16 **Abstract**

17 Volatile organic compounds (VOCs) tend to be consumed by atmospheric oxidants,  
18 resulting in substantial photochemical loss during transport. An observation-based model is  
19 used to evaluate the influence of photochemical loss of VOCs on the sensitivity regime and  
20 mechanisms of ozone formation. Our results showed that a VOC-limited regime based on the  
21 observed VOC concentrations shifted to a transition regime with the photochemical initial  
22 concentration of VOCs (PIC-VOCs) in the morning. The net ozone formation rate was  
23 underestimated by  $3 \text{ ppb h}^{-1}$  ( $36 \text{ ppb day}^{-1}$ ) based on the PIC-VOCs. The relative contribution  
24 of the  $\text{RO}_2$  path to ozone production based on the PIC-VOCs accordingly increased by 13.4%,  
25 particularly, the contribution of alkenes derived  $\text{RO}_2$  increased around 10.2%. The contribution  
26 of local photochemistry might be underestimated to both local and regional ozone pollution if  
27 the consumed VOCs was not accounted for, and policy-making on ozone pollution prevention  
28 should focus on high-reactivity VOCs.

29

## 30 **1. Introduction**

31 Ground surface ozone ( $O_3$ ) is an important atmospheric pollutant that is harmful to human  
32 health, such as connecting with respiratory, cardiovascular diseases and premature mortality  
33 (Cohen et al., 2017). It is also harmful to vegetation growth. For example, it led to annual  
34 reduction of the yield of rice and wheat by 8% and 6%, respectively, and the forest biomass  
35 growth by 11-13% in China (Feng et al., 2019). Surface  $O_3$  concentrations have increased by  
36 11.9% over eastern China under the air pollution control measures implemented in China from  
37 2012 to 2017 (Dang and Liao, 2019). An economic loss will be 0.09% of the Chinese gross  
38 domestic products (78 billion CNY) in 2030 if the policies against  $O_3$  pollution are not properly  
39 implemented (Xie et al., 2019). Therefore, it is urgent to take actions on  $O_3$  pollution in China.

40 Tropospheric  $O_3$  is mainly produced from photochemical reactions between volatile  
41 organic compounds (VOCs) and nitrogen oxides ( $NO_x$ :  $NO+NO_2$ ) (Seinfeld and Johnh, 2006;  
42 Zhang et al., 2021c).  $O_3$  is generated from the collision of  $O_2$  and  $O(3P)$  that are produced from  
43 the photolysis of  $NO_2$  in the atmosphere. Peroxyl radicals ( $HO_2$  and  $RO_2$ ), which produced  
44 from oxidation of VOCs by OH radical, can efficiently convert NO (from the photolysis of  
45  $NO_2$ ) to  $NO_2$ , then lead to net  $O_3$  production by compensating the titration of  $O_3$  by NO (Monks,  
46 2005; Zhang et al., 2021a). Over past two decades, a number of field observations focused on  
47 the pollution level of  $O_3$  and its precursors have been carried out in Beijing-Tianjin-Hebei  
48 (BTH), the Yangtze River Delta (YRD), and Pearl River Delt (PRD) regions (Wang et al., 2017;  
49 Li et al., 2019; Xue et al., 2014; Zhang et al., 2019). Due to the nonlinear relationship between  
50  $O_3$  and its precursors and the variations of meteorological conditions, numerous studies have

51 been performed for understanding the sensitivity regime (Ling and Guo, 2014; Zhang et al.,  
52 2020) and the photochemical process of O<sub>3</sub> formation based on box model or observation-based  
53 model (OBM) (He et al., 2019; Tan et al., 2019), and the source-receptor relationship of O<sub>3</sub>  
54 using a regional chemical transport mode (Li et al., 2016b; Li et al., 2016c). Recently, O<sub>3</sub>  
55 formation process, from the perspective of the instantaneous production rate, has attracted more  
56 attention, such as the radical recycle (OH-RO<sub>2</sub>-RO-HO<sub>2</sub>-OH) relating to production of O<sub>3</sub> (Lu  
57 et al., 2017; Tan et al., 2017; Whalley et al., 2018). It has been found that HCHO photolysis  
58 and alkene ozonolysis contributed about 85 % of the primary production of HO<sub>2</sub> and HO  
59 radicals in Beijing, Shanghai and Guangzhou (Tan et al., 2019; Yang et al., 2017). The  
60 importance of HONO and HCHO photolysis for primary radical production has also been  
61 proposed in suburban and rural areas (Tan et al., 2017; Lu et al., 2012; Lu et al., 2013).

62 It should be pointed out that all of the OBM studies were based on the measured dataset  
63 when investigating the relationship between O<sub>3</sub> and VOCs. However, VOCs is highly reactive  
64 to atmospheric oxidants, such as OH, NO<sub>3</sub>, and O<sub>3</sub>, in which OH is the dominant one. The  
65 lifetimes of some highly reactive VOCs such as isoprene are only as short as several ten minutes  
66 under the typical daytime atmospheric conditions. Thus, the mixing ratio of VOCs observed at  
67 a sampling site may differ from that at the source regions because of the photochemical loss  
68 even during a short-range of transport. This may mislead the O<sub>3</sub> formation sensitivity, net O<sub>3</sub>  
69 production, subsequently, the policy-making on O<sub>3</sub> pollution prevention. Thus, the  
70 photochemical-age-based approach has been applied to evaluate the effect of photochemical  
71 process on VOC measurements (Shao et al., 2011). This method was used to qualitatively or

72 semi-quantitatively estimate the O<sub>3</sub> formation process of the source-receptor (Gao et al., 2018),  
73 such as calculating O<sub>3</sub> formation potential (OFP) (Han et al., 2017), identifying the critical  
74 species for O<sub>3</sub> formation (Gao et al., 2021), and evaluating the VOCs emission ratio (Yuan et  
75 al., 2013). However, it is unclear how the highly reactive VOCs, which has degraded during  
76 transport from the source to the receptor site, will affect the instantaneous formation process  
77 of O<sub>3</sub>.

