9 **Abstract.** Volcanic ash advisories are produced by specialised forecasters who combine several sources of  
10 observational data and volcanic ash dispersion model outputs based on their subjective expertise. These advisories are  
11 used by the aviation industry to make decisions about where it is safe to fly. However, both observations and dispersion  
12 model simulations are subject to various sources of uncertainties that are not represented in operational forecasts.  
13 Quantification and communication of these uncertainties are fundamental for making more informed decisions. Here,  
14 we develop a data assimilation technique which combines satellite retrievals and volcanic ash transport and dispersion  
15 model (VATDM) output, considering uncertainties in both data sources. The methodology is applied to a case study  
16 of the 2019 Raikoke eruption. To represent uncertainty in the VATDM output, 1000 simulations are performed by  
17 simultaneously perturbing the eruption source parameters, meteorology and internal model parameters (known as the  
18 prior ensemble). The ensemble members are filtered, based on their level of agreement with Himawari satellite  
19 retrievals of ash column loading, to produce a posterior ensemble that is constrained by the satellite data and its  
20 uncertainty. For the Raikoke eruption, filtering the ensemble skews the values of mass eruption rate towards the lower  
21 values within the wider parameters ranges initially used in the prior ensemble (mean reduces from 1 Tg h<sup>-1</sup> to 0.1 Tg  
22 h<sup>-1</sup>). Furthermore, including satellite observations from subsequent times increasingly constrains the posterior  
23 ensemble. These results suggest that the prior ensemble leads to an overestimate of both the magnitude and uncertainty  
24 in ash column loadings. Based on the prior ensemble, flight operations would have been severely disrupted over the  
25 Pacific Ocean. Using the constrained posterior ensemble, the regions where the risk is overestimated are reduced  
26 potentially resulting in fewer flight disruptions. The data assimilation methodology developed in this paper is easily  
27 generalisable to other short duration eruptions and to other VATDMs and retrievals of ash from other satellites.

## 28 1 Introduction

29 Volcanic ash in the atmosphere poses a hazard to aircraft (Casadevall, 1994). It is therefore important to accurately  
30 forecast the evolution of volcanic ash cloud in the atmosphere for the aviation industry. Forecasting the distribution  
31 of volcanic ash in the atmosphere at a given time is typically performed using a volcanic ash transport and dispersion  
32 model (VATDM). VATDMs solve dynamic equations to evolve the system state (volcanic ash cloud) forward in time.  
33 However, such simulated volcanic ash distributions are subject to errors due to inaccurate parametrisations of physical  
34 processes, errors in the driving meteorological fields and errors in the volcanic eruption source parameters.  
35 Observations of volcanic ash distributions may be obtained from ground-based, aircraft or satellite-based instruments.

36 These observations can be used to evaluate the accuracy of VATDM simulations (Harvey and Dacre, 2016; Dacre et  
37 al., 2016). Geostationary satellite measurements are of particular interest as they provide information at high temporal  
38 frequency and, thanks to the increasingly growing network of satellites, over large spatial extents. Ash retrievals from  
39 geostationary satellite data use a forward model to transform observations of radiance into vertically integrated  
40 volcanic ash distributions (known as column loadings). However, retrievals of volcanic ash column loading from  
41 satellite data are subject to measurement errors, interference with other atmospheric constituents and to errors in the  
42 forward models (e.g., Krotkov et al., 1999; Francis et al., 2012). This information is often disregarded and only the  
43 mean ash retrievals are used for verification purposes. Therefore, to improve estimates of the volcanic ash cloud in  
44 the atmosphere, VATDM simulations and observations can be combined to create an analysis. Combining satellite-  
45 based observations and VATDM simulations allows the modelled volcanic ash cloud to be continuously adjusted and  
46 thus improves the accuracy of volcanic ash forecasts (Fu et al., 2017).

