# 17 Abstract

| 18 | A large population in China has been increasingly exposed to both severe ozone (O <sub>3</sub> ) pollution  |
|----|---|
| 19 | and extreme heat under global warming. Here, the spatiotemporal characteristics of coupled                  |
| 20 | extremes in surface $O_3$ and heat (OPCs) over China are investigated using surface observations, a         |
| 21 | process-based chemical transport model (GEOS-Chem), and multi-model simulations from Phase                  |
| 22 | 6 of the Coupled Model Intercomparison Project (CMIP6). North China Plain (NCP, 37-41°N; 114-               |
| 23 | 120°E) is identified as a hot spot of OPCs, where more than half of the $O_3$ pollution days are            |
| 24 | accompanied by high temperature extremes. OPCs over NCP exceed 40 days during 2014-2019,                    |
| 25 | exhibiting an increasing trend. Both O3 concentrations and temperatures are elevated during OPCs            |
| 26 | compared to O <sub>3</sub> pollution days occurring individually (OPIs). Therefore, OPCs impose more severe |
| 27 | health impacts to human than OPIs, but the stronger health effects are mainly driven by the higher          |
| 28 | temperatures. GEOS-Chem simulations further reveal that enhanced chemical production resulting              |
| 29 | from hot and stable atmospheric condition under anomalous weather pattern primarily contributes             |
| 30 | to the exacerbated O3 levels during OPCs. In the future, CMIP6 projections suggest increased                |
| 31 | occurrences of OPCs over NCP in the middle of this century, but by the end of this century, OPCs            |
| 32 | may decrease or increase depending on the pollutant emission scenarios. However, for all future             |
| 33 | scenarios, extreme high temperature will play an increasingly important role in modulating $O_3$            |
| 34 | pollution in a warming climate.   |
|    |   |

36

# 38 1. Introduction

| 39 | With the rapid economic development, car ownership and fossil fuel consumption, China has                                |
|----|--|
| 40 | been struck by severe air pollution in the recent decades (Lu et al., 2018). Research and air quality                    |
| 41 | controls have been prioritized to tackle the problem of particulate matter, e.g., PM <sub>2.5</sub> (T Wang et al.,      |
| 42 | 2017). Since the implementation of China's Action Plan on the Prevention and Control of Air                              |
| 43 | Pollution Plan in 2013, anthropogenic emissions of many air pollutants and their precursor gases,                        |
| 44 | including sulfur dioxide (SO <sub>2</sub> ), nitrogen oxides (NO <sub>x</sub> ), carbon monoxide (CO), black carbon (BC) |
| 45 | and organic carbon (OC), decreased by 21-59% between 2013 and 2017, despite a 11% increase in                            |
| 46 | anthropogenic emissions of non-methane volatile organic compounds (NMVOCs) (Zheng et al.,                                |
| 47 | 2018). Correspondingly, the annual average $PM_{2.5}$ concentrations decreased from 72 $\mu g/m^3$ to 47                 |
| 48 | $\mu g/m^3$ in 74 major cities in China (Huang et al., 2018). In contrast, ozone (O_3) concentrations in                 |
| 49 | China show an apparent increasing trend during 2013-2017, with the annual average $O_3$                                  |
| 50 | concentrations in 74 key cities increasing from 140 $\mu g/m^3$ to 160 $\mu g/m^3$ (Huang et al., 2018). During          |
| 51 | the warm season (April-September) of the same period, the daily maximum 8-hour average $O_3$                             |
| 52 | concentration (MDA8 O <sub>3</sub> ) increased at a rate of 3% per year, far exceeding the rates in many other           |
| 53 | countries, such as Japan, Korea, and Europe (Lu et al., 2018). Long-term exposure to high $O_3$                          |
| 54 | concentrations can seriously damage human health, agriculture, buildings, and ecology (Sharma et                         |
| 55 | al., 2017, Yue et al., 2017). Therefore, the rising O <sub>3</sub> concentration in recent years has caused great        |
| 56 | public concerns in China.  |
| 57 | With global warming, extreme high temperatures and heat events have become natural hazards                               |

in China in the recent decades, with substantial effect on socioeconomics, ecosystems and human
health (Lau and Nath, 2014, Meehl and Tebaldi, 2004). For instance, southern China was hit by a

