June 29, 2021

Dear Editor:

We highly appreciate the constructive comments from the reviewers, and we have addressed the comments in the revised paper. We hope that the following responses are satisfactory and that the paper can be accepted for publication in Atmospheric Chemistry and Physics without further delay. The reviewers’ comments have been reproduced in blue text below, followed by our point-by-point replies.

Reviewer comments:

Reviewer: 1

S. Chee and co-workers have used computational methods to study the stabilities and formation rates of acid-base clusters relevant to atmospheric new-particle formation. The study has two main parts. First, the authors investigate whether the formation free energy (“stability”) of a “heterodimer” (a cluster of one acid molecule and one base molecule) can be predicted based on various single-molecule properties, including both experimental and easily computed parameters. Second, the authors then study how well this heterodimer stability correlates with particle formation rates computed with a cluster population dynamic model using quantum chemistry data (at the same level) as input. The study is interesting, well carried out, and useful to the atmospheric aerosol community. In addition to the main results, the study also has some very useful discussion connecting various molecular and/or cluster properties or property trends to the actual structures. I especially liked figures 3 and 6, and the associated discussion. I thus recommend publication in ACP subject to some fairly minor revisions.

Author reply:

We highly appreciate these valuable comments and suggestions.

Suggestions for revision:

- Please define what is meant by a “weak salt” e.g. in the abstract (or rephrase this).

Author reply:

We have clarified “weak salt” as a salt having a difference in gas-phase acidity greater than 95 kcal/mol, like ammonium sulfate and methylaminium sulfate in both the abstract and the end of the introduction.

- When the authors discuss “gas phase acidity”, as well as pKa, they mean both the acidities of the studied acids, and the acidities of the conjugate acids of the bases (which are in turn measures of the “basicities” of the parent bases). Or in other words, when they discuss for example the “pKa of methylamine”, they do NOT literally mean the negative base-10 logarithm of the equilibrium constant for the reaction CH3NH2 + H2O <=> CH2NH2- + H3O+ (that would be the technical literal interpretation of the phrase), but instead that of the reaction CH3NH3+ + H2O <=> CH3NH2 + H3O+. This is obvious to most chemists, but not necessarily to all
-Give a few more details on the conformational sampling please: the Kubecka et al 2019 study contains quite a few different options and possible parameter (e.g. cut-off energy) values. Also, did the authors use e.g. quasi-harmonic corrections?

Author reply:
We provide more information about the sampling settings and computational details.

Added to Section 2.1 to give details about sampling procedure: “Briefly, to create the initial cluster structures, we used 3000 random guesses and 100 exploration loops, with a scout limit of 4 in the ABCluster program, and for each building block combination we saved 300 of the lowest energy structures that were subsequently optimized by the tight-binding method GFN2-xtB with a very tight optimization criteria—citep{ab-rigid,abcluster,xtb2}. Based on the electronic energies, radius of gyration, and dipole moments, we separated different conformers, which were then optimized using the \ce{\omega}B97X-D/6-31+G* level of theory. Based on the obtained electronic energies, we selected structures with a maximum of $N$ kcal/mol from the lowest electronic energy (where $N$ is the number of molecules in the cluster).”

Added to Section 2.1 to specify usage of RRHO: “using rigid rotor--harmonic oscillator approximation”

-Also explain a bit more about what ACDC does, e.g. the fact that collision rates correspond to hard-spheres, and then evaporation rates are computed from quantum chemical free energies using detailed balance.

Author reply:
We have added to Section 2.2 more details: “The collision coefficients are computed from kinetic gas theory and the evaporation rates from quantum chemical Gibbs free energies assuming detailed balance.”

-I suggest using capital letters for the abbreviations (so tma => TMA etc); e.g. “put” is easily confused with the corresponding verb when written in lower case.

Author reply:
We thank the reviewer for the suggestion. Changes have been made.

-Page 11, “volatility of the constituent acid and base plays a relatively minor role in heterodimer stability”. This is true as stated, but maybe to avoid misunderstandings you could note in this discussion that e.g. the low volatility of H2SO4 is still a big part of why this molecule is so important for atmospheric new-particle formation. (This does not contradict anything the authors state, it’s just a complementary fact.)

Author reply:
This is a good point. We aim to further discuss the effect of volatility in the future, especially in the context of particle’s acid-to-base ratios. We have also added a clause in the text after the comment on volatility’s minor role in heterodimer stability: “However, volatility plays a key role in cluster and nanoparticle growth, wherein low volatility compounds in the atmosphere (i.e., \ce{H2SO4}) are still very important for understanding NPF.”

-Please explain what is meant by “lognormal” in the context of Fig 8a.

Author reply:
Lognormal here refers to the fit of the trendline. We have removed the word from the discussion and rephrased the sentence as: “the fit curve shape remains the same as \ce{J_{4x4}} is shifted upwards with increasing starting concentrations until the kinetic limit is reached”
W(1/2) in equation 2 should presumably be W(1,2). Also please explain this notation in a bit more detail. E.g. p(1,2) is the number concentration of what species? (Also presumably J is proportional to concentration, not the other way around!)