47 The most straightforward combination of VATDM and satellite observations is data insertion, whereby satellite  
48 observations of volcanic ash column loading are used as initial conditions in a VATDM simulation (Wilkins et al.,  
49 2015). More sophisticated combinations of VATDM simulations and satellite observations involve data assimilation  
50 techniques such as variational and sequential methods. In variational data assimilation a cost function is defined to  
51 quantify the difference between a VATDM simulation and a satellite observation of volcanic ash column loading,  
52 weighted by the VATDM and observation uncertainties. The cost function is typically minimised by adjusting one or  
53 more eruption source parameters (e.g., plume height, mass eruption rate, particle size distribution, ash density) to  
54 estimate their optimum value for simultaneously fitting the simulated column loadings to the satellite retrievals and  
55 for fitting to prior estimates of the eruption source parameters at a given time. In the volcanic ash literature this  
56 technique is often referred to as source inversion (Stohl et al., 2011; Kristiansen et al., 2012; Denlinger et al., 2012;  
57 Pelley et al., 2015). Variational data assimilation uses observations from a fixed time window, thus allowing time  
58 evolving eruption source parameters to be estimated, so is suitable for long duration volcanic eruptions which undergo  
59 several eruptive pulses. Alternatively, sequential data assimilation provides an estimation of the system state  
60 sequentially as it evolves forward in time using observations as they become available. Thus, sequential data  
61 assimilation is suitable for short duration single pulse volcanic eruptions (Chai et al., 2017; Zidikheri et al., 2017).

62 In most cases eruption source parameters (input parameters), physical processes (internal parameters) and the driving  
63 meteorology are uncertain so an ensemble of VATDM simulations can be formed by perturbing the input,  
64 meteorological and internal parameters. This results in a probability density function (pdf) of simulated volcanic ash  
65 distributions. In this case, the data assimilation step involves conditioning the VATDM simulated pdf based on a  
66 comparison with the observed volcanic ash cloud to create a filtered pdf at each time the data assimilation is performed.  
67 In volcanic ash forecasting, ensemble source inversion (Harvey et al., 2020) and ensemble sequential filtering  
68 methods, such as Ensemble Kalman Filters (EnKFs) (Fu et al., 2015; Pardini et al., 2020; Osores et al., 2020) and  
69 Particle Filters (Wang et al., 2017; Zidikheri and Lucas, 2021), have been employed. EnKFs were developed for non-  
70 linear systems and so are suitable for dispersion problems. However, they assume that the parameters to be estimated  
71 have Gaussian prior pdfs, which may not be true. Conversely, no assumptions on the form of the prior pdf of simulator

72 states are needed for Particle Filtering techniques meaning that they are more sensitive to the tails of the prior  
73 distribution, although this is at the cost of a lot more simulations.

74 Bayesian inference is used in particle filtering to derive constraints on the parameters of a simulation from  
75 observations. In this framework, the posterior pdf of the simulation parameters given the observed data is derived  
76 from a prior pdf and from the likelihood of the data given a choice of simulator parameters. Bayesian inference  
77 therefore relies on the ability to compute a formal likelihood function. For volcanic eruption source parameters their  
78 exact likelihood function is unknown or computationally intractable and so direct Bayesian analysis is therefore not  
79 possible. A technique known as Approximate Bayesian Computation uses simulations to bypass the need to evaluate  
80 a likelihood function. Approximate Bayesian Computation systematically explores the prior parameter space and  
81 compares the simulated and observed data sets using a distance metric. By accepting simulations for which this  
82 distance metric is smaller than a given threshold, the method provides an approximation to the Bayesian posterior pdf.  
83 One Approximate Bayesian Computation method frequently used in hydrology forecasting is known as Generalised  
84 Likelihood Uncertainty Estimation (GLUE) (Beven and Binley, 1992). The GLUE methodology is based on the  
85 concept of equifinality, which acknowledges that there exist many combinations of simulation input and internal  
86 parameters that provide equally good simulations of the observed system.