78 In this study, an OBM is used to evaluate the local O<sub>3</sub> formation process in summer in  
79 Beijing based on the concentrations of the observed and photochemical initial concentrations  
80 of VOCs (PIC-VOCs). The O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity, the instantaneous O<sub>3</sub> formation rate and  
81 the in-situ O<sub>3</sub> formation process are discussed. The aim of this study is to understand the  
82 possible influence of photochemical loss of VOCs on the diagnosis of the formation sensitivity  
83 regime of O<sub>3</sub>. This study can provide a new insight for better understanding atmospheric O<sub>3</sub>  
84 pollution.

## 85 **2. Methodology**

### 86 **2.1 Experimental section**

87 Field observations were carried out in the Qingyuan campus of Beijing Institute of  
88 Petrochemical Technology (BIPT, 39.73°N and 116.33°E) (Figure S1). The details about the  
89 observation site has been described in our previous work (Zhan et al., 2021). Briefly, the site is  
90 a typical suburb site in Daxing District between the 5<sup>th</sup> ring road and the 6<sup>th</sup> ring road. The field  
91 campaign was carried out during August 1<sup>st</sup>-28<sup>th</sup> in 2019 when photochemistry was the most  
92 active while rainfall was rare in Beijing.

93           The concentrations of non-methane hydrocarbons (NMHCs) were detected by both a gas  
94 chromatography-flame ionization detector (GC/FID) and a single photon ionization (SPI) TOF-  
95 MS (SPI-MS 3000, Guangzhou Hexin Instrument Co., Ltd., China). A detailed description of  
96 instrumentation can be found in previous publications (Zhan et al., 2021; Chen et al., 2020).  
97 The SPI-MS was also deployed to detect halohydrocarbons. More details of this instrument  
98 and the parameter-setting have been described in previous studies (Zhang et al., 2019; Liu et al.,  
99 2020a). Briefly, a polydimethylsiloxane (PDMS; thickness of 0.002 int; Technical Products  
100 Inc., USA) membrane was used to gathering VOCs and diffuse from the sample side to the  
101 detector side under high vacuum conditions. A vacuum ultraviolet (VUV) light generated by a  
102 commercial D2 lamp (Hamamatsu, Japan) was utilized for ionization at 10.8 eV. For ion  
103 detection, two microchannel plates (MCPs, Hamamatsu, Japan) assembled with a chevron-type  
104 configuration are employed. This TOF-MS has an LOD varied from 50 ppt to 1 ppb with 1  
105 minute of time resolution for most trace gases without any pre-concentration procedure. To  
106 verify the data compatibility of the SPIMS and GC/FID, we compared the concentrations of  
107 toluene measured using these two different instruments (Figure S2). The correlation coefficient  
108 is 0.92, indicating that the concentrations of NMHCs are comparable using these two  
109 measurement techniques.

110           Oxygenated VOCs (OVOCs) were collected and analyzed using a high-performance  
111 liquid chromatography (HPLC, Inertsil ODS-P 5  $\mu\text{m}$  4.6  $\times$  250 mm column, GL Sciences) with  
112 acetonitrile-water binary mobile phase (Ma et al., 2019). OVOCs were collected into 2,4-  
113 dinitrophenylhydrazine (DNPH)-coated silica gel cartridges (Sep-Pak, Waters) by an automatic

114 sampling device, with the sampling flow rate of 1.2 L min<sup>-1</sup> and the duration of 2 h for each  
115 sample. To avoid possible contamination or desorption after sampling, cartridges were capped,  
116 placed into tightly closed plastic bags and kept in a refrigerator before analysis. The sampled  
117 cartridges were eluted by 5 mL acetonitrile and analyzed by HPLC as soon as possible after  
118 they were shipped back to the laboratory. This system was calibrated through 8-gradient  
119 standard solutions (TO11/IP-6A Aldehyde/Ketone-DNPH Mix, SUPELCO). The correlation  
120 coefficients were all greater than 0.999. The LOD for most OVOCs is about 10 ppt.

121 Trace gases, including NO<sub>x</sub>, SO<sub>2</sub>, CO, and O<sub>3</sub>, were measured using the corresponding  
122 analyzer (Thermo Scientific, 42i, 43i, 48i, and 49i, respectively). The HONO concentration  
123 was measured using a home-made long path absorption photometer (LOPAP) (Liu et al.,  
124 2020c). The meteorological parameters, including temperature (T), pressure (P), relative  
125 humidity (RH), wind speed, and wind direction, were measured using a weather station  
126 (AWS310, Vaisala). The photolysis rate ( $J_{NO_2}$ ) was measured via a continuous measurement of  
127 the actinic flux in the wavelength range of 285-375 nm using a  $J_{NO_2}$  filter-radiometer ( $J_{NO_2}$   
128 radiometer, Metcon).