Author reply:
Thanks for spotting the typo. We have explained p(1,2) in more detail in the text and rearranged the sentence to make sure J is proportional to concentration: “$J$ is directly proportional to heterodimer concentrations ($p(1,2)$, which is related to the starting concentrations of acid and base), whereas temperature contributes from within the exponential expression, which matches the behavior seen in Figure 8a.”

Please confirm that the delta-Gs are calculated from partition functions at each temperature (and not from equation 1 assuming temperature-independent delta-H and delta-S, which would introduce a completely unnecessary extra error source). Also you could note if the calculations are based on lowest free-energy minima (at 298 K, or checked at each temperature?), or if multiple minima are included.

Author reply:
We have only used the global minimum energy structures found at 298 K and at other temperatures the Gibbs free energies are calculated from enthalpy and entropy values calculated for that structure at 298 K. Indeed, this might introduce an additional error, and this is now commented in Section 2.2 as: “It should be noted that the cluster sampling procedure were performed at 298~K and those structures and thermodynamic data (H and S) have been used in simulations at all temperatures. Thus, at lower or higher temperatures, slightly different global minimum structures might exist.”

“deltaGheterodimer predicts theoretical J 1.5 well at cold temperatures, but additional factors become more prominent at warmer temperatures”. Isn’t this just reflecting the fact that especially for the stronger bases, evaporation of clusters larger than the heterodimer are negligible for lower temperatures, so J is then determined by the heterodimer evaporation rate? While, for higher temperatures also evaporation rates of larger clusters (which correlate with, but are not directly determined by, the heterodimer delta-G) start to matter?

Author reply:
Yes, this is correct. At high temperatures larger clusters evaporate as well which affect to the particle formation efficiency (and this is consistent with reviewer’s comment that the 4x4 box size might not be large enough for weak bases at high temperatures).

Is Figure 11 only for SA:AMM, or for all bases with SA? (Based on the text probably the latter, but I’m not 100% sure.) Please note this in the caption.

Author reply:
It is for all sulfuric acid salts which is now specified in the caption.

Comparing equations 3 and 5, the normalised heterodimer concentration seems to be simply $([\text{acid}][\text{base}]/c_{\text{ref}})^{0.5} \times \exp(-\Delta G/RT)$. I.e. the same as the mass balance equation but with a square root around the prefactor. This could perhaps be noted. Also, to me this seems to be maybe be somehow related to the concept of saturation ratio (perhaps it depicts the saturation of the monomers with respect to the heterodimer)? If the authors have any insight into such a connection, please feel free to speculate :-).

Author reply:
Indeed, this is true. We acknowledge this in Section 3.4 as “It can be noted that Equation \ref{phi} is same as Equation \ref{hetdim} but with a square root around the concentration term.”
In the conclusion, the authors write “The effects of temperature and concentration on heterodimer concentration were much less than that of those on deltaGhetodimer”. I was under the impression that their delta-G was defined for c_ref = 1 atm, i.e. the actual value should not depend on the monomer concentrations. Perhaps they need to reformulate this sentence?

Author reply:

Yes, this is confusing sentence as deltaG has only linear dependency on the temperature as Equation 1 shows. We modified the sentence as: “Then in order to devise a simple model to predict $J_{4x4}$, heterodimer stability values were used to calculate heterodimer concentrations. Indeed, the relationship between heterodimer concentration and $J_{4x4}$ varied much less with changes to temperature and concentration compared to the relationship between $\Delta G_{\text{heterodimer}}$ and $J_{4x4}$”

In addition, we modified section 3.3 to reflect the same conclusion: “the $\Delta G_{\text{heterodimer}}$ vs. $J_{4x4}$ relation varies strongly with temperature and concentration”

-As the authors themselves note, the proposed approach for using heterodimer stability to predict new-particle formation rates is valid only for acid-base clusters, and for conditions where the acid and base concentrations are fairly similar. In the literature, the stabilities of heterodimer of type (X)(H2SO4) is very often used to (in my opinion incorrectly) argue for e.g. “nucleation enhancement” by a great multitude of (usually non-basic oxidised organic) species X. For example, dicarboxylic acids, such as oxalic acid mentioned by the authors, often bind quite strongly to one H2SO4 molecule - but are incapable of promoting the addition of further H2SO4 to the cluster. In such cases, “heterodimer stability” is clearly NOT a sufficient or good indicator of particle formation efficiency. To avoid other researchers misrepresenting their results, I strongly recommend that the authors explicitly state that the proposed relation between heterodimer stability and new-particle formation holds ONLY for acid-base clusters, and NOT for the general case of H2SO4 clustered with an arbitrary other (non-basic) molecule.

Author reply:

This is a very important point!

Added to the end of Section 3.2.1: “It is worth of mentioning that our model for using heterodimer stability to predict particle formation rates is valid only for acid--base clusters, not for organic acid--inorganic acid clusters. Thus, for instance a formation free energy value of oxalic acid--sulfuric acid heterodimer cannot be used to predict particle formation efficiency using any formula presented in this paper.”

And to the Section 4: “It is important to emphasize that all of these predictions of $J_{4x4}$ based on heterodimer stability is only possible for heterodimers made up of one acid and one base molecule, and not any other combination of molecules wherein the word heterodimer may apply.”
