Abstract. Based on source-specific saccharide tracers, the characteristic of biomass burning (BB) and biogenic emissions to saccharides was investigated in three rural sites at Lincang, where covered with 65% of forest in the southwest border of China. The total saccharides accounted for 8.4±2.7% of OC, and 1.6±0.6% of PM$_{2.5}$. The measured anhydrosugars accounted for 48.5% of total saccharides, among which levoglucosan was the most dominant species. The high level of levoglucosan was both attributed to the local BB activities and biomass combustion smoke transported from the neighboring regions of Southeast Asia (Myanmar) and the northern Indian Peninsula. The measured mono (di) saccharides and sugar alcohols accounted for 24.9±8.3% and 26.6±9.9% of the total saccharides, respectively, were both proved to be mostly emitted by direct biogenic volatilization from plant materials/surface soils, rather than as byproducts of polysaccharides breakdown during BB processes. Five sources of saccharides were resolved by non-negative matrix factorization (NMF) analysis, including BB, soil microbiota, plant senescence, airborne pollen and plant detritus with the contribution of 34.0%, 16.0%, 21.0%, 23.7% and 5.3%, respectively. The results provide the information on the magnitude of levoglucosan and contributions of BB, as well as the characteristic of biogenic saccharides, at the remote sites of Southwest China, which can be further applied to regional source apportionment models and global climate models.

1 Introduction

Biomass burning (BB) and biogenic aerosols are thought to play important roles on air quality, human health and climate through direct or indirect effects (Jacobson et al., 2000; Christner et al., 2008; Pöschl et al., 2010; Després et al., 2012; Chen et al., 2017, Tang et al., 2019). Atmospheric saccharides components have been extensively reported to be originate from biomass burning (natural or anthropogenic), suspended soil or dust and primary biological aerosol particles (PBAPs) (e.g., fungal and fern spores, pollens, algae, fungi, bacteria, and plant debris), as well as biogenic secondary organic aerosol (SOA) (e.g., Rogge et al., 1993; Graham et al., 2003; Jaenicke, 2005; Medeiros et al., 2006; Elbert et al., 2007; Fu et al., 2013). As one of the major classes of water-soluble organic compounds, saccharides in atmospheric aerosols have been detected over urban areas, forests, mountains, and remote marine regions (Pashynska et al., 2002; Yttri et al., 2007; Fu et al., 2009; Burshtein et al., 2011; Jia and Fraser, 2011; Chen et al., 2013; Pietrogrande et al., 2014; Li et al., 2016a, b). It has been
reported that saccharides account for 13-26% of the total organic compound mass identified in continental aerosols, and as much as 63% in oceanic aerosols (Simoneit et al., 2004).

Levoglucosan and related anhydrosugar isomers (mannosan and galactosan), produced from pyrolysis of cellulose and hemicellulose, are considered to be relatively stable in the atmosphere (Schkolnik et al., 2005; Puxbaum et al., 2007), and thus have been recognized as specific molecular markers for BB source emissions (Simoneit et al., 1999, 2000; Fraser and Lakshmanan, 2000; Sullivan et al., 2014; Du et al., 2015). However, some studies have challenged this knowledge and proved that levoglucosan alone was not suitable to be a distinct marker for BB in various regions and periods. Because there were evidences that levoglucosan is also emitted from non-BB sources (Wu et al., 2020), such as coal burning (Rybicki et al., 2020; Yan et al., 2018), open waste burning (Kalogridis et al., 2018), incense burning (Tsai et al., 2010), and food cooking (Reyes-Villegas et al., 2018). It was reported that the levoglucosan emission contribution of BB sources ranged from 21.3 to 95.9% (Wu et al., 2021). The current studies in China have reported the value of 2.6-289.1 ng m$^{-3}$ and 11.6-1803.1 ng m$^{-3}$ respectively over Beijing and Wangdu in summer (Yan et al., 2019), 2.4-1064.1 ng m$^{-3}$ over Shanghai all year round (Xiao et al., 2018), 15.6-472.9 ng m$^{-3}$ over Guangzhou (Zhang et al., 2010), 21.1-91.5 ng m$^{-3}$ over Hongkong (Sang et al., 2011), 60.2-481.9 ng m$^{-3}$ over Xi’an (Yang et al., 2012), 36.0-1820.9 ng m$^{-3}$ over Chengdu (Yang et al., 2012) and 10.1-383.4 ng m$^{-3}$ over the Tibetan Plateau (Li et al., 2019). In north China, high concentrations of levoglucosan is a serious problem due to drastic enhancement of coal and BB for house heating in winter and autumn (Zhang et al., 2008; Zhu et al., 2016). The BB pollution might be exacerbated under unfavorable meteorological conditions, such as in the Chengdu basin (Chen and Xie, 2014). In general, BB is an important source of fine particulate matter and with notable contribution to OC in China (Zhang et al., 2008; Cheng et al., 2013; Chen et al., 2017), controls on BB could be an effective method to reduce pollutant emissions. Recently study reported that BB activities have been reduced in China, because the total levoglucosan emission of China exhibited a clear decreasing trend from 2014 (145.7 Gg) to 2018 (80.9 Gg) (Wu et al., 2020).