## 129 2.2 Calculation of photochemical loss of VOCs.

130 The photochemical loss of VOC was calculated using the ratio method (Wiedinmyer et  
131 al., 2001; Yuan et al., 2013). The initial mixing ratio of a specific VOC was calculated using  
132 the equations (Mckeen et al., 1996):

$$133 \quad [VOC_i]_t = [VOC_i]_{t0} \times \exp(-k_i \times [OH] \times \Delta t) \quad (1)$$

$$134 \quad \Delta t = \frac{1}{[OH] \times (k_X - k_E)} \times \left\{ \ln \left( \frac{X_0}{E_0} \right) - \ln \left( \frac{X_t}{E_t} \right) \right\} \quad (2)$$

135 where  $[VOC_i]_t$  and  $[VOC_i]_{t0}$  are the observation concentration and the initial concentration of  
136  $VOC_i$ ;  $k_i$  is the second-order reaction rates between the compound  $i$  and  $[OH]$ ;  $[OH]$  and  $\Delta t$  are  
137 the concentration of OH radical and photochemical aging time, respectively.  $k_X$  and  $k_E$  are rate  
138 constant for the reaction between OH radicals and xylene ( $7.00 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ ) and  
139 ethylbenzene ( $1.87 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ ) (Atkinson and Arey, 2003), respectively.  $(X_0/E_0)$   
140 is the ratio between the initial xylene and ethylbenzene mixing ratios, and  $(X_t/E_t)$  is the ratio  
141 between the observed xylene and ethylbenzene mixing ratios at time. In this study, we chose  
142 the mean concentrations of xylene and ethylbenzene at 05:00-06:00 as the initial concentrations  
143 (no photochemical loss) to calculate the photochemical loss of OH exposure. As can be seen  
144 from [Figure S3](#), the concentrations of xylene and ethylbenzene are well correlated, which  
145 indicates that they are homologous emitted simultaneously. The calculated OH exposure ( $[OH]$   
146  $\times \Delta t$ ) was  $4.3 \pm 1.9 \times 10^6 \text{ molecule cm}^{-3} \text{ h}$ . Accordingly, the mean photochemical ages were  $1.7$   
147  $\pm 0.9 \text{ h}$  using the mean daytime (8:00-17:00 LT) OH concentrations ( $4.3 \pm 3.1 \times 10^6 \text{ molecules}$   
148  $\text{cm}^{-3}$ ) estimated using our previous method (Liu et al., 2020b; Liu et al., 2020c). This means  
149 that the VOCs would undergo obvious degradation even in a short-range of transport in the  
150 atmosphere.

151 It should be noted that the  $k_{OH}$  of isoprene is  $9.98 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298.15 K  
152 (Atkinson and Arey, 2003), almost two orders than other VOCs. The ratio method assumes  
153 constant emissions for VOCs. However, the emission of isoprene greatly depends on  
154 temperature and solar irradiation intensity (Zhang et al., 2021b). Besides the photochemical  
155 loss, additional correction of daytime isoprene concentrations was performed using the average

156 diurnal flux of isoprene emissions (Figure S4) (Zhang et al., 2021b). The emission of isoprene  
157 shows a clear unimodal curve, and the volume concentration of isoprene is calculated based on  
158 the daily emission curve using Eq. (S1).

### 159 2.3 Observation-based model simulation

160 A box model based on the Master Chemical Mechanism (MCM3.3.1) and the Regional  
161 Atmospheric Chemical Mechanism (RACM2) were used in this study. The MCM3.3.1 was  
162 used to understand the instantaneous ozone formation process, and the RACM2 was used to  
163 depict the ozone isopleth due to the high computational efficiency (Sect. 2.4). Table S1 shows  
164 the model inputs. The model calculation is constrained with the measured meteorological  
165 parameters (RH, T, P, and  $J_{NO_2}$ ) and the concentrations of trace gases, including inorganic  
166 species (NO, NO<sub>2</sub>, CO, SO<sub>2</sub>, and HONO) and 61 organic species (NMHCs (46), OVOCs (8),  
167 and halohydrocarbons (7)). The model was validated using the observed and simulated O<sub>3</sub>  
168 concentrations, which showed good consistency as shown in Figure. S5. The slope and  
169 correlation coefficient were 0.90 and 0.82 (Figure. S6), respectively, indicating the rationality  
170 of model simulation.

171 The ozone formation rate  $P(O_3)$  can be quantified by the oxidation rate of NO to NO<sub>2</sub> by  
172 peroxy radicals (Tan et al., 2019), as expressed in Eq. (3). In this study, the modeled peroxy  
173 radical concentrations are used to calculate the ozone production rate.

$$174 \quad P(O_3) = k_{HO_2+NO}[HO_2][NO] + k_{RO_2+NO}[RO_2][NO] \quad (3)$$

175 where  $P(O_3)$  is the ozone formation rate;  $[HO_2]$  and  $[RO_2]$  are the number concentrations of  
176  $HO_2$  and  $RO_2$  radicals;  $k_{HO_2+NO}$  and  $k_{RO_2+NO}$  are the second reaction rates between the  $HO_2$  and

177  $RO_2$  and  $NO$ . Once ozone formed, it will be consumed by  $OH$ ,  $HO_2$ , and alkenes. Also, a part  
178 of  $NO_2$  can react with  $OH$ , resulting in the formation of nitrate before photolysis. The chemical  
179 loss of both  $O_3$  and  $NO_2$  is considered in the calculation of the net ozone production rate (Tan  
180 et al., 2019),

$$181 \quad L(O_3) = (k_{O_3+OH}[OH] + k_{O_3+HO_2}[HO_2] + k_{O_3+alkenes}[alkenes])[O_3] +$$
$$182 \quad k_{NO_2+OH}[NO_2][OH] \quad (4)$$