87 There are several steps in the GLUE methodology:

- 88 1. Realistic ranges are defined for the simulator input and internal parameters. These are known as prior pdfs  
89 since they are defined prior to the comparison with observational data. When there is a lack of strong prior  
90 information about the parameter distributions and their interactions uniform pdfs are often used.
- 91 2. Rejection criteria are defined to determine the accepted agreement between the simulators and the observed  
92 system state. These can be based on subjectively chosen thresholds limits or as accepted minimum levels of  
93 performance allowing for the expected uncertainties in the observational data.
- 94 3. Input and internal parameter sets are sampled from the prior pdfs to generate an ensemble of simulation  
95 predictions of the system for a given analysis time.
- 96 4. Simulations that are not in agreement with the observed system, using the selected rejection criteria, are  
97 discarded from the analysis. The subset of retained simulators with known parameter sets forms the posterior  
98 pdfs for each input and internal parameter. Thus, the posterior pdfs are the conditional pdfs of each parameter  
99 given the observations.
- 100 5. Input and internal parameter values are then sampled from the posterior pdf to generate an ensemble  
101 prediction of the system at a future time.
- 102 6. Steps 4–5 can be repeated for subsequent analysis times and the joint posterior distributions compared to the  
103 preceding analysis time.

104 The main aim of this paper is to contribute to the development of data assimilation methods to improve quantitative  
105 ash dispersion forecasts. To this end we will determine whether satellite retrievals of volcanic ash column loading can  
106 be used to filter an ensemble of volcanic ash simulations using the particle filtering methodology. We determine which

of the input and internal model parameters are most constrained by the satellite observations and quantify how the assimilation of satellite data changes the uncertainty estimate of the ensemble. Finally, for communicating the volcanic ash forecasts, we apply to the ensemble output the risk-matrix approach described in Prata et al. (2019) and applied retrospectively to the 2011 Grimsvotn eruption by Harvey et al. (2020), where risk is defined as the likelihood of exceeding ash concentrations considered a potential risk to aircraft. This approach will be demonstrated using simulations and observations of the Raikoke volcanic eruption which was a short duration eruption lasting less than 24 hours occurring between the 21–22 June 2019.

## 2 Methods and data

In this study, the Numerical Atmospheric–dispersion Modelling Environment, NAME (Jones et al., 2007), was used to simulate the dispersion of volcanic ash. It is the VATDM used by the London Volcanic Ash Advisory Centre (LVAAC) for producing volcanic ash advisories following an eruption. Each simulated ash cloud was quantitatively evaluated using retrievals from Himawari–8.

### 2.1 Himawari–8

Himawari–8 is a geostationary satellite that came into operation in July 2015 (Bessho et al., 2016). It has 16 spectral channels and provides observations of high temporal frequency (10 min) and spatial resolution (2 km for the infrared bands). The high temporal and spatial resolution make these observations ideally suited to evaluate the transport of volcanic ash following an eruption. The volcanic ash retrievals used in this study are based on the method by Francis et al. (2012) with slight adaptations for the channels of the AHI instrument aboard the Himawari–8 satellite.

The Met Office volcanic ash retrieval algorithm has two steps. The first step detects which pixels contain volcanic ash using the channels at 8.6  $\mu\text{m}$ , 10.4  $\mu\text{m}$  and 12.4  $\mu\text{m}$ . The second step runs a one–dimensional variational (1D–Var) analysis to determine an optimal estimate between the assumed background and the observed radiances in the channels at 10.4  $\mu\text{m}$ , 12.4  $\mu\text{m}$ , and 13.3  $\mu\text{m}$  for the column loading, ash cloud height and effective radius. The detection is based on a combination of brightness temperature difference (BTD) tests and beta ratio tests (Pavolonis, 2010). The beta ratio tests use a derived radiative parameter  $\beta$ , that is the effective absorption optical depth ratio of two channels and are used to filter pixels marked as ash by the BTD tests. These tests have been improved by fine tuning of the operational thresholds, to optimise coverage of the June 2019 Raikoke eruption. In addition, several geographical filters have been added, to reduce false detections at high satellite zenith angle and over arid land surfaces, and further false detections have been removed by checking the consistency of ash detection in neighbouring pixels.

The retrieval algorithm also provides a measurement of the error on each of the retrieved values. The retrieval relies on the minimization of a cost function to determine the optimal estimate from the assumed background and the observed radiances. How well defined the minimum of the cost function is provides an indication of the likely accuracy of the retrieval, in that the more well defined the minimum of the cost function is, the more accurate the retrieval is likely to be. By considering the inverse of the second derivative of the cost function with respect to each of the

140 variables considered in the retrieval, we can provide an estimate of the error for the retrieved ash plume pressure, ash  
 141 column loading and ash effective radius.