Saccharide compounds including a variety of primary saccharides (monosaccharides and disaccharides) and sugar alcohols (reduced sugars) have been measured to estimate the contribution of biogenic aerosols, including fungi, viruses,
bacteria, pollen, and plant as well as animal debris (Simoneit et al., 2004; Jaenicke et al., 2007). For instance, arabitol and mannitol have been proposed as biomarkers for airborne fungal spores (Bauer et al., 2008; Zhang et al., 2010; Holden et al., 2011; Liang et al., 2013a, b), because both of them can function as storage or transport carbohydrates to regulate intracellular osmotic pressure (Bauer et al., 2008). Glucose and sucrose are thought to originate from natural biogenic detritus, including numerous microorganisms, plants, and animals (Simoneit et al., 2004; Tominaga et al., 2011). As the oxidation products of isoprene, methylditos (including 2-methylthreon and 2-methylerithrol) have been suggested as tracers of isoprene-derived SOA (Claeys et al., 2004; Kleindienst et al., 2007; Ding et al., 2016).

In the previous study, the contributions of fungal spores to OC were estimated to be 14.1 ± 10.5% and 7.3 ± 3.3% respectively at the rural and urban sites of Beijing (Liang et al., 2013b). Airborne pollen and fungal spores contributed 12-22% to the total OC in ambient aerosols collected in Toronto (Womiloju et al., 2003). Jaenicke (2005) found that PBAPS can comprise from 20 to 30% of the total atmospheric PM (>0.2 mm) from Lake Baikal (Russia) and Mainz (Germany). However, there is still a limited number of studies on quantifying the abovementioned biogenic aerosol contributions to ambient aerosol.

Lincang located in the southwest border of China is a traditional agricultural area of Yunnan province, where planting a large area of tea, sugar cane, rubber, macadamia nuts, etc. It is the largest production base of black tea and macadamia nut in China. The forest coverage rate of Lincang reaches to 65%. It has a wide variety of plant species, and has 6 nature reserves covering an area of ~222,000 hectares, accounting for 8.56% of the total area. As a residential area for ethnic minorities, Lincang has unique culture, humanity and living habits. A high portion of houses with wood burning used for cooking in villages in proximity and a large area of Southeast Asia constitute, and forest fires were frequently happened in this area especially in the dry seasons (March-April). All implies that there are abundant biogenic aerosols in the area, and BB pollution may be an important potential source of air pollution. However, little information on the magnitude of biogenic and BB tracers in this area is available. The contributions of biogenic aerosol and BB, and BB types are poorly understood.

In this study, the sampling were conducted from March 8 to April 8, 2019 at three mountaintop sites of Lincang, where is an ideal site for investigating the BB emission characteristics. BB tracers (including anhydrosugars and K⁺) and biogenic aerosol
tracers (primary saccharides and sugar alcohols) were measured to gain the information on source and contributions of BB and biogenic emissions in PM$_{2.5}$ over the rural Lincang. This study would be useful and valuable for providing reliable information on sources and magnitudes of saccharides involving rural BB and biological emissions in China.

2 Experimental section

2.1 Aerosol sampling

The PM$_{2.5}$ samples were simultaneously collected on three mountaintop sites, respectively of Datian (24.11° N, 100.13° E, 1960 m asl), Dashu (24.12° N, 100.11° E, 1840 m asl) and Yakoutian (24.12° N, 100.09° E, 1220 m asl), in Lincang, Yunnan Province, China, which are located ~300 km west to Kunming (the capital of Yunnan province) and ~120 km east from the Burma border. These sites are surrounded by massive mountains and scattering villages without obvious nearby traffic or major industry emissions. Each sampling was performed over a 23.5 h period every day, and was collected on quartz by high-volume air samplers (Thermo) equipped with a size selective inlet to sample PM$_{2.5}$ at a flow rate of 1.13 m$^3$ min$^{-1}$. Altogether, 91 samples were collected during 8 March to 9 April 2019.

Quartz filters (Whatman, 8 × 10 in.) were prebaked at 550 °C for 4 h in a muffle furnace to remove organic material, and were then stored in pre-baked aluminum foils. The samples were stored at about −20 °C in a refrigerator until analysis. Field blanks were collected by mounting filters in the sampler without air flow to replicate the environmental exposure. The data reported were corrected by the blanks at the sampling sites.

2.2 Measurements

The concentrations of organic carbon (OC) and elemental carbon (EC) were measured using a Multiwavelength Carbon Analyzer (DRI Model 2015; Atmoslytic Inc., USA). Typically, a 0.58 cm$^2$ punch of the filter was placed on a boat inside the thermal desorption chamber of the analyzer, and then stepwise heating was applied. Carbon fractions were obtained following the Interagency Monitoring of Protected Visual Environments (IMPROVE-A) thermal/optical reflectance (TOR) protocol (Chow et al., 2007). Replicate analyses were conducted once every ten samples. Blank sample was also analyzed and used to correct the sample results.