| 60 | widespread heat wave with a record-breaking maximum temperature of 43.2°C during summer 2003.                              |
|----|--|
| 61 | The extreme heat event lasted for more than 40 days and caused heightened levels of human                                  |
| 62 | mortality (Tan et al., 2007, P Wang et al., 2017a). Such disastrous high temperatures have become                          |
| 63 | more frequent in China, as recorded subsequently in the summers of 2006, 2010, and 2013 (W Wang                            |
| 64 | et al., 2016). Recent studies found that extreme high temperatures and heat events have intensified                        |
| 65 | in the past 60 years and are expected to become more frequent and severe in the coming decades (P                          |
| 66 | Wang et al., 2019a; 2017b).  |
| 67 | Extreme high temperatures are conducive to O3 pollution. Specifically, high temperatures can                               |
| 68 | increase the production rate of surface O <sub>3</sub> in the presence of abundant O <sub>3</sub> precursors (Camalier et  |
| 69 | al., 2007, Lu et al., 2019a). As O3 concentration increases nonlinearly with temperature, extreme                          |
| 70 | high temperatures have disproportionate impacts on O <sub>3</sub> (Lin et al., 2020). Therefore, O <sub>3</sub> pollution  |
| 71 | often co-occurs with extreme heat (Schnell and Prather, 2017). Besides the direct impacts of air                           |
| 72 | temperatures on O <sub>3</sub> production, the co-occurrence of extreme heat and O <sub>3</sub> pollution arise from their |
| 73 | shared underlying drivers, i.e., persistent high pressure, strong solar radiation, low humidity and                        |
| 74 | weak wind speeds (P Wang et al., 2017a; 2017b;Perkins, 2015). Hence despite reductions in                                  |
| 75 | anthropogenic emissions of O3 precursors in the U.S., Europe and China, high O3 episodes will                              |
| 76 | likely continue in the future due to increasing heat waves under climate warming (Zhang et al.,                            |
| 77 | 2018).   |
| 78 | The coupled extremes in heat and O <sub>3</sub> pollution lead to higher mortality rates than O <sub>3</sub> pollution     |
| 79 | or hot extreme acting alone (Krug et al., 2019). While the impacts of extreme high temperatures on                         |
| 80 | O3 pollution have been investigated using case studies in China (Ma et al., 2019; Pu et al., 2017),                        |
| 81 | there is a gap in understanding the spatiotemporal characteristics and underlying mechanisms of                            |

| 82 | coupled extremes in high temperatures and O3 pollution due to a lack of systematic analyses.                     |
|----|--|
| 83 | Although extreme high temperatures are expected to be more frequent and intense in the future with               |
| 84 | accelerated warming, surface O3 concentrations are expected to decrease because of curtailment in                |
| 85 | O <sub>3</sub> precursor emissions. Therefore, considerable uncertainties exist in the future changes of coupled |
| 86 | extremes in heat and O <sub>3</sub> .  |
| 87 | In this study, based on the available surface O3 concentrations and air temperatures                             |
| 88 | observations during 2014-2019, we investigate the spatiotemporal characteristics of co-occurrences               |
| 89 | of extremes in air temperatures and surface O3 in China, highlighting North China Plain (NCP,                    |
| 90 | defined here as 37-41°N; 114 -120°E, see Fig.1) as a hot spot which has already suffered from the                |
| 91 | most severe O <sub>3</sub> pollution in recent years (K Li et al., 2019). The underlying mechanisms governing    |
| 92 | the coupled extreme are examined using the global chemical transport model GEOS-Chem. The                        |
| 93 | associated health burden during the coupled extreme days is also discussed. In addition, future                  |
| 94 | projections of the coupled extremes in the warming climate are explored based on the latest multi-               |
| 95 | model simulations from Phase 6 of the Coupled Model Intercomparison Project (CMIP6).                             |
| 96 | 2. Data and Method   |

# 97 2.1 Observed O<sub>3</sub> concentration and reanalysis data

98 Hourly O<sub>3</sub> concentrations for 2014–2019 are obtained from China National Environmental 99 Monitoring Centre (CNEMC). The network covered 944 sites in 2014 that grew to about 1600 sites 100 in 2019. The daily maximum air temperatures (Tmax) for more than 2000 observation sites during 101 the same period are provided by the National Meteorological Information Center of the China 102 Meteorological Administration (CMA). The dataset has been quality-controlled and homogenized 103 (Q Li et al., 2004) and widely used in previous works (P Wang et al., 2019b). Here in this study, we

- 104 focus on the extreme high temperatures and surface O<sub>3</sub> of warm season during May to September.
- 105 To unify the spatial resolutions of Tmax and O3 concentration, the two observational datasets are
- 106 mapped to  $1^{\circ} \times 1^{\circ}$  grid boxes, and the values in each box represent the averaged observations within
- 107 that box. The spatial distributions of averaged daily Tmax and MDA8 O<sub>3</sub> over May-September
- 108 during 2014-2019 are shown in Figure S1.
- 109 Meteorological conditions during extremes of O<sub>3</sub> and high temperatures are calculated using 110 variables derived from the new Japanese 55-year Reanalysis (JRA-55) at  $1.25^{\circ} \times 1.25^{\circ}$  resolution 111 (Ebita et al., 2011), including geopotential height (HGT), winds, relative humidity (RH), 2m air 112 temperature (T2m), surface soil moisture (SM), downward solar radiation flux (DSR) and sensible 113 heat flux (SH). Following Gong and Liao (2019), daily time series of a meteorological parameter x 114 at a specific model grid cell over the months of May to September in the years 2014–2019 is 115 standardized by
- 116  $[x_i] = \frac{x_i \frac{\sum_{i=1}^{n} x_i}{n}}{s}$ , (1)

117 where x<sub>i</sub> indicates the parameter x on day i, n is the total number of days during May to 118 September for 2014-2019, s indicates the standard deviation of the daily time series and [x<sub>i</sub>] is the 119 standardized anomaly for parameter x on day i.

