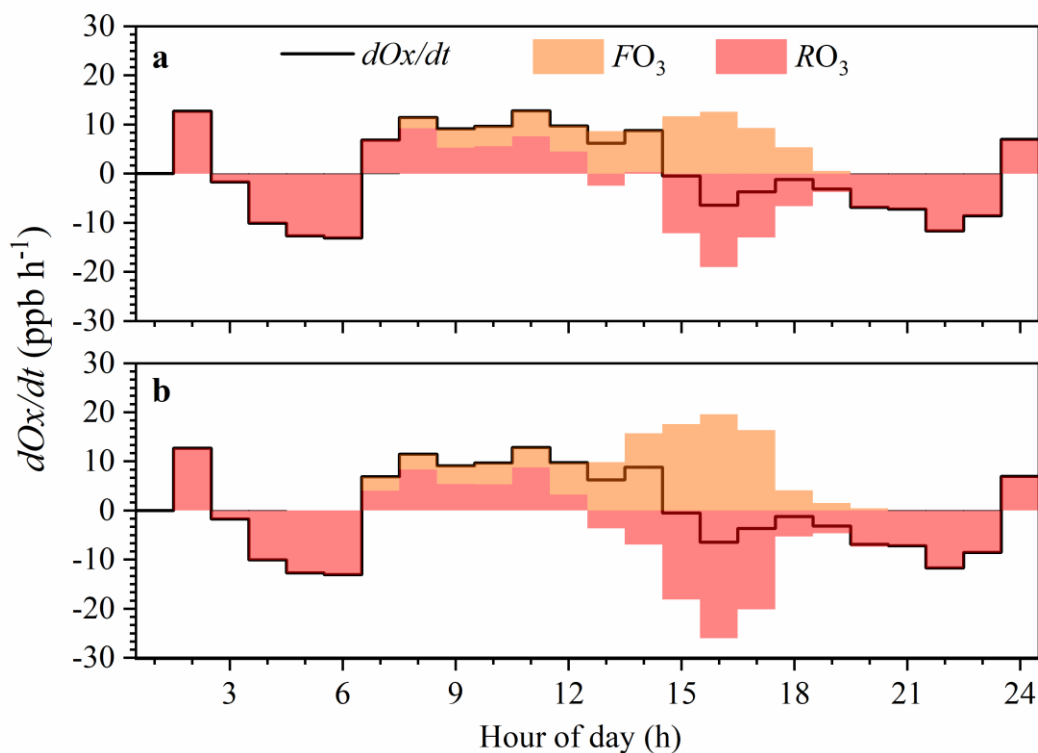

393 VOCs under daytime conditions (07:00 to 19:00 LT). The green, black, red and yellow boxes  
394 denote the sources of radicals, radical sinks, radical propagation, and radical equilibrium,  
395 respectively. The numbers or percentages outside and inside the brackets are the average  
396 formation rates ( $\text{ppb h}^{-1}$ ) or relative contributions to a specific radical of the corresponding  
397 reaction path based on observed VOCs and PIC-VOCs, respectively.

### 398 **3.4 In situ O<sub>3</sub> formation process**

399 In addition to chemical processes, which can be simulated using the OBM-MCM model,  
400 transport processes, including horizontal, vertical transportation and dry deposition processes  
401 (Tan et al., 2019), also have an important influence on the O<sub>3</sub> concentration. Thus, the change  
402 in instantaneous ozone concentration can reflect the combined effect between photochemical  
403 and physical transport processes (Tan et al., 2019). This change can be expressed as,

$$404 \quad \frac{dO_x}{dt} = F(O_3) + R(O_3) \quad (6)$$

405 where  $dO_x/dt$  is the O<sub>3</sub> concentration change rate based on the measured data ( $\text{ppb h}^{-1}$ );  $F(O_3)$   
406 is the net O<sub>3</sub> formation rate ( $\text{ppb h}^{-1}$ ), and  $R(O_3)$  indicates transportation ( $\text{ppb h}^{-1}$ ). A positive  
407 value of  $R(O_3)$  indicates an inflow of O<sub>3</sub> with air mass and vice versa. O<sub>3</sub> was replaced with Ox  
408 (O<sub>3</sub>+NO<sub>2</sub>) to correct the titration of O<sub>3</sub> by NO (Pan et al., 2015).

409

410 **Fig. 5.** The variation in Ox concentration and formation rate during an O<sub>3</sub> pollution episode  
 411 (Aug. 1<sup>st</sup>). (a and b present the local ozone formation processes of the measured and PIC-VOCs,  
 412 respectively.)