A punch (4.7 cm$^2$) of each quartz filter was ultrasonically extracted with 10.0 mL of
de-ionized water (resistivity = 18.2 MU) for 40 min. The aqueous extracts were filtrated through syringe filters (PTFE, 0.22 μm) to remove insoluble materials. Ion chromatography (Metrohm, Switzerland) coupling with Metrosep C6-150 and A6-150 columns was used to detect water-soluble ions (Cl\(^-\), NO\(_3\)\(^-\), PO\(_4\)\(^{3-}\), Na\(^+\), NH\(_4\)\(^+\), K\(^+\), Mg\(^{2+}\), and Ca\(^{2+}\)) with a detection limit (DL) range of 0.001-0.002 μg m\(^{-3}\). Five saccharide alcohols (glycerol, erythritol, inositol, arabitol and mannitol) and five primary saccharides (fructose, glucose, mannose, sucrose and trehalose), together with three anhydrosugars (levoglucosan, mannosan and galactosan) were quantified by an improved high performance anion-exchange chromatography system coupled with a pulsed amperometric detector (HPAEC-PAD) (Engling et al., 2006; Caseiro et al., 2007; Zhang et al., 2013). This method developed by Engling et al. (2006) was validated to be a powerful method for the detection of carbohydrates without derivatization techniques, and has been successfully applied for the atmospheric tracers (e.g., Zhang et al., 2010; Holden et al., 2011; Liang et al., 2013a, b; Li et al., 2016a, b; Kalogridis et al., 2018; Yan et al., 2018). The separation of the saccharides was performed on an ion chromatograph (Metrohm, Switzerland) equipped with a Metrosep Carb 2-250 analytical column and a guard column. The aqueous eluent of sodium hydroxide and sodium acetate was pumped by a dual pump module at a flow rate of 0.4 mL min\(^{-1}\). The low concentration of 50 mM sodium hydroxide and 10 mM sodium acetate (eluent A) was applied to pump 1, while the high concentration of 250 mM sodium hydroxide and 50 mM sodium acetate (eluent B) was applied to pump 2. The gradient generator was set as: 0-10 min, 100% of eluent A; 10-20 min, 50% of eluent A and 50% of eluent B; 20-50 min, 100% of eluent B; 50-60 min, 100% of eluent A for equilibration. The extraction efficiency of this analytical method was determined to be better than 90% based on analysis of quartz filters spiked with known amounts of mannitol. The method DL of the referred carbohydrate compounds were 0.005-0.01 mg L\(^{-1}\). All carbohydrate species were below detection limits in the field blanks.

2.3 Other data

The meteorological parameters, including temperature (T), relative humidity (RH), solar irradiation (W m\(^{-2}\)), and rainfall (mm) were obtained from the Physical Sciences Laboratory of NOAA (https://psl.noaa.gov). The temporal changes in meteorological variables over the observation sites during the sampling periods are shown in Figure
In order to characterize the origin and transport pathway of the air masses to the sampling sites, 72 h back-trajectories of the aerosol were calculated using Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model developed by NOAA/ARL (Draxler and Hess, 1998) via NOAA ARL READY Website (http://ready.arl.noaa.gov/HYSPLIT.php) with an endpoint height of 1500 m. To investigate the influence of BB emissions, fire pixel counts were obtained from Moderate Resolution Imaging Spectroradiometer (MODIS) observations on NASA satellites (https://earthdata.nasa.gov/).

### 2.4 Statistical analysis

A Pearson's correlation test was performed using the Statistical Product and Service Solutions (SPSS) software for the dataset containing ambient concentrations of the measured saccharides, inorganic ions and solar irradiation. Non-negative matrix factorization (NMF) analysis was utilized to resolve potential emission source and estimate their contribution to atmospheric saccharides. NMF introduced by Lee and Seung (1999) was similar to positive matrix factorization (PMF). Both methods find two matrices (termed the contribution matrix of \( W \) and the source profile matrix of \( H \)) to reproduce the input data matrix (\( V \)) using the factorization approach (\( V = WH \)) as a positive constraint (\( W \geq 0 \) and \( H \geq 0 \)). However, PMF forces the negative factors to be positive, but NMF method only retains nonnegative factors. NMF minimizes the conventional least-squares error and the generalized Kullback-Leibler divergence (Shang et al., 2018). Therefore, the results obtained from NMF are more responsive to the original characteristics of input data set and less number of factors will be extracted (Zhang et al., 2019). Half of the DL was used for the value below the detection limit. In this study, galactosan, mannose and inositol were excluded because their concentration was mostly below the DL. Concentrations of the other ten saccharide species for the total 91 samples were subjected for NMF analysis. The uncertainties in NMF analysis were estimated as 0.3 plus the analytical detection limit according to the method of Xie et al. (1999). The constant 0.3 corresponding to the log (Geometric Standard Deviation, GSD) was calculated from the normalized concentrations for all measured species, and was used to represent the variation of measurements.