### 120 2.2 GEOS-Chem model

To explore the physical and chemical mechanisms related to the O<sub>3</sub> extremes, the 3-D global chemical transport model (GEOS-Chem, version 12.9.3) is utilized to simulate O<sub>3</sub> concentrations during May-September for 2014-2017, driven by assimilated meteorological data of Version 2 of Modern Era Retrospective-analysis for Research and Application (MERRA-2) (Gelaro et al., 2017).

| 125 | The simulations are performed at a horizontal resolution of 2° latitude $\times$ 2.5° longitude with 47   |
|-----|---|
| 126 | vertical levels. The anthropogenic emissions of O <sub>3</sub> precursor gases including CO, NOx and VOCs |
| 127 | in China are obtained from the MEIC emission inventory (http://meicmodel.org/), which includes            |
| 128 | emissions from industry, power, residential and transportation sectors. Lacking anthropogenic             |
| 129 | emissions for 2018-2019, simulations are conducted for 2014-2017 by GEOS-Chem and we use                  |
| 130 | observations during 2014-2017 to validate the model results.  |
| 131 | 2.3 CMIP6 data  |
| 132 | We use O3 and Tmax outputs from future projections of Scenario Model Intercomparison                      |
| 133 | Project (ScenarioMIP) in the CMIP6 archive to determine how the coupled extremes will change in           |
| 134 | a warmer climate. ScenarioMIP is the primary activity within CMIP6 that provides multi-model              |
| 135 | climate projections driven by different scenarios of future emissions and land use changes (O'Neill       |
| 136 | et al., 2016), produced based on the Shared Socioeconomic Pathways (SSPs) combining                       |
| 137 | socioeconomic developments and the feedback of global climate changes (Z Li et al., 2020). More           |
| 138 | details about the SSP scenarios can be found in O'Neill et al. (2016).                                    |
| 139 | Currently, four SSP scenarios in ScenarioMIP simulations provide hourly O3 concentration                  |
| 140 | and daily Tmax from the present day to the end of the 21st century (2015 to 2100), i.e., SSP1-2.6,        |
| 141 | SSP2-4.5, SSP3-7.0 and SSP5-8.5 (combination of low, intermediate, relatively high and high               |
| 142 | societal vulnerabilities and forcing levels, respectively). Among the four SSPs, SSP3-7.0 and SSP2-       |
| 143 | 4.5 have the weakest and medium air pollution controls pathways, respectively, while strong air           |
| 144 | pollution controls are assumed in SSP1-2.6 and SSP5-8.5 (Gidden et al., 2019). Five global climate        |
| 145 | models (GCMs), MOHC.UKESM1-0-LL, CESM2-WACCM, GFDL-ESM4, MPI-ESM-1-2-HAM                                  |
| 146 | and EC-Earth3-AerChem from ScenarioMIP under CMIP6 that provide both hourly O3 and daily                  |

| 147 | Tmax are adopted in this work. The horizontal resolutions and institutions of the five GCMs are                    |
|-----|--|
| 148 | listed in Table S1. Note that the numbers of available models vary across different scenarios (see                 |
| 149 | Table S2 for details). The results from the five GCMs are regridded to the observation boxes using                 |
| 150 | linear interpolation to facilitate spatial comparison. In this study, 2015-2019 is regarded as the                 |
| 151 | historical period and the overall performance of the CMIP6 simulations in reproducing the                          |
| 152 | occurrences of coupled extremes is evaluated against the observations during 2015-2019. For the                    |
| 153 | projection of coupled extremes, we focus on two periods of 2046-2050 and 2096-2100 in the mid                      |
| 154 | and end of the 20th century, respectively, under different SSPs.   |
| 155 | 2.4 Identification of extremes in O <sub>3</sub> and temperature   |
| 156 | Following Schnell and Prather (2017), in this study, we use the local-specific thresholds for                      |
| 157 | each grid to identity the extreme cases of surface air temperatures and O3 concentrations,                         |
| 158 | specifically, the 90th percentile of daily Tmax and daily MDA8 O3 from May to September for                        |
| 159 | 2014-2019. To characterize the co-occurrences of extremes in high temperatures and surface O <sub>3</sub> and      |
| 160 | investigate the impacts of extreme high temperatures on O <sub>3</sub> pollution, the following extremes are       |
| 161 | defined:   |
| 162 | • Total O <sub>3</sub> pollution days (OPs): All days when daily MDA8 O <sub>3</sub> is above its threshold.       |
| 163 | • Individual O <sub>3</sub> pollution days (OPIs): Days when MDA8 O <sub>3</sub> is above its threshold while Tmax |
| 164 | is lower than its threshold.   |
| 165 | • Coupled extreme days (OPCs): Days when both daily Tmax and daily MDA8 O3 exceed their                            |
| 166 | corresponding thresholds.  |
| 167 | We use a co-occurrence frequency ratio (CF) in percent to characterize the dependence of extreme                   |
| 168 | high $O_3$ levels on extreme high temperatures. CF is defined as the ratio of the frequency of OPCs 8              |