183 where  $L(O_3)$  is the ozone chemical loss rate;  $[HO]$  is the number concentration of  $HO$  radical;  
184  $k_{O_3+OH}$ ,  $k_{O_3+HO_2}$ , and  $k_{O_3+alkenes}$  are the second reaction rate between the  $O_3$  and  $OH$ ,  $HO_2$  and  
185 alkenes, respectively; and  $k_{NO_2+OH}$  is the second reaction rate between the  $NO_2$  and  $OH$ . Finally,  
186  $F(O_3)$  is the net ozone formation rate by the difference between the  $P(O_3)$  and  $L(O_3)$  as  
187 expressed in Eq. (5),

$$188 \quad F(O_3) = P(O_3) - L(O_3) \quad (5)$$

#### 189 **2.4 Empirical Kinetic Modeling Approach**

190 The empirical kinetic modeling approach (EKMA) used in this work is a set of imaginary  
191 tests to reveal the dependence of photochemical oxidation products on the change in precursors.  
192 We set up  $30 \times 30$  matrixes by reducing or increasing the measured VOCs and NOx  
193 concentrations to the model input. The resulting radical concentrations and ozone production  
194 rates are calculated correspondingly.

195 In this stage, the observed VOCs are grouped into different parcels according to the  
196 classification of RACM2, and more details can be found in the previous publication (Tan et al.,  
197 2017). The chemical model simulates the photochemical reactions with the parameters at a

198 time interval of 5 minutes, which is enough for the NO, NO<sub>2</sub>, OH, HO<sub>2</sub>, and RO<sub>2</sub> reaching  
199 steady state due to the typical relaxation time of the chemical system is 5-10 minutes in summer  
200 (Tan et al., 2018). The ozone production rate is calculated as described in Sect. 2.3.

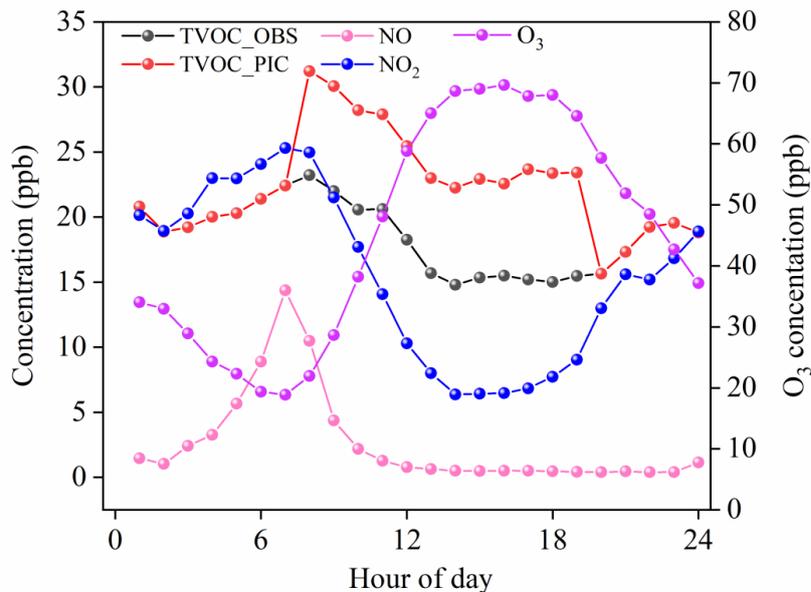

### 201 **3. Results and discussion**

#### 202 **3.1 Overview of diurnal variation of O<sub>3</sub>, NO<sub>x</sub>, TVOC**

203 [Figure 1](#) shows the average diurnal variation of O<sub>3</sub>, NO<sub>x</sub>, and TVOCs (includes alkanes,  
204 alkenes, OVOCs, and halohydrocarbons), driven by the emissions, photochemical reactions  
205 and the evolution of the mixing layer height (MLH). The ozone concentration during the  
206 observation period was  $44.8 \pm 27.2$  ppb with a maximum of 119.1 ppb as reported in our  
207 previous study (Zhan et al., 2021), which is generally comparable with the O<sub>3</sub> concentrations  
208 during 2014-2018 (Ma et al., 2020). O<sub>3</sub> followed a unimodal curve with a minimum ( $18.8 \pm 15.4$   
209 ppb) at 07:00, then increased to the maximum (69.6 ppb) at 15:00 as photochemical ozone  
210 formation. On the contrary, NO<sub>x</sub> was up to the maximum concentration ( $39.7 \pm 14.2$  ppb) at  
211 07:00, and then decreased. After 07:00, the mixing ratio of NO went down all the time, while  
212 the concentration of NO<sub>2</sub> decreased at first, while started to grow at 14:00. The diurnal  
213 variations of the observed TVOCs were generally consistent with NO<sub>2</sub>. The observed TVOCs  
214 concentrations ranged from 2.2 to 23.2 ppb, with a mean value of  $18.6 \pm 2.6$  ppb. Compared to  
215 the same period ( $45.4 \pm 15.2$  ppb) in August 2015 (Li et al., 2016a), the concentration of VOCs  
216 in Beijing has been effectively reduced. However, the photochemical initial concentrations  
217 (PICs) of TVOCs, which varied from 2.2 to 31.2 ppb with a mean value of  $22.4 \pm 3.8$  ppb,  
218 showed a different diurnal curve compared with the observed one. It slightly increased from

219 14:00 to 17:00, which is similar with the diurnal variation of the VOCs in previous work (Zhan  
220 et al., 2021). The daytime PIC-VOCs was  $7.7 \pm 0.46$  ppb higher than the observed concentration  
221 of TVOCs, indicating an underestimated contribution of local photochemistry of VOCs to  $O_3$   
222 and organic aerosol formation.