### 3 Results and Discussion
3.1 Saccharides concentration and composition

The temporal variations of PM$_{2.5}$ mass, OC, EC, and various saccharides measured in all samples are shown in Figure 1. A statistical summary of all the data are listed in Table S1. During the sampling periods, the PM$_{2.5}$ mass concentrations ranged between 13.7-87.8 µg m$^{-3}$ with average values of 41.8 µg m$^{-3}$. The concentrations of OC and EC varied between 2.5-22.4 and 0.3-4.3 µg m$^{-3}$ with average values of 8.4 and 1.7 µg m$^{-3}$, respectively. OC accounted for 19.9 ±3.7% of total PM$_{2.5}$ mass.

The ambient concentrations of the total saccharides varied between 244.5-1291.6 ng m$^{-3}$ with average values of 638.4 ng m$^{-3}$. The total saccharides quantified in PM$_{2.5}$ accounted for 8.4 ±2.7% (range: 3.8%-20.6%) of the OC, and accounted for 1.6±0.6% (range: 0.6%-3.0%) of the PM$_{2.5}$. Figure 2 presents the mean concentration levels of 12 measured saccharide compounds, categorized into anhydrosugar, sugar and sugar alcohol, as well as the relative contribution of these saccharides for the all samples. The values for each site are shown in Figure S2. The absolute concentration and relative contribution of each saccharide displayed no distinct variation between the three sites.

3.1.1 Anhydrosugars

The mean concentrations of levoglucosan and mannosan were 287.7 and 31.6 ng m$^{-3}$, respectively with a range of 95.6-714.7 and 0-134.7 ng m$^{-3}$ for all the 91 samples. Galactosan was only detected in 6 samples, with a range of 2.5-5.5 ng m$^{-3}$. The anhydrosugars accounted for 48.5% of total measured saccharides. Levoglucosan was the most dominant specie among all the saccharides. The mean levoglucosan concentration in this study was comparable to the value at urban Beijing collected in spring of 2012 (above 200 ng m$^{-3}$) (Liang et al., 2016) and at urban Xi’an collected in winter of 2015 (268.5 ng m$^{-3}$) (Wang et al., 2018). It was higher than the value at rural Tengchong mountain site (193.8 ng m$^{-3}$) (Sang et al., 2013), at urban Shanghai collected in spring of 2012 (66.0 ng m$^{-3}$) (Li et al., 2016) and at urban Hong Kong collected in spring of 2004 (36.0 ng m$^{-3}$) (Sang et al., 2011), as well as at urban Beijing collected in summer of 2013 (49.4 ng m$^{-3}$) (Yan et al., 2019), but was lower than that at a rural site of Xi’an (0.93 mg m$^{-3}$) (Zhu et al., 2017) and at a rural site in eastern central India (2258 ng m$^{-3}$) (Nirmalkar et al., 2015). During the observation period, several instances of elevated levoglucosan occurred, peaked on March 8, 16, 23 and April 1. It was thought the ambient levoglucosan were primarily attributed to
domestic biomass fuel burning, the high levoglucosan emission on these peak days might be from open BB events.

Regression analyses of levoglucosan and the other two anhydrosugars (mannosan, galactosan) are shown in Figure 3a. Levoglucosan was highly correlated with mannosan and galactosan, with coefficients of determination (R) of 0.81 (P < 0.01) and 0.89 (P < 0.01), respectively, indicating similar combustion sources of them. The ratios of levoglucosan to mannosan (L/M) and mannosan to galactosan (M/G) had been employed to identify the specific types of BB, although these ratios were quite variable (Fabbri et al., 2009; Sang et al., 2018). Previous studies suggested that L/M ratios for burning of softwood were 3-10, hardwood were 15-25, and those from crop residues were often above 40 (Cheng et al., 2013; Zhu et al., 2015; Kang et al., 2018). The average L/M and M/G ratios were statistically reported as 32.6 and 1.2 for crop residues combustion, 4.0 and 3.9 for softwood combustion, 21.5 and 1.5 for hardwood combustion, respectively (Sang et al., 2013; Shen et al., 2018). In this study, the ratios of L/M and M/G ranging from 4.7 to 16.1 (mean: 9.7, n=91) and from 3.9 to 6.1 (mean: 4.8, n=6), respectively, crudely indicating major contribution from softwood burning. The sample collected during 31 March-1 April and during 8-10 March respectively had considerably lower and higher concentrations of mannosan than predicted by the levoglucosan-mannosan regression model (Figure 3a). The results suggested that BB aerosols collected during 31 March-1 April (L/M = 11.52 ± 1.34) and during 8-10 March (L/M = 6.57 ± 0.53) have originated from different types of BB as compared with the remaining sampling periods (L/M = 9.34± 1.20). Therefore, the high levoglucosan emission during 31 March-1 April and during 8-10 March might be from different open BB events, possibly an open agricultural waste burning event or a forest fire, whilst the BB of most sampling days originated from biomass fuel for domestic cooking and heating. It was worth noting that these peak days neared the Qingming Festival. Another possibility of BB events was that people burned ghost money to sacrifice ancestor according to Chinese tradition.