| 169 | (days) to the frequency of OPs (days). Thus, a higher CF value indicates a higher dependence of O <sub>3</sub>  |
|-----|---|
| 170 | pollution on extreme high temperatures:   |
| 171 | $CF = OPCs/OPs \times 100\%, $ (2)  |
| 172 | 2.5 Health impact of coupled extremes   |
| 173 | In this study, we apply the mortality ratio (MR) to describe the combined human health impacts  |
| 174 | from O <sub>3</sub> and temperature levels during OPCs, following Lee et al. (2017). The MR ratio   |
| 175 | characterizes the differences in health burden related to O3 and temperature levels between OPCs  |
| 176 | and OPIs, and MR is defined as below:   |
| 177 | MR=Daily Mortality during OPCs<br>Daily Mortaliyu during OPIs   |
| 178 | $= \frac{\sum_{i \text{ RR}_{ozone,i}} \sum_{\tau} \sum_{i \text{ RR}_{temperature,i}}}{\sum_{j \text{ RR}_{ozone,j}} \sum_{\tau} \sum_{j \text{ RR}_{temperature,j}}},  (3)$ |
| 179 | $MRozone = \frac{\frac{\sum_{i RR_{ozone,i}}}{m}}{\frac{\sum_{j RR_{ozone,j}}}{n}},$ (4)  |
| 180 | $MRtemperature = \frac{\sum_{j \text{ RR}_{temperature, j}}{\frac{m}{\sum_{j \text{ RR}_{temperature, j}}},} (5)$   |
| 181 | $RR_{ozone} = exp^{(\beta_1(C-C_0))}, $ (6)   |
| 182 | $RR_{temperature} = exp^{(\beta 2(T-T_0))}, $ (7)   |
| 183 | Here, $RR_{ozone,i}$ ( $RR_{ozone,j}$ ) and $RR_{temperature,i}$ ( $RR_{temperature,j}$ ) are the relative risks due to $O_3$   |
| 184 | concentration and temperature exceeding the threshold of $C_0$ and $T_0$ , respectively, on a coupled   |
| 185 | extreme day i (an individual O <sub>3</sub> pollution day j); m is the total days of coupled extremes and n is the  |

186 total days of individual O<sub>3</sub> pollution day. MR<sub>ozone</sub> (MR<sub>temperature</sub>) is the mortality ratio attributed to

- 187 O<sub>3</sub> concentration (temperature) changes, while MR is the combined effects from both O3 and
- 188 temperature changes.
- 189 For the calculation of RRozone in Eq. 6, C0 is the minimum O3 concentration below which O3 190 has no health impacts.  $C_0$  is set to zero here as previous work found no significant threshold for the 191  $O_3$  related mortality (K Chen et al., 2017).  $\beta_1$  is the concentration response factor corresponding to 192 a 0.24% [95% confidence interval: 0.13%, 0.35%] increase in daily mortality per 10  $\mu$ g/m<sup>3</sup> increase 193 in MDA8 O<sub>3</sub> (Yin et al., 2017). Following Huang et al. (2018) in calculating RR<sub>temperature</sub> in 66 194 Chinese communities,  $\beta_2$  indicates a 1.09% (95% confidence interval: 0.72% to 1.46%) excess 195 mortality per 1°C increase in temperature above T<sub>0</sub>, which is the minimum mortality temperature 196 set as 26°C in this study (C Wang et al., 2014).
- 197 **3. Results**

### 198 **3.1** Spatial and temporal patterns of coupled extremes

199 The spatial patterns of OPCs and their ratio to the total O3 pollutions days (CF values) during 200 May-September for the recent 6 years (2014-2019) highly resemble each other (Figure 1), with the 201 highest values located over NCP which has suffered the most severe O3 pollution in recent years 202 (Fig.S1a). The highest OPCs exceed 40 days over NCP and the corresponding CF is more than 56% 203 (Fig. 1). That means, the coupled extreme days account for more than half of the total O<sub>3</sub> pollution 204 days, indicating a strong dependence of O<sub>3</sub> pollution on extreme high temperatures over NCP. It has 205 been suggested that the dependence of  $O_3$  concentration on high temperature increases with the  $O_3$ 206 levels (Lin et al., 2020). However, coupled extremes occur much less frequently over the Yangtze 207 River Delta (YRD, 30-33°N, 118-122°E) compared to NCP, and the regional averaged CF in YRD 208 is below 20%, even though MDA  $O_3$  level and temperature in YRD are both as high as those in 10