142 Where ash is detected, these pixels are flagged as ash and this algorithm determines the ash column loading. If a pixel  
 143 is free from both ash and meteorological cloud, then it is flagged as a clear sky pixel. Pixels that neither have detectable  
 144 ash nor are flagged as clear skies are unclassified. As in Harvey et al. (2020), further processing is performed to regrid  
 145 the retrieved column loadings on to a grid of  $0.375^\circ$  latitude by  $0.5625^\circ$  longitude (approximately 40 km x 40 km in  
 146 mid-latitudes) and averaged over 1 h. This is to match the resolution of the VATDM ash concentration output and to  
 147 reduce data volumes. If all classified pixels within a grid box are flagged as clear sky pixels, then the grid box is  
 148 deemed to be a clear sky observation. Otherwise, the grid box is deemed to be an ash grid observation with the column  
 149 loading in this grid box given by the mean of all the classified pixels (including clear skies).

## 150 2.2 VATDM

151 All the simulations were performed using NAME version 8.1 on the Joint Analysis System Meeting Infrastructure  
 152 Needs (JASMIN) super data cluster (Lawrence et al., 2012). To simulate the dispersion and removal of volcanic ash,  
 153 NAME includes parametrization of the effects of turbulence on the transport and dispersion, sedimentation, dry  
 154 deposition and wet deposition. In the operational configuration used by the LVAAC (Beckett et al., 2020) aggregation  
 155 of ash particles, near source plume rise and processes driven by the eruption dynamics (e.g., Woodhouse et al., 2013)  
 156 are not explicitly modelled. The default particle size distribution used is based on data from Hobbs et al. (1991) and  
 157 the shape of the particles are assumed to be spherical.

158 Ensembles of NAME simulations were created by varying nine parameters covering the meteorology, information  
 159 about the eruption source and the parameterisation of turbulence in NAME (as in Harvey et al., 2018; Prata et al.,  
 160 2019). Uniform distributions between the specified ranges were used as prior probability distributions to generate the  
 161 initial ensemble (Table 1). Full details of how these parameters are sampled is given in Sect.4.1.

162 All simulations share the same start and end time, 18:00 UTC on 21 June 2019 and 1200 UTC on 25 June 2019  
 163 respectively, for a total run time of 96 hours. The eruption start time matches the simulation start time. Volcanic ash  
 164 within the simulations is released along a vertical line, between the lower and upper plume heights (Witham et al.,  
 165 2019). Ash column loadings ( $\text{g m}^{-2}$ ) and ash concentrations ( $\text{g m}^{-3}$ ) are output onto a global grid of  $800 \times 600$  points,  
 166 corresponding to a grid of  $0.45^\circ$  longitude and  $0.3^\circ$  latitude, giving a horizontal resolution of approximately 40 km in  
 167 midlatitudes every 6 hours using a 6-hour time average. Ash concentrations are output at 22 Flight Levels (FL000–  
 168 FL550) with a vertical resolution of 25 FL (“thin layers”) that are then combined to form three “thick” layers (FL000–  
 169 200, FL200–350, FL350–550) by taking the maximum concentration values from the component thin layers for the  
 170 corresponding thick layer value (Witham et al., 2019).

171

172

Parameter	Symbol	Control value	Initial sampling range
Plume height (km) <sup>1</sup>	$H$	12.45	9–17
Mass eruption rate factor <sup>2</sup>	$MER F$	1	0.33–3
Ash density (kg m <sup>-3</sup> )	$\rho$	2300	1350–2500
Source duration (hr)	$L$	12	9–15
Distal fine ash fraction (%)	$DFAF$	5	0.5–20
Horizontal (vertical) Lagrangian timescale for free tropospheric turbulence (s)	$\tau$	300 (100)	100–900 (33.33–300)
Standard deviation of horizontal (vertical) velocity for free tropospheric turbulence (m s <sup>-1</sup> )	$\sigma$	0.25 (0.1)	0.0025–2.5 (0.001–1)
Standard deviation ( $\sigma$ ) of horizontal velocity for unresolved mesoscale motions (m s <sup>-1</sup> )	$m\sigma U$	0.8	0.27–1.74
Meteorological fields	$MET$	Met Office Unified Model global analysis	MOGREPS-G members 0–17

<sup>2</sup>scaling factor applied to the default mass eruption rate value calculated using the equation from Mastin et al. (2009); see Sect. 4.1.1 for details on how mass eruption rate is calculated.