Anhydrosugars and water-soluble potassium (K⁺) have been both widely utilized as source tracers of BB emissions (e.g., Puxbaum et al., 2007; Wang et al., 2007; Zhang et al., 2008; Engling et al., 2011). The daily variation on concentrations of levoglucosan and K⁺ are shown in Figure S3, the regression analysis of K⁺ and three anhydrosugars is shown in Figure 3b. K⁺ was weakly correlated with levoglucosan, mannosan, and galactosan, with R values of 0.33, 0.28, and 0.74, respectively. It could
be explained by the additional emissions of K$^+$ from soil and sea water. Since Lincang is far from the coast, sea salt could be negligible. Because the inhomogeneity of crustal K$^+$ associated with soil types, it was difficult to fully account for crustal K$^+$ contributions from soil (Harrison et al., 2012; Cheng et al., 2013). The ratio of levoglucosan to K$^+$ (L/K$^+$) was also used to track possible sources of BB in the previous studies. The ratios of L/K$^+$ strongly depended on BB processes, namely smoldering and flaming. Studies suggested that relatively high L/K$^+$ ratios were obtained from smoldering combustion at low temperatures compared with flaming combustion (Schkolnik et al., 2005; Lee et al., 2010). Previous results showed the emissions from the combustion of crop residuals such as rice straw, wheat straw and corn straw exhibited comparable L/K$^+$ ratios, typically below 1.0. The averages of L/K$^+$ ratios in this study was 0.48 ± 0.20, which was higher than the ratio for corn straw (0.21 ± 0.08), but was lower than the ratio for Asian rice straw (0.62 ± 0.32) (Cheng et al., 2013). In this study, higher L/K$^+$ ratios were observed during 8-10 March (1.20 ± 0.19) than those during 31 March-1 April (0.40 ± 0.13), which suggested that the open fire event during 8-10 March was more possibly due to smoldering combustion of residues at low temperatures.

Figure 3c and 3d show the scatter plots and regression analyses of K$^+$ versus PM$_{2.5}$, OC and EC, and levoglucosan versus PM$_{2.5}$, OC and EC, respectively. Linear regression of K$^+$ on PM$_{2.5}$, OC and EC resulted in R values of 0.64, 0.63 and 0.62, respectively, which were generally higher than those of levoglucosan on PM$_{2.5}$, OC and EC, with R values of 0.40, 0.54 and 0.48, respectively. It showed that K$^+$ is more highly correlated with PM$_{2.5}$, OC and EC. This can be explained by either the photo-oxidative decay of levoglucosan (Hennigan et al., 2010) and/or different types of BB processes (Schkolnik et al., 2005; Lee et al., 2010). Even so, the results supported that the BB posed great impact on fine aerosols. The ratio of levoglucosan to PM$_{2.5}$ (L/PM$_{2.5}$) is also helpful in distinguishing the contributions of different levoglucosan sources (Wu et al., 2020). The ratios of L/PM$_{2.5}$ in this study was 0.0041-0.0162 (mean: 0.0072), indicating that levoglucosan emission in the areas might mainly come from woods (0.01-0.09) and crop straws (0.001-0.008), not excluding incense burning (0.001-0.007), ritual item burning (0.004-0.086), and meat cooking (0.005-0.06). However, it is certainly that it was not from corncob burning (0.0092-0.032), coal burning (0.0001-0.001) and waste incineration (0.0022).

An empirical ratio of levoglucosan to OC (8.2%), calculated from main types of
Chinese cereal straw (rice, wheat and corn) based on combustion chamber experiments (Zhang et al., 2007), was used to estimate the BB-derived OC. The average mass concentration of BB-derived OC was 3534.4 ng m$^{-3}$, whilst the contributions of BB to OC was 41.3%, with a large range of 19.1 to 81.3%. The contributions are higher than those previous reported, such as 6.5-11% in Hong Kong (Sang et al., 2011), 18-38% in Beijing (Zhang et al., 2008), 18.9-45.4% over southeastern Tibetan Plateau (Sang et al., 2013), 26.4-30.2% in Xi'an (Zhang et al., 2014). The large range of 19.1 to 73.9% revealed that the daily contribution of BB varied greatly, suggesting open BB event or forest fire happened occasionally. However, the contribution apportionment of primary BB might be underestimated due to the degradation of levoglucosan during atmospheric aging of BB influenced air mass after long-range transport (Hennigan et al., 2010; Mochida et al., 2010; Lai et al., 2014). Moreover, Wu et al (2020) have reported that the total levoglucosan emission of China exhibited a clear decreasing trend and biomass burning activities have been reduced in China. However, it is noteworthy that the mean concentration of levoglucosan (287.7 ng m$^{-3}$) and the biomass burning contributions to OC (41.3%) at Lincang mountain site in this study are both higher than the values of 191.8 ng m$^{-3}$ and 28.4% at Tengchong mountain site in 2004 spring (Sang et al., 2013). The result suggested no significant reduction in BB emissions in Southwest Yunnan Province to some extent.