| 209  | NCP (Fig. S1). The distinctive relationships between extreme high temperature and O <sub>3</sub>  |
|--|---|
| 210  | concentration over NCP and YRD are driven by their different climatology during warm season.  |
| 211  | Southern China receives substantial monsoon rainfall during summer, accompanied by increased  |
| 212  | relative humidity (RH) and reduced radiation (Zhou and Yu, 2005), which can suppress surface O <sub>3</sub>   |
| 213  | levels (Han et al., 2020). Delineating the local daily maximum air temperatures (Tmax) and RH of  |
| 214  | all O3 pollution days over NCP and YRD (Figure S2), OPCs occur more frequently over NCP than  |
| 215  | over YRD, and a higher fraction of the O3 pollution days over NCP co-occur with extreme high  |
| 216  | temperatures and low-to-moderate RH (Fig. S2a). Humid environment dampens the occurrence of   |
| 217  | O3 pollution over YRD and extreme O3 pollution mostly occurs on days with relatively low RH   |
| 218  | when air temperatures are moderate (Fig. S2b), which explains the lower OPCs and CF in YRD  |
| 219  | compared to NCP. Therefore, we focus on the coupled extremes over NCP.  |
|  |   |

The abrupt increase in the occurrence of<br>coupled extremes in 2017 is consistent with the significant increasing trends of both MDA8 O <sub>3</sub> and<br>Tmax (95% confidence level) over NCP in recent years (Fig. 2b). The strong increasing trend of<br>MDA8 O <sub>3</sub> and temperature. The strong increasing trends of MDA8 O <sub>3</sub> and air temperatures are<br>consistent with previous results (K Li et al., 2019; 2020). As addressed previously (K Li et al.,<br>2020), the temperature trends during 2014-2019 reflect interannual climate variability rather than a<br>long-term warming trend. Notably, daily MDA8 O <sub>3</sub> exhibits increasing sensitivity to Tmax from   |
| <ul> <li>220</li> <li>221</li> <li>222</li> <li>223</li> <li>224</li> <li>225</li> <li>226</li> <li>227</li> <li>228</li> <li>229</li> </ul> | Daily variations of the occurrence of OPIs and OPCs over NCP during 2014-2019 are shown<br>in Figure 2. O <sub>3</sub> pollution days have appeared since 2015 but coupled extremes OPCs have only been<br>observed since 2017, mostly during May–July (Fig. 2a). The abrupt increase in the occurrence of<br>coupled extremes in 2017 is consistent with the significant increasing trends of both MDA8 O <sub>3</sub> and<br>Tmax (95% confidence level) over NCP in recent years (Fig. 2b). The strong increasing trend of<br>MDA8 O <sub>3</sub> and temperature. The strong increasing trends of MDA8 O <sub>3</sub> and air temperatures are<br>consistent with previous results (K Li et al., 2019; 2020). As addressed previously (K Li et al.,<br>2020), the temperature trends during 2014-2019 reflect interannual climate variability rather than a<br>long-term warming trend. Notably, daily MDA8 O <sub>3</sub> exhibits increasing sensitivity to Tmax from<br>2014 to 2019 (Fig. 2c), supporting the increase in OPCs during the same time period. Note that the |

| 231   | For example, the slopes are 3.96 ppbv/°C, 3.43 ppbv/°C and 4.56 ppbv/°C in 2017, 2018, and 2019   |
|---|---|
| 232   | (Fig. 2c). In fact, the yearly occurrences of OPCs are 15, 13, 18 days in 2017, 2018, 2019, consistent  |
| 233   | with ozone and temperature relationship. Thus, what we emphasize here is the overall increasing   |
| 234   | OPCs during 2014 to 2019 with an abrupt increase of OPCs since 2017. The contrasting MDA8 $O_3$   |
| 235   | and Tmax associated with OPCs and OPIs over NCP are evident in Fig. 3. Both O <sub>3</sub> levels and air   |
| 236   | temperatures are higher during OPCs than during OPIs over NCP region (Fig.3a&3b), with the  |
| 237   | regional mean anomalies of Tmax and MDA8 O3 during OPCs reaching 3.36°C and 5.49 ppbv,  |
| 238   | respectively, compared to those during OPIs. A north-south contrast in the MDA8 O3 and Tmax   |
| 239   | difference between OPCs and OPIs is evident (Fig. 3b), suggesting that contrasting environments   |
| 240   | north and south of the Yangtze River during the summer monsoon may play a key role in the   |
|   |   |

Associated<br>with the anomalous high-pressure system is clear sky with enhanced downward solar radiation<br>(DSR) at the surface (Fig.4c), leading to hotter near surface temperature (Fig.4b), reduced RH and<br>soil moisture (Fig. 4d&4e), and enhanced surface sensible heat flux (Fig.4f) that further intensifies |

251 NCP (Fig. S3) and more conducive to O3 pollutions (Lu et al., 2019b). Among the meteorological

252 factors, the intensification in surface temperatures is the strongest among different meteorological