223

224

**Figure 1.** Overview of diurnal variations of  $O_3$ ,  $NO_x$ , and TVOC

225

### 3.2 Influence of photochemical loss of VOCs on $O_3$ formation sensitivity regime

226

227

228

229

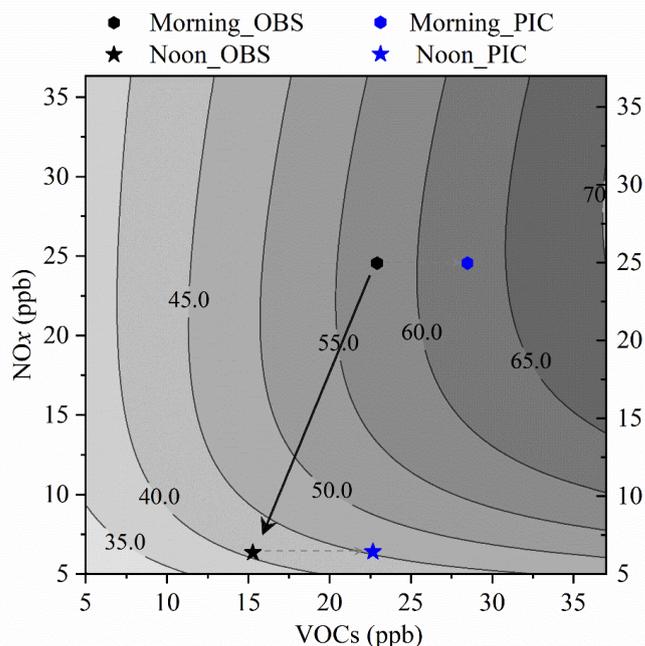

230

231

The sensitivity of  $O_3$  formation is analyzed using the isopleth diagram which was generated from the EKMA model, which is widely use to study  $O_3$ - $NO_x$ -VOCs sensitivity qualitatively. As described in Sect. 2.4, the concentrations of  $NO_2$  and VOCs were artificially scaled  $\pm 75\%$  of the observed values to disclose the response of  $O_3$  concentration to an imaginary change in the concentrations of  $NO_2$  and VOC with other constrained conditions unchanged. Figure 2 shows the typical EKMA curves during our observations. The black full

232 star and pentagon denote the observed concentrations of NO<sub>x</sub> and VOCs in the morning and at  
233 noon, respectively, while the blue symbols are the corresponding values of PICs. Based on the  
234 measured data, the O<sub>3</sub> formation was in a VOCs-limited regime in the morning and a NO<sub>x</sub>-  
235 limited regime at noon. The black arrow indicated a linearly decreasing trend of NO<sub>x</sub> and VOCs  
236 from 08:00 to 15:00 in the chemical coordinates system, and the ozone production shifted from  
237 VOC-limited to NO<sub>x</sub>-limited conditions from morning to noon, which was consistent with the  
238 mean diurnal profiles (Figure. 1). This is similar to that reported in Wangdu (Tan et al., 2018).  
239 As expected, the ozone production shifted from a VOC-limited regime (the observed VOCs)  
240 to a transition one based on the PIC-VOCs in the morning. It further obviously moved to a  
241 NO<sub>x</sub>-limited regime at noon after the photochemically consumed NO<sub>x</sub> and VOCs had been  
242 accounted for (Figure. 2). These results denoted that the O<sub>3</sub> formation mechanism might be  
243 misdiagnosed, misleading the mitigation measures for O<sub>3</sub> prevention if not considering the  
244 consumed VOCs in the real atmospheric condition because the average photochemical aging  
245 time was only  $1.7 \pm 0.9$  h.

246

247 **Figure 2.** Isopleth diagram of the ozone concentration as functions of the concentration of  
248 NO<sub>x</sub> and VOCs derived from an empirical kinetic modeling approach. The pentagons and  
249 stars indicate the status in the morning and at noon, respectively. The black-filled and blue  
250 filled are the observed and corrected status, respectively.

### 251 3.3 Contribution of VOC species to O<sub>3</sub> production

252 The time series of simulated OH, HO<sub>2</sub>, and RO<sub>2</sub> concentrations are used to calculate the  
253  $P(O_3)$  and  $L(O_3)$ . The diurnal averaged  $P(O_3)$  and  $L(O_3)$  are shown in Figure 3. The ozone  
254 formation can be divided into RO<sub>2</sub>+NO and HO<sub>2</sub>+NO related processes (Sect. 2.3). According  
255 to VOC precursors, the peroxy radical groups are divided into alkane-derived (ALKAP),  
256 alkene-derived (AIKEP), aromatic-derived (AROMP), isoprene-derived (ISOP), oxygenated-  
257 VOC-derived (OVOCP), and halohydrocarbon-derived (HALOP) RO<sub>2</sub> and HO<sub>2</sub>P. The ozone  
258 destruction processes include the reaction between O<sub>3</sub> and HO<sub>x</sub> (O3D1), the reaction between  
259 O1D and H<sub>2</sub>O (O3D2), alkenes (O3D3), and the reaction between NO<sub>2</sub> and OH (O3D4).