3.1.2 Mono (di) saccharides

The total concentrations of five mono (di) saccharides, including glucose, fructose, mannose, sucrose and trehalose, were 25.2-373.7 ng m$^{-3}$ (mean: 158.9 ng m$^{-3}$), which contributed 24.9±8.3% of the total measured saccharides. The mean values of glucose, fructose, mannose, sucrose and trehalose were 31.2, 24.6, 2.7, 86.4 and 13.8 ng m$^{-3}$, respectively. Sucrose was the dominant mono (di) saccharides. The results was consistent with the previous studies of Yttri et al. (2007), Jia et al. (2010), and Fu et al. (2012), which had found that sucrose was one of the dominate specie in spring fine aerosols. The ruptured pollen may be an important source of sucrose in particular of spring blossom season (Yttri et al., 2007; Fu et al., 2012; Miyazaki et al., 2012). In spring and early summer, farmland tilling after the wheat harvest causes an enhanced exposure of soil containing wheat roots to the air, which is beneficial to the release of sucrose stored in the root (Medeiros et al., 2006), thus resulting in a sharply increased...
It was reported that sugars, such as glucose, sucrose and fructose, could be emitted from developing leaves (Graham et al., 2003). Glucose could be released from both soils and plant materials (e.g., pollen, fruits and their fragments) (Graham et al., 2003; Simoneit et al., 2004; Fu et al., 2012). Glucose and sucrose were rich in biologically active surface soils (Rogge et al., 2007). In this study, the positive correlations were found between sucrose and glucose ($R = 0.52$) (Table S2), suggesting a similar origin of glucose and sucrose in this study. Glucose and fructose have also been identified as a minor product of cellulose pyrolysis, because they were found to be enrich in BB emission (Nolte et al., 2001), and correlated well with $K^+$ (Graham et al., 2002) and levoglucosan (Kang et al., 2018). Herein, no significant correlation were found between $K^+$, levoglucosan and these mono (di) saccharides. Therefore, the detected glucose, fructose and sucrose might mostly be emitted by direct volatilization from plant materials/surface soils, rather than as products of polysaccharides breakdown during BB processes. The high abundance of sucrose, as well as glucose and fructose were responsible for biogenic aerosols associated with developing leaves and flowers, and surface soil suspension.

Trehalose as a stress protectant of various microorganisms and plants (Medeiros et al., 2006; Jia and Fraser, 2011) was found to be abundant in the fine mode soil, and has been proposed as a marker compound for fugitive dust from biologically active surface soils (Simoneit et al., 2004; Medeiros et al., 2006; Rogge et al., 2007; Fu et al., 2012). Previous study found a positive correlation between trehalose and calcium (Nishikawa et al., 2000). In this study, there was no significant correlation between trehalose and calcium. Besides, mannose has been reported to be one of the major monosaccharide components in phytoplankton, which is originate from marine biological fragments (Tanoue and Handa, 1987). Mannose was detected in only a few samples and presented in low concentrations in this study.

### 3.1.3 Sugar alcohols

Five sugar alcohol compounds, including glycerol, threitol, mannitol, arabitol and inositol were detected in PM$_{2.5}$. These reduced sugars are often reported to be related with the plant senescence and decay by microorganisms (Simoneit et al., 2004; Tsai et al., 2013), and are produced by fungi, lichens, soil biota and algae (Elbert et al., 2007; Bauer et al., 2008). The average concentration of the total sugar alcohols were 159.9
ng m\(^{-3}\) with a range of 53.1-254.0 ng m\(^{-3}\), which contributed 26.6\(\pm\)9.9\% of the total measured saccharides. Glycerol has been widely found in soil biota (Simoneit et al., 2004). Herein, glycerol was the second most abundant saccharide with an average concentration of 123.7 ng m\(^{-3}\), which comprised 5.1-44.6\% (mean: 22.6\%) of the total measured saccharides.

Mannitol and arabitol have been proposed as tracers for airborne fungal spores (Elbert et al., 2007; Bauer et al., 2008; Zhang et al., 2010; Burshtein et al., 2011). Mannitol and arabitol were detected with a concentration range of 0.0-38.6 ng m\(^{-3}\) (14.7 ng m\(^{-3}\)) and 0.0-21.1 ng m\(^{-3}\) (5.8 ng m\(^{-3}\)), respectively. The mean concentrations of mannitol and arabitol were comparable to those (mean 11.3 and 9.1 ng m\(^{-3}\)) reported in the Beijing spring aerosols (Liang et al., 2013b), but were lower than those (mean 21.9 and 8.43 ng m\(^{-3}\)) in the Mediterranean summer aerosols (Burshtein et al., 2011) and (30 and 24 ng m\(^{-3}\)) at Hyytiälä, Finland in summer (Yttri et al., 2011). Poor correlations \((r = 0.38)\) were found among mannitol and arabitol in this study. Nevertheless, a positive correlations was found between trehalose and mannitol \((r = 0.79, P < 0.05)\) (Table S2).