253

254 influential meteorological variable of surface O3 over NCP (K Li et al., 2019). 255 The impacts of weather patterns on surface O<sub>3</sub> level can be understood via changes in physical and chemical processes, both sensitive to meteorology (L Chen et al., 2020). The contributions of 256 257 different chemical and physical processes to OPCs over NCP under the anomalous weather pattern 258 of Fig. 4 are quantified by GEOS-Chem simulations of O3 during May to September of 2014–2017. 259 GEOS-Chem can reasonably capture the spatial pattern and magnitude of OPCs in observations 260 during 2014-2017 (Text S1 and Figure S4). Four processes affecting O3 levels are considered, 261 including net chemical production, horizontal advection, vertical advection, and mixing (diffusion 262 plus dry deposition) and are listed in Table 1. For both OPIs and OPCs, chemical production 263 contributes the most to O<sub>3</sub> mass within the boundary layer. Compared to OPIs, the higher O<sub>3</sub> level 264 during OPCs (Fig. 3b) are contributed by stronger chemical production and mixing but vertical 265 advection and horizontal advection tend to reduce the O<sub>3</sub> concentrations, with enhanced chemical 266 production playing the dominant role. Therefore, we conclude that the hotter near surface 267 temperature induced by anomalous weather pattern and amplified by land-atmosphere feedbacks 268 during OPCs (Fig. 4) is the primary cause of the enhanced formation of  $O_3$  and eventually a higher 269 surface O3 level than during OPIs.

variables with the highest magnitudes (Fig.S3b), supporting that air temperature is the most

270 **3.3 Health impacts of coupled extremes** 

As both surface O<sub>3</sub> and air temperatures are amplified during coupled relative to individual O<sub>3</sub> pollution days (Fig. 3), we investigate the potential influences of OPCs on human health. The mortality ratios between OPCs and OPIs during May to September for each year of 2017-2019 are illustrated in Figure 5 and attributed to air temperature and/or O<sub>3</sub> concentration changes

am

1.1.00

275

| 275 | (MR <sub>Temperature</sub> , MR <sub>ozone</sub> and MR, see Sec.2). It should be noted that coupled extreme days are only |
|-----|--|
| 276 | observed since 2017. MR, $MR_{ozone}$ and $MR_{Temperature}$ are above 1.0 for all three years, indicating a               |
| 277 | harsher environment for people to survive during OPCs. Importantly, MR <sub>temperature</sub> is significantly             |
| 278 | higher than $MR_{ozone}$ for all years of 2017-2019, suggesting that extreme high temperature caused                       |
| 279 | many more mortalities than extreme $O_3$ concentrations over NCP. The averaged $MR_{ozone}$ ,                              |
| 280 | MR <sub>Temperature</sub> , and MR for 2017-2019 are 1.003, 1.037, and 1.040, respectively. Compared to the                |
| 281 | individual O3 pollution days OPIs, daily mortality rate in NCP increases by 4.0% during coupled                            |
| 282 | extremes OPCs, the majority of which is attributed to the temperature increase, with less than one-                        |
| 283 | tenth contributed by the O3 concentration increase. That is, coupled extremes amplify health impacts                       |
| 284 | compared to individual O <sub>3</sub> pollution days primarily because of the higher mortality risk associated             |
| 285 | with elevated air temperatures.  |

1.1

### 286 **3.4 Projected coupled extremes in future climate**

287 As O3 precursors (i.e., NOx and NMVOCs) are expected to keep declining due to the continued 288 emission controls in China while extreme high temperatures will become more frequent and intense 289 under global warming, uncertainties exist in the projection of the co-occurrences of extremes in 290 high temperatures and O<sub>3</sub> pollution. Here, we investigate the projections of OPCs and CF values 291 based on CMIP6 simulations under SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5. OPCs in the 292 simulations are identified in the same way as for the observations (see Text S2 and Fig S5 for details). We focus on the historical period of 2015-2019 (referred to as 2019) and the projected periods of 293 294 2046-2050 (referred to as 2050) and 2096-2100 (referred to as 2100) by the mid and end of the 295 century. Note that OPCs during the projected periods are identified based on the historical 296 thresholds for extreme O<sub>3</sub> level and high temperatures. The multi-model ensemble means can

| 297 | reasonably capture the observed spatial pattern of coupled extremes and their magnitudes over NCP |
|-----|---|
|     |   |

298 during 2015-2019 (Fig. S5).