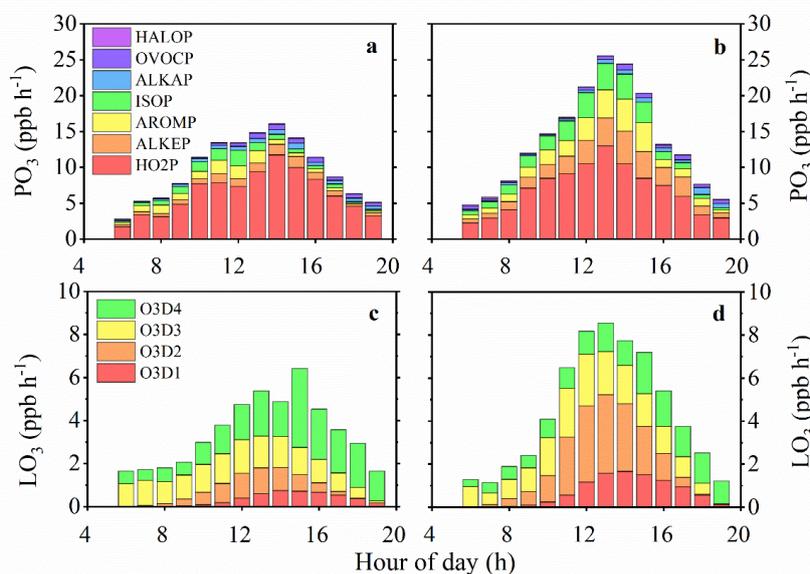

260 Based on the observed VOCs (or PIC-VOCs), the fast O<sub>3</sub> production rate was observed at  
261 14:00 (or 13:00), with a diurnal maximum value of 16.1 (or 25.6) ppb h<sup>-1</sup> (Figure 3a and 3b),  
262 while the peaked destruction rate was 6.4 (or 8.6) ppb h<sup>-1</sup> at 15:00 (or 13:00) (Figure 3c and  
263 3d). The average daytime P(O<sub>3</sub>) based on the initial concentrations of VOCs was 4.0±3.1 ppb  
264 h<sup>-1</sup> higher than that based on the measured concentrations (Figure 3b). At the same time, the  
265 F(O<sub>3</sub>) based on the initial concentrations of VOCs was also 3.0±2.1 ppb h<sup>-1</sup> higher than the  
266 counterpart (Figure S7). Thus, the net O<sub>3</sub> production can accumulatively be underestimated by  
267 36 ppb day<sup>-1</sup> if the consumption of VOCs was not considered. This means the contribution of  
268 local formation of O<sub>3</sub> should be underestimated using the directly measured VOCs  
269 concentrations.

270 The HO<sub>2</sub> path contributed 64.8% to the total ozone formation on average, which is slightly  
271 higher than the reported value (57.0%) in Wangdu (Tan et al., 2018); whereas, the RO<sub>2</sub> path  
272 contributed to the rest part, in which aromatics (9.4%), alkenes (8.4%), isoprene (7.8%),  
273 alkanes (4.7%), OVOCs (4.3%) and halohydrocarbons (0.6%) were the main contributors. As  
274 for the PIC-VOCs, the dominant path of production of O<sub>3</sub> (51.7%) was still the HO<sub>2</sub> path,  
275 followed by the RO<sub>2</sub> path related to alkenes (14.7%), aromatics (12.8%), and isoprene (11.7%).  
276 The relative contribution of the RO<sub>2</sub> path to P(O<sub>3</sub>) increased by 13.4% compared with the  
277 measured-VOCs, particularly alkenes derived RO<sub>2</sub> increased 10.2%. As shown in Figure 3c  
278 and 3d, the destruction of total oxidants was dominated by the reaction between O<sub>3</sub> and alkenes  
279 (O3D3) in the morning. It gradually shifted to the reaction between NO<sub>2</sub> and OH (O3D4) from  
280 11:00 to 16:00, the photolysis of O<sub>3</sub> followed by reaction with water (O3D2) from 12:00 to

281 15:00 because O<sub>3</sub> concentration increased while NO<sub>2</sub> decreased (Figure 3c). The O<sub>3</sub> destruction  
282 of HO<sub>x</sub> and O<sub>3</sub> reaction (O3D1) gradually increased with the continuous photochemical  
283 reaction. In addition, the maximum O<sub>3</sub> formation rate of the RO<sub>2</sub> derived from OVOCs and  
284 halohydrocarbons were 0.75 and 0.18 ppb h<sup>-1</sup>. These values could be underestimated due to the  
285 incomplete gas reaction mechanism of OVOCs and halohydrocarbons in the MCM3.3.1. In  
286 general, the measured VOCs as model input could not truly reflect the oxidation capacity and  
287 underestimate the local formation of O<sub>3</sub> and organic aerosol (Zhan et al., 2021).