In the previous studies, the total measured mannitol has been measured and used for estimating the contribution of fungal spores to organic carbon (Elbert et al., 2007; Bauer et al., 2008; Zhang et al., 2010). A factor of mannitol per spore \((0.49 \pm 0.20 \text{ pg})\) was used to calculate the number concentrations of fungal spores (Liang et al., 2013a), then the carbon content of fungal spores can be calculated using a conversion factor of 13 pg C per spore obtained earlier as the average carbon content of spores from nine airborne fungal species, with an uncertainty of 20\% (Bauer et al., 2008). The diagnostic tracer ratio of mannitol to OC was calculated to be 0.0377 according to these researches (Bauer et al., 2008; Liang et al., 2013a), and then used to estimate the contribution of fungal spores to the OC. The average mannitol concentrations were 14.7 \(\pm\) 11.2 ng m\(^{-3}\) during the observation period. The average spore-derived OC was calculated to be 390.3 ng C m\(^{-3}\), which contributed of 4.9\% of the total OC.

Claeys et al. (2004) firstly identified two diastereoisomeric 2-methyltetrols as oxidation products of isoprene in the Amazonian rain forest aerosols. Henceforward, 2-methyltetrols has been used as tracers for isoprene-derived SOA (Liang et al., 2012; Fu et al., 2016; Yan et al., 2019). In the previous studies, erythritol was often quantified as surrogate of 2-methyltetrols (2-methylthreitol and 2-methylerythritol) due to lack of standards (Claeys et al., 2004; Ding et al., 2013; Ding et al., 2016).
this study, concentration ranges of erythritol were 0.4-19.8 ng m$^{-3}$ (mean 11.1 ng m$^{-3}$). The values of inositol ranged from 0.0 to 22.8 ng m$^{-3}$ with average values of 5.8 ng m$^{-3}$. Moreover, the sugar alcohols not only originates from biological emissions, but also derives from BB (Wan and Yu, 2007; Jia et al., 2010). Different levels of glycerol, arabitol, mannitol, erythritol and inositol in fine particles have been found during burning of crop residues and fallen leaves as well as indoor biofuel usage for heating and cooking (Graham et al., 2002; Burshtein et al., 2011; Wang et al., 2011; Yang et al., 2012; Kang et al., 2018). Herein, only inositol exerted correlation with levoglucosan ($r = 0.42$), suggesting inositol may be linked to biomass combustion sources. Hence, the primarily source of sugar alcohols associated with fine particles was biogenic aerosols at observation sites.

3.2 Sources and transport

Since the distinct concentration of studied compounds was caused by different emission sources arising from different wind direction, the 72 h backward trajectories for the samples at Dashu site (24.12° N, 100.11° E) and the spatial distribution of the fire spots (March 8-April 8, 2019) were calculated to understand the source of saccharides in aerosol (Figure 4). The analysis of air mass backward trajectories suggested that the air mass over Lincang were almost from the westerlies during the sampling periods, and could be separated into two episodes of remote western source over 2000 meters and local western source below 2000 meters, as shown in wine red and green lines. The air masses over 2000 meters were mainly from the regions of South Asia, such as India and Myanmar. The air masses below 2000 meters were mainly attributed to the local air flows in the east of Hengduan Mountains.

Mean concentrations of saccharide compounds, as well as the contribution of them, for the episodes over and below 2000 meters are shown in Figure 5. The mean concentration of levoglucosan and mannosan for the below 2000 meters samples (327.4 and 35.6 ng m$^{-3}$) were higher than those for the over 2000 meters samples (250.3 and 27.3 ng m$^{-3}$). The anhydrosugars accounted for 49.2% and 36.9% of total saccharides, respectively for the below and above 2000 meters samples. It implied that the levoglucosan at the observation site was both attributed to the local BB activities and biomass burning smoke transported from the neighboring regions of Southeast Asia (Myanmar) and the northern Indian Peninsula. These results were in agreement with the fact that residents across the Southeast Asia used to utilize woods.
as energy source to cook and generate heat.

While for glucose, fructose and sucrose, it was a little higher in the over 2000 meters samples (mean 33.5, 26.4 and 106.2 ng m\(^{-3}\)) than that in the below 2000 meters samples (mean 29.2, 22.9 and 67.8 ng m\(^{-3}\)). It implied that biogenic aerosols (such as ruptured pollen) carrying sugars could pass long distance, which was supported by previous study, which have observed long-range atmospheric transport of fine pollen from the Asian continent to the remote island Chichi-Jima under the influence of westerlies (Rousseau et al., 2008). Although the pollen are usually coarse with various shapes and hard shells, which results in the relatively short retention time in the atmosphere. Therefore, it could be concluded that, in addition to the local pollen, the concentration of sucrose in Lincang was also influenced by the transport of airborne pollen derived from South Asia areas.