| 299 | The averaged OPCs over NCP under each SSP increase from the historical period to the mid-                         |
|-----|---|
| 300 | century (Fig. 6a), with a maximum increase under SSP5-8.5 (spatial distribution shown in Fig. S6).                |
| 301 | From the mid-century to the end-century, OPCs decrease under SSP1-2.6, SSP2-4.5 and SSP5-8.5,                     |
| 302 | but OPCs by 2100 obviously surpass that in 2050 under SSP3-7.0, with an average increase from                     |
| 303 | 46 days to 196 days (spatial patterns in Fig.S6e&S6f). Due to the weak air pollution control under                |
| 304 | SSP3-7.0 (Turnock et al., 2020), MDA8 O <sub>3</sub> in 2100 under this scenario is highest among the four        |
| 305 | SSPs (Fig. S8). In contrast, OPCs are substantially reduced to below 5 days by 2100 under SSP1-                   |
| 306 | 2.6 and SSP2-4.5, highlighting the benefit of strong actions in mitigating climate and reducing air               |
| 307 | pollutant emissions. In the future by 2050 and 2100, NCP will still be the most vulnerable region in              |
| 308 | China to the coupled extreme (Figure S6), while most other areas will be much less threatened by                  |
| 309 | the coupled extremes by the end of the century under SSP1-2.6, SSP2-4.5 and SSP5-8.5 (Fig. S6b,                   |
| 310 | S6d, and S6h).  |
| 311 | Unlike OPCs, CF over NCP obviously increases by the 2050 and 2100 compared to 2019 under                          |
| 312 | all four SSPs (Fig. 6b). The projected increases of CF over NCP indicate the higher dependence of                 |
| 313 | O <sub>3</sub> pollution on extreme high temperatures in the future, consistent with the increased sensitivity of |

MDA8 O<sub>3</sub> to Tmax at higher Tmax in historical period (Fig. 2c). Spatially, the NCP region will still see the highest CF values in the future, especially under SSP1-2.6, SSP2-4.5 and SSP5-8.5 (Fig. S7). This means regardless of the economic pathways, extreme high temperature will play an increasingly important role in modulating O<sub>3</sub> pollution in the warming climate. Therefore, besides

- 318 the management strategies on pollutants emission, global warming mitigations will undoubtedly
- 319 benefit O<sub>3</sub> pollution control, especially for regions facing severe air quality issues.

#### **320 4. Discussion and conclusions**

321 Climate change can impact local air quality. Higher temperatures associated with climate 322 change can lead to an increase in surface O<sub>3</sub>, and high temperatures and surface O<sub>3</sub> are highly 323 temporally correlated over many regions (Porter et al., 2019). A large population in China has been 324 increasingly exposed to both severe O3 pollution and extreme heat under global warming. With 325 combined surface observations of air temperature and O<sub>3</sub> concentration, process-based model 326 simulations and multi-model projections, this study firstly present a comprehensive analysis of the 327 co-occurrences of extreme high temperatures and O<sub>3</sub> pollution in China. It is highlighted that NCP 328 is a hot spot in China most threatened by the co-occurrence of extremes in heat and O<sub>3</sub> pollution. 329 The higher co-occurrence over NCP than other regions in China is linked to their distinctive 330 relations to meteorological variables, as temperature is the top meteorological factor directly leading 331 to O<sub>3</sub> pollution over NCP whereas relative humidity is the most influential variable for O<sub>3</sub> pollution 332 over southern China (Han et al., 2020).

The concurrent increasing trends in both surface  $O_3$  and temperature over NCP in recent years account for the increasing coupled extremes in surface  $O_3$  and heat in recent years. Besides, it is previously reported that the increasing trend of temperature is higher over northern China than southern China (P Wang et al., 2017b; Qian et al., 2006). The increase in air temperature can accelerate the  $O_3$  production. Using a physically based model (GEOS-Chem), we have provided support for the dominant role of higher temperatures associated with stable atmospheric condition under favorable weather pattern in amplifying  $O_3$  pollution through enhanced

| 340 | chemical production during coupled extremes, compared to the individual ozone pollution days                             |
|-----|--|
| 341 | not accompanied by extreme temperatures. In addition, the increases in surface O3 over NCP are                           |
| 342 | much stronger than the other regions in recent years, which is also possibly linked to the stimulation                   |
| 343 | effect from enhanced hydroperoxyl radicals (HO <sub>2</sub> ) due to a reduction in aerosol sink resulting from          |
| 344 | the decrease in PM2.5 during this period (K Li et al., 2019). Thus, the hot spot of co-occurrences of                    |
| 345 | extremes in heat and O <sub>3</sub> over NCP could be attributed to the co-effects of stronger increasing trends         |
| 346 | of temperature and surface O <sub>3</sub> therein.   |
| 347 | It is a prevalent concept that the coupled extremes pose greater health impacts or risks to human                        |
| 348 | than the simply summed impacts of the single extremes acting alone (Smith et al., 2014). It is                           |
| 349 | revealed here that both the O <sub>3</sub> concentration and air temperatures are elevated during the coupled            |
| 350 | extremes than the individual O <sub>3</sub> pollution, leading to an even heavier health burden to human. And            |
| 351 | this study underscores the elevated air temperatures during the coupled extremes as the major driver                     |
| 352 | for increased mortality rates, while the simultaneously elevated O3 concentrations act as an                             |
| 353 | additional stressor. It should be noted that the algorithm we use to calculate MR, $\ensuremath{MR_{ozone}}$ and         |
| 354 | MR <sub>temperature</sub> (see Sec.2) does not consider the possible amplification/inhibition effect of combining        |
| 355 | O <sub>3</sub> and air temperature in affecting human health. Previous studies have claimed that O <sub>3</sub> -related |
| 356 | mortality changes with different air temperature levels, with O3-related mortality increasing with                       |
| 357 | higher temperatures, although several studies presented contrasting results or inconsistent                              |
| 358 | relationships for different regions (R Chen et al., 2014; Jhun et al., 2014; Ren et al., 2008). Therefore,               |
| 359 | how the interactions between temperature and O <sub>3</sub> influence human health during coupled extremes               |
| 360 | is still an open question that deserves future studies using more health-related data.                                   |