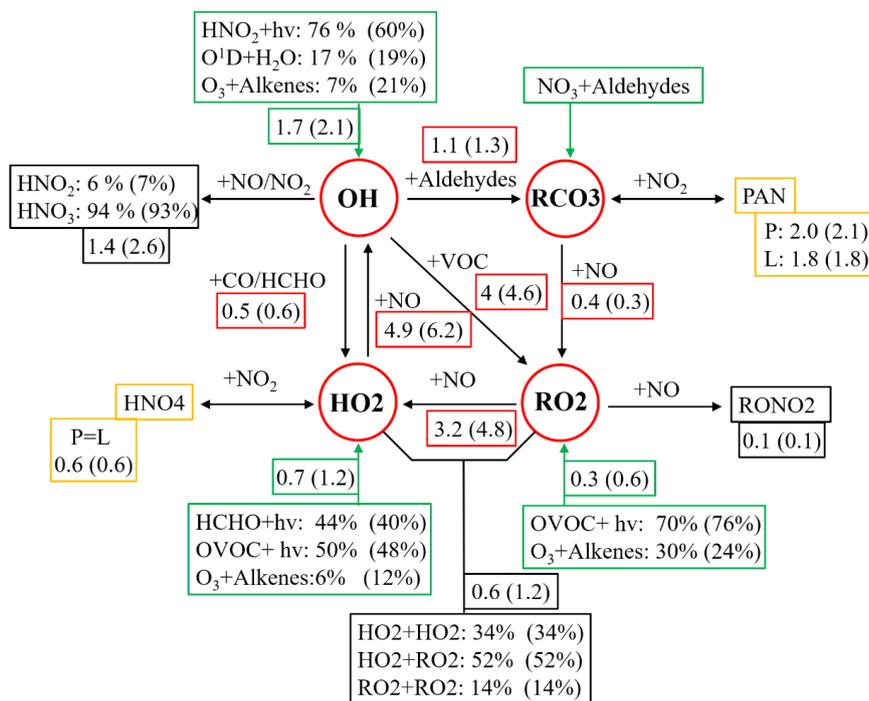

288  
289 **Figure 3.** Mean diurnal profile of the instantaneous ozone production and destruction rate  
290 calculated from the MCM-OBM model (instantaneous ozone rate derived from observed VOCs  
291 in a and c, and from PIC-VOCs in b and d). The upper panel presents the speciation ozone  
292 formation rate. The lower panel presents the speciation ozone destruction rate.

293 The budget of OH-HO<sub>2</sub>-RO<sub>2</sub> radicals was further analyzed to understand the  
294 photochemical O<sub>3</sub> formation process. All radical cycles are divided into four groups (source,  
295 sink, propagation, and equilibrium between radical and reservoir species) based on the different

296 radical reaction processes (Tan et al., 2019). The comparison of radical budget derived from  
297 the observed and PIC-VOCs is shown in [Figure 4](#). The values of different radical paths based  
298 on observed VOCs are in the range of radical budget analysis reported in Beijing, Shanghai,  
299 and Guangzhou(Tan et al., 2019). The average formation rates (the numbers in [Figure 4](#)) of  
300 these four processes (OH, HO<sub>2</sub>, RCO<sub>3</sub>, and RO<sub>2</sub>) derived from PIC-VOCs were higher than  
301 that from the observed VOCs. In particular, the reaction between NO and RO<sub>2</sub> and HO<sub>2</sub>  
302 increased by 1.6 and 1.3 ppb h<sup>-1</sup>, respectively, which was equal to average F(O<sub>3</sub>) in the process  
303 analysis above. The contribution for the reaction between O<sub>3</sub> and alkenes to HO and HO<sub>2</sub>  
304 radical increased 14% and 6%, respectively. As for the radical sink, radical propagation, and  
305 equilibrium, they were consistent with the radical source. Furthermore, the O<sub>3</sub> formation from  
306 the RO<sub>2</sub> path based on the radical budget analysis increased 4.1% from 39.5% (observed-VOCs)  
307 to 43.6% (PIC-VOCs). These results denote that the O<sub>3</sub> formation process between the  
308 observed and initial VOCs showed no significant difference, while the formation rate should  
309 be underestimated if the consumed VOCs was not considered.

310

311 **Figure 4.** Comparison of the OH-HO<sub>2</sub>-RO<sub>2</sub> radical budget derived from the observed and PIC-  
 312 VOCs under the daytime conditions (07:00 to 19:00 LT). The green, black, red and yellow  
 313 boxes denote the sources of radicals, radical sink, radical propagation, and the radical  
 314 equilibrium, respectively. The numbers outside and inside the brackets in the boxes are the  
 315 average formation rates (ppb h<sup>-1</sup>) from the observed and PIC-VOCs.

### 316 3.4 In-situ O<sub>3</sub> formation process

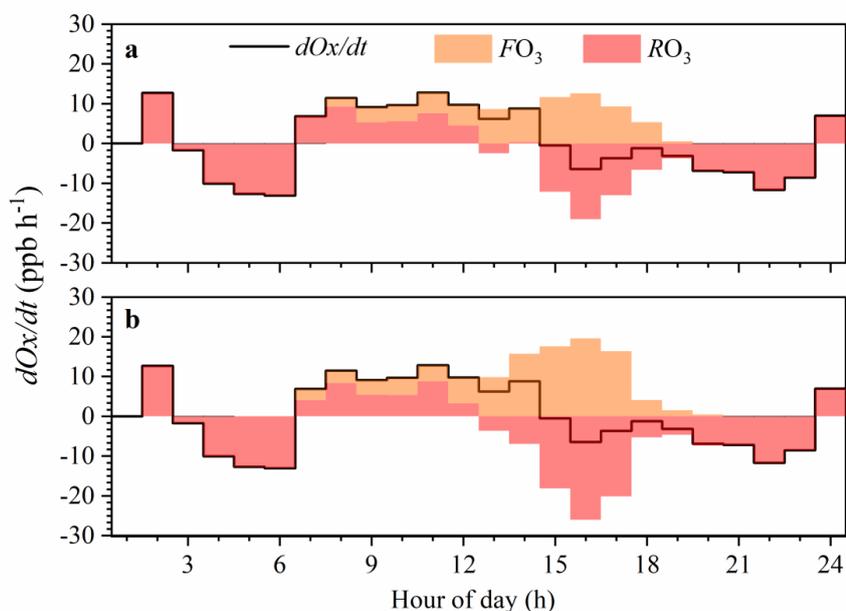

317 Besides chemical processes, which can be simulated using the OBM-MCM model, the  
 318 transport processes includes horizontal, vertical transportation and dry deposition processes  
 319 (Tan et al., 2019) also have important influence on the O<sub>3</sub> concentration. Thus, the change of  
 320 instantaneous ozone concentration can reflect the combination effect between the  
 321 photochemical and the physical transport processes (Tan et al., 2019). It can be expressed as,

$$322 \frac{dO_x}{dt} = F(O_3) + R(O_3) \quad (6)$$

323 where  $dO_x/dt$  is the O<sub>3</sub> concentration change rate based on the measured data (ppb h<sup>-1</sup>);  $F(O_3)$

324 is the net  $O_3$  formation rate ( $\text{ppb h}^{-1}$ ), and  $R(O_3)$  indicates the transportation ( $\text{ppb h}^{-1}$ ). The  
325 positive value of  $R(O_3)$  means the inflow of  $O_3$  with the airmass, and vice versa.  $O_3$  was  
326 replaced with Ox ( $O_3 + NO_2$ ) to correct the titration of  $O_3$  by NO (Pan et al., 2015).