### 3.3 Source apportionment of saccharides

Based on the compositional data of saccharides and key representative markers for difference sources, five factors associated to the emission sources of saccharides were finally resolved by NMF. As shown in Figure 6a, factor 1 was characterized by high level of levoglucosan (71.8%) and mannosan (78.7%), suggesting the source of BB (Simoneit et al., 1999; Nolte et al., 2001). Factor 2 was characterized by trehalose (99.9%) and mannitol (100.0%), and was enriched in the other saccharides components, i.e., arabitol (44.1%), glucose (29.6%), erythritol (18.2%), glycerol (17.8%), levoglucosan (14.7%), and sucrose (8.6%). These saccharide compounds had all been detected in the suspended soil particles and associated microbiota (e.g., fungi, bacteria and algae) (Simoneit et al., 2004; Rogge et al., 2007). Hence, this factor was attributed to suspended soil dust and soil microbiota. Factor 3 has high levels of glycerol (71.4%) and erythritol (58.2%), and showed loadings of glucose (12.8%) and fructose (11.8%). This factor was thought as the sources from plant senescence and decay by microorganisms. Factor 4 exhibited a predominance of sucrose (78.7%), and showed loadings of glucose (17.2%), arabinol (11.8%). This factor was regarded as the source of airborne pollen, because pollen is the reproductive unit of plants and contains these saccharides and saccharide alcohols as nutritional components (Bieleski, 1995; Miguel et al., 2006; Fu et al., 2012). Factor 5 characterized by the dominance of fructose (88.2%) was resolved, and was enriched in glucose (38.2%) and arabinol (21.2%), thus it could be regarded as the source of
The pie charts in Figure 6b shows the contribution of each source to total saccharides. BB of factor 1 (34.0\%) was found as the dominant contributor to total saccharides. Factor 2-5 could all be labeled to a biogenic source accounting for a total contribution of 66.0\%. The sources of soil microbiota (factor 2), plant senescence (factor 3), airborne pollen (factor 4) and plant detritus (factor 5) respectively contributed 16.0\%, 21.0\%, 23.7\% and 5.3\% to total saccharides. During the sampling periods, daily variations on proportion of the five factors are shown in Figure S4. Factor 2 soil microbiota emissions could be associated to soil reclamation and cultivation of farming periods, and factors 3 plant senescence and factor 5 plant detritus could be associated to harvesting of vegetation or crop. During the observation period of a month, along with the weather warming as sunshine enhanced, human left two obvious traces of cultivated soil during 9-17 March and 27 March-8 April and a trace of vegetation or crop harvest during 17-30 March. The stronger pollen discharge occurred in March, probably due to the flowering of certain plants. The BB emissions peaked on 9, 16 March, and 1 April were more prone to be open burnings.

Since there is still some uncertainty of the factor apportionment, the proportion of sources are only relative and uncertain. It is still difficult to distinguish the contributions of microorganisms and plants to biogenic aerosols. Furthermore, all the above speculations about farming and harvesting periods are based on only one month's observation, and long-term observations are needed to obtain more accurate and effective information.

4 Conclusion

With the help of the various atmospheric saccharides, this study presents the characteristic of BB and various biogenic emissions to ambient aerosol in the rural sites of Southwest China. Levoglucosan was the most dominant specie among all the saccharides with the concentration of 287.7 µg m⁻³. The ratios of levoglucosan/OC were 1.9-8.9\% (mean: 3.7\%). BB contributed to 19.1-73.9\% of OC (mean: 41.3\%). The results indicated that domestic biomass fuel burning, open BB events, possibly open agricultural waste burning, forest fire, or sacrificial activity appeared to be significant during the spring in this area. The total concentrations of five mono (di) saccharides and five sugar alcohols respectively contributed 24.9±8.3\% and 26.6±9.9\%
of the total measured saccharides. Based on the regression analysis, these mono (di) saccharides and sugar alcohols were mostly emitted by direct biogenic volatilization from plant materials/surface soils, rather than BB processes. The sampling sites suffered from both local emissions and BB via long-range transport from Southeast Asia (Myanmar) and the northern Indian Peninsula. Five sources of saccharides were resolved by NMF analysis, including BB (34%), soil microbiota (16.0%), plant senescence (21.0%), airborne pollen (23.7%) and plant detritus (5.3%) at rural Lincang in spring.

The data herein indicated that biofuel and open BB activities in the rural Southwest China and neighboring regions could have a significant impact on ambient aerosol levels. In addition to the residential biofuel usage, field burnings of agricultural residues and fallen leaves, as well as forest fire, were non-negligible. Some new technical measures of biomass resource utilization are urgently needed to improve the open burning emission scenario in rural areas, along with strict prohibition policy of BB. Meanwhile, the characteristics analysis of saccharides in the region can serve as a valuable reference for future studies to evaluate temporal variations of biomass combustion and biogenic emission during modeling predictions and policy making.

Supporting Information

Temporal variations of RH, temperature, solar irradiation and rainfall are shown in Figure S1. Mean concentrations of saccharide compounds and the contribution of them for the Datian, Dashu, and Yakoutian samples are shown in Figure S2. Daily variation on average concentrations of levoglucosan and K⁺ (a), arabinol and mannitol (b), PM₂.₅, Ca²⁺ and trehalose (c) at the three sites throughout the sampling period are shown in Figure S3. Figure S4 showed daily variations on proportion of the five factors to the total saccharides in PM₂.₅ sampled at three sites during the sampling periods. Table S1 lists the concentrations of the carbonaceous components and soluble inorganic ions in PM₂.₅ during the sampling periods of spring 2019. Correlation matrix for the dataset of the determined saccharides compounds in PM₂.₅ samples is shown in Table S3.