| 361 | Currently, China has the highest emission of greenhouse gases, and the emission rates have                       |
|-----|--|
| 362 | increased significantly since the 21st century (Friedlingstein et al., 2020). To prevent the dangerous           |
| 363 | climate change impacts, the Chinese government has declared an ambitious goal by pledging to                     |
| 364 | peak emissions before 2030 and reaching carbon neutrality before 2060. With global warming, hot                  |
| 365 | extremes in China are projected to be more frequent, stronger, and longer lasting under global                   |
| 366 | warming, which may present challenges for O3 pollution control of China. Based on ScenarioMIP                    |
| 367 | simulations from CMIP6, this study demonstrates that the coupled extremes over NCP are projected                 |
| 368 | to be more frequent in the middle of this century but their frequency decreases or increases by the              |
| 369 | end of the century under strong or weak air pollution control scenarios, respectively. And with                  |
| 370 | higher sensitivity of O3 concentration to temperatures at higher temperatures, O3 extreme will                   |
| 371 | increasingly co-occur with extreme high temperatures over NCP as the climate warms, regardless                   |
| 372 | of the economic pathways. Thus, our results further reinforce the notion that determined actions are             |
| 373 | vital to make our communities less vulnerable to climate change impacts already in progress. On                  |
| 374 | the other hand, tropospheric O <sub>3</sub> level are projected to be increasing in the near decades (Turnock et |
| 375 | al., 2020) (also see Fig. S8b). As the third important anthropogenic greenhouse gas after $CO_2$ and             |
| 376 | CH4, tropospheric O3 radiative forcing over the industrial era is 0.4 $\pm$ 0.2 W $m^{-2}$ (Myhre et al.,        |
| 377 | 2014). Higher tropospheric O <sub>3</sub> level can cause temperature changes by altering the energy balance     |
| 378 | between the atmosphere and the Earth (Dang and Liao, 2019), which may feedback on the air quality.               |
| 379 | Thus, potential co-benefits may be gained through O3 pollution control and climate change                        |
| 380 | managements, in suppressing the occurrences of coupled extremes and tackling their consequences                  |
| 381 | to air quality, human health, and climate.   |

382

#### 383 Data availability

| 384 | Hourly O <sub>3</sub> concentrations are obtained from the public website of the China National Environmental |
|-----|---|
| 385 | Monitoring Centre ( <u>http://www.cnemc.cn/en/</u> ). Daily maximum air temperature is provided by the        |
| 386 | National Meteorological Information Center of the China Meteorological Administration (CMA,                   |
| 387 | http://data.cma.cn/en/). Reanalysis datasets are derived from the new Japanese 55-year Reanalysis             |
| 388 | (https://rda.ucar.edu/datasets/ds628.0/). Multi-model projections are from Scenario Model                     |
| 389 | Intercomparison Project in Phase 6 of the Coupled Model Intercomparison Project (https://esgf-                |
| 390 | node.llnl.gov/search/cmip6/). The GEOS-Chem model is available at   |
| 391 | http://acmg.seas.harvard.edu/geos/.   |

#### 392 Author contributions

- 393 P. Wang performed the analyses and wrote the initial draft. Y. Yang conceived and supervised the
- 394 study. H. Li performed the GEOS-Chem simulations. Y. Yang and L.R. Leung reviewed and edited
- 395 the initial draft. All the authors discussed the results and contributed to the final manuscript.
- **396** Competing interests
- 397 The authors declare that they have no competing interest.

Figure 5 MR<sub>ozone</sub>, MR<sub>temperature</sub> and MR between OPCs and OPCs during May to September for
 each year of 2017-2019. The average values for 2017-2019 are given in the left corner. MR<sub>ozone</sub>,

591 MR<sub>temperature</sub> and MR indicate the mortality changes between OPCs and OPIs due to differences

592 in O<sub>3</sub> levels alone, air temperatures alone and both O<sub>3</sub> levels and temperatures, respectively.

Figure 6 Averaged (a) OPCs and (b) CF values over NCP based on CMIP6 simulations under
different SSPs for the periods of 2015-2019, 2046-2050, and 2096-2100. The error bar shows the
minimum and maximum values simulated by the CMIP6 models for each SSP. Note that only one
GCM is available for SSP1-2.6.