### 3 Description of the 2019 Raikoke eruption

Raikoke is an uninhabited volcanic Island near the centre of the Kuril Island chain in the Sea of Okhotsk in the northwest Pacific Ocean located at 48.2°N, 153.3°E. Its most recent explosive eruption, after 95 years of dormancy, started at approximately 1800 UTC on 21 June 2019 and is estimated to have an initial eruptive plume height of 10–13 km above sea level (asl) (Global Volcanism Project, 2019). The eruption lasted approximately 12 hours and ended at approximately 0600 UTC on 22 June 2019. There is evidence from visible satellite imagery to suggest that there was an umbrella cloud which was quickly advected eastwards towards a large extratropical cyclone which distorted the dispersed ash cloud (Fig. 1).

The number of satellite grid boxes that are classified as containing ash at each time are the ones available to be used to refine the prior pdfs. The largest number of boxes are available at 1800 UTC on 22 June. Before 0600 UTC on 22 June the number of grid boxes available is limited by the small time the ash has had to be transported. After 1800 UTC on 24 June the number of grid boxes is limited due to the presence of meteorological cloud associated with an extratropical cyclone situated to the east of Raikoke (Fig. 1).

**Figure 1:** Hourly mean ash column loadings from the Himawari satellite at (a) 0600 UTC, (b) 1200 UTC, (c) 1800 UTC on 22 June 2019, (d) 0000 UTC, (e) 0600 UTC, (f) 1200 UTC, (g) 1800 UTC on 23 June 2019, (h) 0000 UTC, (i) 0600 UTC, (j) 1200 UTC, (k) 1800 UTC on 24 June 2019. Grey shading indicates grid boxes that are classified as clear sky. The red triangle indicates the location of Raikoke. N indicates the number of gridboxes classified as containing ash.

#### 4 Particle filter construction

Drawing from the GLUE methodology described in Sect. 1, we developed a new particle filter for refining a series of ensembles moving forward in time based on their level of agreement with Himawari satellite observations. All ensemble members are evaluated and filtered by comparing the NAME-simulated ash column loadings ( $\text{g m}^{-2}$ ) with the satellite-detected ash column loadings ( $\text{g m}^{-2}$ ) for a given analysis time. Column loading retrievals from Himawari cover a time range from 1800 UTC on 21 June 2019 to 0000 UTC on 24 June 2019. However, due to the low number of grid boxes containing ash before 1800 UTC on 22 June (Fig. 1), for the initial ensemble (*ENS01*) we chose as first verification time, *T1*, the observations at 0600 UTC on 22 June 2019. For this given time, 32 grid boxes containing ash are available (Fig. 1).

The particle filtering operation is designed such that, once all the members of an ensemble have been evaluated based on user defined rejection criteria, only those within the limits of acceptability are retained and used to produce posterior pdfs. A posterior ensemble is created by resampling the perturbed parameters from the posterior pdfs which are then compared forward in time with a new set of observations, *Tn*. Therefore, each posterior ensemble represents a new possible state of our simulated ash cloud at a future time based on the evaluation performance of the prior ensemble at a previous time. The main steps involved in the methodology are summarised (Fig. 2):

1. Prior pdfs are created for the 9 perturbed parameters, including eruption source parameters, driving meteorology, and NAME model internal parameters (Table 1; Fig. 2). We assign an initial range for each parameter that is then sampled independently from a uniform distribution to create an ensemble of 1000 members, *ENS01*. Perturbed parameters and their initial ranges are detailed in Sect. 4.1.