413 The O<sub>3</sub> budget analysis was performed during an O<sub>3</sub> pollution episode (Aug. 1<sup>st</sup>). Figure  
 414 5 shows the simulated local ozone formation process based on the measured and PIC-VOCs.  
 415 The hourly variation in O<sub>3</sub> concentrations from 19:00 to 6:00 the next day was dominated by  
 416 regional transportation without O<sub>3</sub> formation, while local photochemical O<sub>3</sub> formation could  
 417 explain all or part of the O<sub>3</sub> concentration change during the time window from 07:00 to 19:00.  
 418 The d(O<sub>3</sub>)/dt shows an increase from 07:00 to 15:00 LT. However, d(O<sub>3</sub>)/dt sharply changed to  
 419 negative values at 16:00, which was consistent with diurnal O<sub>3</sub> (the O<sub>3</sub> peaks at 15:00) in Figure  
 420 1.

421 The average daytime  $F(O_3)$  based on the observed and photochemical initial  
422 concentrations was  $6.4 \pm 4.0$  and  $8.9 \pm 6.7$  ppb  $h^{-1}$ , respectively. Photochemical  $O_3$  formation  
423 under both conditions started at 07:00 and reached maximum values of 12.6 and 19.6 ppb  $h^{-1}$   
424 at 15:00, respectively. The maximum daily value of  $P(O_3)$  was higher than those in the urban  
425 areas of Japan, America, and England (Whalley et al., 2018; Ren et al., 2006; Griffith et al.,  
426 2016; Kanaya et al., 2009) and lower than those in the suburbs of Guangzhou (Lu et al., 2012)  
427 and the urban areas and suburbs of Beijing (Lu et al., 2013). Before 12:00, the  $O_3$  formation  
428 rate based on the PIC-VOCs was slightly higher than that based on the measured VOCs, while  
429 both rates were within a range of 2.0~6.5 ppb  $h^{-1}$ . From 12:00 to 17:00, the  $O_3$  formation rate  
430 based on the PIC-VOCs and the observed concentration of VOCs greatly increased due to  
431 active photochemistry.

432 As shown in Figure 5, the increased  $O_3$  concentration was larger than the local  $O_3$   
433 photochemical production from 07:00 to 12:00 ( $R(O_3)$  was positive). This was mainly because  
434 the residual layer (RL) that formed at night was unfavourable for the inversion of air mass in  
435 the early morning (Tan et al., 2021). The RL usually contains an air mass with a higher  
436 concentration of  $O_3$  than that in the nocturnal boundary layer. Vertical transport becomes  
437 prominent due to the fast entrainment when the boundary layer is gradually uplifted. However,  
438  $R(O_3)$  was negative in the afternoon, which indicated that the local  $O_3$  formation at the  
439 measurement site contributed to not only the changes in the in situ  $O_3$  concentration but also  
440 the  $O_3$  source of the downwind regions. This was more clearly shown in Figure 4B under the  
441 PIC-VOCs condition. These results illustrated that local  $O_3$  photochemistry played a crucial

442 role in both the local and regional O<sub>3</sub> concentrations, which can be underestimated if consumed  
443 VOCs with high reactivities are ignored.

#### 444 **4. Conclusions**

445 In this study, we presented the local O<sub>3</sub> formation process in August 2019 in Beijing based  
446 on the concentrations of observed and PIC-VOCs. The mean diurnal profile of O<sub>3</sub> was  
447 unimodal with a peak at 15:00, while NO<sub>x</sub> and observed TVOCs showed an opposite diurnal  
448 curve, and the PICs of TVOCs showed a different diurnal curve compared with that of the  
449 observed VOCs, with a slight increase from 07:00 to 14:00. The EKMA curve indicated that  
450 instantaneous O<sub>3</sub> production was dependent on the real-time concentrations of NO<sub>x</sub> and VOCs,  
451 i.e., the VOC-limited regime in the morning (09:00-10:00) and the NO<sub>x</sub>-limited regime at noon  
452 (14:00-15:00). The sensitivity regime of O<sub>3</sub> formation could be misdiagnosed if the consumed  
453 VOCs are not considered, for example, the VOC-limited regime (observed) shift to a transition  
454 regime (PIC-VOCs) in the morning is ignored. The mean F(O<sub>3</sub>) based on PIC-VOCs was 3.0  
455 ppb h<sup>-1</sup> higher than that based on the measured VOCs, indicating that the underestimation of  
456 local photochemistry in the local O<sub>3</sub> concentration could reach ~36 ppb day<sup>-1</sup> if the consumed  
457 VOCs are not accounted for. The radical budget analysis explained the observed increases in  
458 F(O<sub>3</sub>) (3 ppb h<sup>-1</sup>), which were mainly driven by the reaction of missed reactive VOCs, such as  
459 alkenes, with O<sub>3</sub>. In addition, the OH-HO<sub>2</sub> radical cycle was obviously accelerated by highly  
460 reactive alkenes after the photochemical loss of VOCs was accounted for. Finally, the results  
461 of the in situ O<sub>3</sub> formation process indicated that local O<sub>3</sub> photochemical formation played a  
462 key role in both local and regional O<sub>3</sub> concentrations. In conclusion, our results suggested that

463 PIC-VOCs were more suitable than the observed VOC concentrations for diagnosing O<sub>3</sub>  
464 formation sensitivity.