327  
328 **Fig. 5.** The variation of Ox concentration and formation rate on  $O_3$  pollution episode (1<sup>st</sup> Aug).  
329 (a and b present the local ozone formation process of the measured and PIC-VOCs,  
330 respectively.)

331 Here shows the  $O_3$  budget analysis occurred on a  $O_3$  pollution episode (1<sup>st</sup> Aug). [Figure 5](#)  
332 shows the simulated local ozone formation process based on the measured and PIC-VOCs. The  
333 hourly variation of  $O_3$  concentrations from 19:00 to 6:00 in the next day was dominated by the  
334 regional transportation without  $O_3$  formation, while the local photochemical  $O_3$  formation  
335 could explain all or a part of the  $O_3$  concentration change during the time window from 07:00  
336 to 19:00. The  $d(O_3)/dt$  shows an increase from 07:00 to 15:00 LT. However, the  $d(O_3)/dt$  sharply  
337 changed to negative values at 16:00, which was consistent with the diurnal of  $O_3$  (the  $O_3$  peaks

338 at 15:00) in [Figure 1](#).

339 The average daytime  $F(O_3)$  based on the observed and photochemical initial concentration  
340 was  $6.4 \pm 4.0$  and  $8.9 \pm 6.7$  ppb  $h^{-1}$ , respectively. The photochemical  $O_3$  formation under both  
341 conditions started at 07:00 and reached the maximum value of 12.6 and 19.6 ppb  $h^{-1}$  at 15:00,  
342 respectively. The maximum daily value of  $P(O_3)$  is higher than the urban of Japan, America,  
343 and England (Whalley et al., 2018; Ren et al., 2006; Griffith et al., 2016; Kanaya et al., 2009),  
344 lower than the suburb in Guangzhou (Lu et al., 2012), the urban and suburb of Beijing (Lu et  
345 al., 2013). Before 12:00, the  $O_3$  formation rate based on the PIC-VOCs was slightly higher than  
346 that based on the measured ones, while both of them were within the range of 2.0~6.5 ppb  $h^{-1}$ .  
347 From 12:00 to 17:00, the  $O_3$  formation rate based on the PIC-VOCs and the observed  
348 concentration of VOCs greatly increased due to the active photochemistry.

349 As shown in [Figure 5](#), the increased  $O_3$  concentration was larger than the local  $O_3$   
350 photochemical production from 07:00 to 14:00 ( $R(O_3)$  was positive). This implied an additional  
351  $O_3$  source from the outside regions. However, the  $R(O_3)$  was negative in the afternoon, which  
352 meant that the local  $O_3$  formation at the measure site contributed to not only the changes of in-  
353 situ  $O_3$  concentration but also the  $O_3$  source of the downwind regions. This is more obviously  
354 observed in [Figure 4B](#) in the condition of the PIC-VOCs. These results illustrated that local  $O_3$   
355 photochemistry plays a crucial role in both the local and regional  $O_3$  concentrations, that will  
356 be underestimated if the consumed VOCs with high reactivities are ignored.

#### 357 **4. Conclusions**

358 In this study, we present the local  $O_3$  formation process in August 2019 in Beijing based

359 on the concentrations of the observed and PIC-VOCs. The mean diurnal profile of O<sub>3</sub> was  
360 unimodal with peaks at 15:00, while NO<sub>x</sub> and observed TVOCs showed an opposite diurnal  
361 curve, and the PICs of TVOCs showed a different diurnal curve compared with the observed  
362 one with slight increase from 14:00 to 17:00. The EKMA curve indicated that the instantaneous  
363 O<sub>3</sub> production was dependent on the real-time concentrations of NO<sub>x</sub> and VOCs, i.e., VOCs-  
364 limited regime in the morning and NO<sub>x</sub>-limited regime at noon. The sensitivity regime of O<sub>3</sub>  
365 formation could be misdiagnosed without considering the consumed VOCs, such as a VOC-  
366 limited regime (observed) shifting to a transition regime (PIC-VOCs) in the morning. The mean  
367 F(O<sub>3</sub>) based on PIC- VOCs was 3.0 ppb h<sup>-1</sup> higher than that based on the measured VOCs,  
368 indicating that the underestimation of local photochemistry to local O<sub>3</sub> concentration could  
369 reached 36 ppb day<sup>-1</sup> if the consumed VOCs were not accounted for. The radical budget analysis  
370 illustrated that the O<sub>3</sub> formation processes between the observed and photochemical initial  
371 VOCs showed no significant difference, but the former one underestimated the O<sub>3</sub> production  
372 rate obviously. Finally, the results of in-situ O<sub>3</sub> formation process denoted that local O<sub>3</sub>  
373 photochemical formation plays a key role in both local and regional O<sub>3</sub> concentrations. In a  
374 conclusion, our results suggest that the PIC-VOCs should be more suitable to diagnose the O<sub>3</sub>  
375 formation sensitivity than the observed VOCs concentrations.