214 2. We define our rejection criteria, based on the threshold values for our verification metrics: Hit Rate (*HR*) and  
 215 Mean Percentage Difference (*MPD*). Sect. 4.2 describes how we calculate *HR*, *MPD* and how we set the  
 216 thresholds (Fig. 2).

217 3. Each model prediction from *ENS01* is compared with the satellite observations at a given time, *T1*. All  
 218 posterior ensembles are verified at a future time using observations every 6 hours (Fig. 2):

219  $ENS01 \rightarrow T1 = 22/06/19 \text{ 0600 UTC}$

220  $ENS02 \rightarrow T2 = 22/06/19 \text{ 1200 UTC}$

221 ...

222  $ENS\ n \rightarrow T_n = T_{n-1} + 6h$

223 4. Simulations that, based on the rejection criteria, are not in agreement with the satellite observations are  
 224 discarded. The retained simulations are used to form the posterior pdfs for each input and internal model  
 225 parameter (Sect. 4.3; Fig. 2).

226 5. Posterior pdfs are generated from the parameter sets of the retained simulations, also considering possible  
 227 interaction among them by including effects of covariation between eruption source parameters. Parameters  
 228 are resampled from these posterior pdfs for the posterior ensemble (Fig. 2). The newly created posterior  
 229 ensemble represents a possible state of our system at a future time (Sect. 4.3).

230 6. Each model prediction from the posterior ensemble is compared forward in time with a new set of satellite  
 231 observations. The ensemble output is also compared with all the previous times, to determine sensitivity for  
 232 the resampled parameters of the posterior pdf to the observations used (Fig. 2).

233 7. The steps 4–6 are repeated until all the available satellite observations are covered.

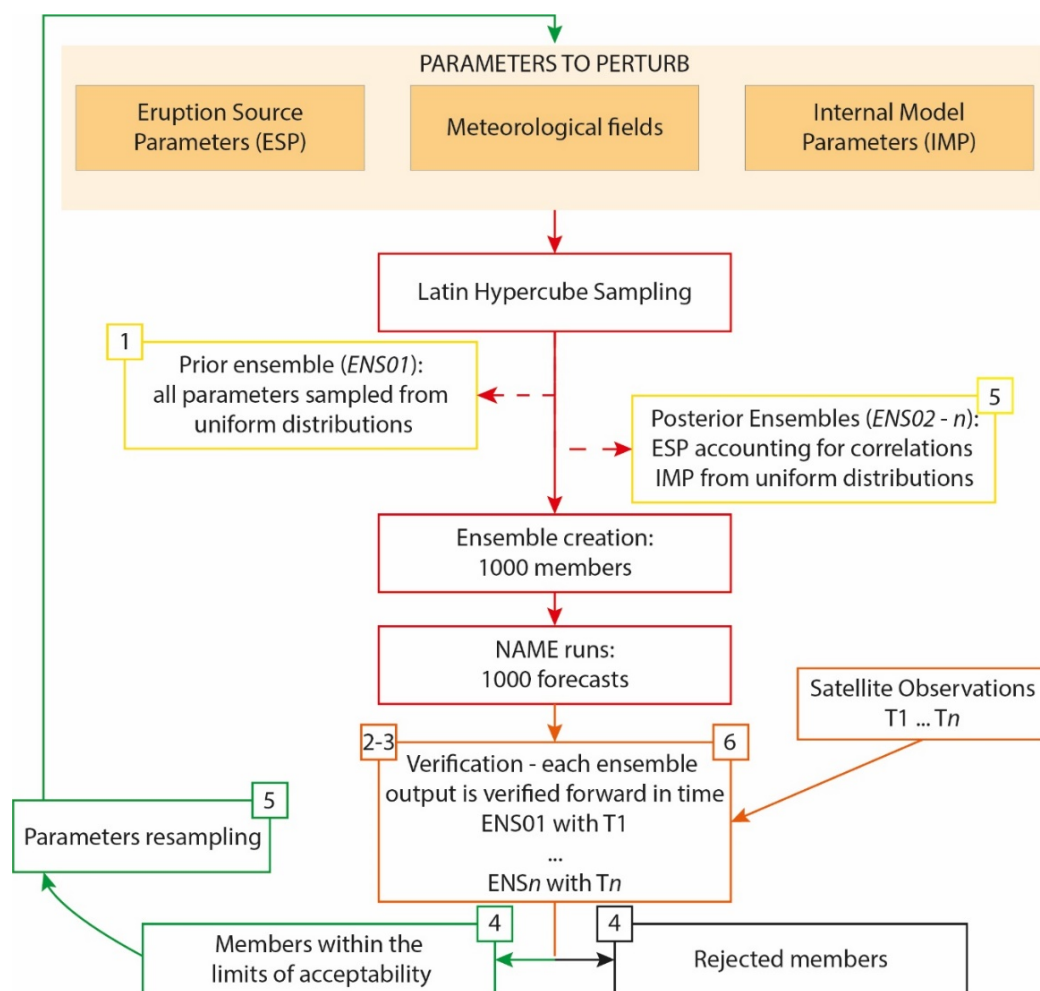

Figure 2: Overall workflow of the developed methodology.

#### 4.1 Ensemble creation

Each ensemble of NAME simulations is created by perturbing nine parameters, including eruption source parameters, driving meteorology, and internal NAME parameters. To generate the ensemble efficiently, we use Latin Hypercube Sampling (LHS), that covers our entire parametric space maintaining orthogonality among the different perturbed parameters (Prata et al., 2019). For *ENS01*, each parameter in the LHS is chosen from prior pdfs which ranges are defined by a set of minima and maxima (Table 1) and sampled from a uniform distribution assuming that all values within these ranges are equally likely. For each posterior ensemble the ESPs in the updated LHS designs are chosen from the posterior pdfs, while NAME internal parameters and members of MOGREPS forecasts continue to be sampled from uniform distributions (Sect.4.3).

#### 245 4.1.1 Eruption Source parameters (ESPs)

246 To represent an initial uncertainty associated with ESPs for *ENS01*, we define a minimum and a maximum possible  
 247 value for each perturbed parameter. Then, a parameter value is sampled from a uniform distribution across this range.

248 We selected a total of 5 ESPs to perturb from those that have been shown to have most effect on the simulated ash  
 249 cloud (e.g., Dacre et al., 2013, Harvey et al., 2018, Prata et al., 2019): plume height (*H*), Distal Fine Ash Fraction  
 250 (*DFAF*), Mass Eruption Rate factor (*MERF*), ash density ( $\rho$ ) and eruption duration (*L*). *H* is used to calculate the Mass  
 251 Eruption Rate (*MER*) for each member using the empirical relationship from Mastin et al. (2009). For each ensemble  
 252 member, *MER* is scaled by the *DFAF*, representing the percentage of ash transported at long distances, and multiplied  
 253 for the *MERF*, to account for uncertainties associated with the Mastin et al. (2009) relationship. Hence, *MER* is not  
 254 perturbed explicitly.

#### 255 *Plume height*

256 Plume height (*H*) constrains the lower and upper limits of the ash particles' release height, therefore significantly  
 257 impacts both the vertical and horizontal structure of the simulated ash cloud. Although the Raikoke eruption was  
 258 characterized by the formation of an umbrella cloud, in the NAME ash release is defined as a vertical line along which  
 259 the ash is uniformly distributed, with the lower and upper bounds representing the volcano summit height (551 m asl)  
 260 and the reported plume height respectively. We based our initial *H* range on information available at that time. The  
 261 Kamchatkan Volcanic Eruption Response Team (KVERT) and the Tokyo and Anchorage VAAC reported a large ash  
 262 plume extending from 10 to 13 km (asl) within the first few hours of eruption (Crafford et al., 2019), while data from  
 263 CALIPSO satellite indicate that the plume may have reached altitudes up to 17 km (asl; Hedelt et al., 2019). For our  
 264 initial ensemble, we selected *H* ranges between 9–17 km (asl) and for the control run we set *H* = 13 km (asl; Table 1).

#### 265 *Mass Eruption Rate (MER)*

266 Mass eruption rate, *MER*, is estimated from the plume height using the empirically derived relationship from Mastin  
 267 et al. (2009):

$$268 \quad MER = 50.7 \times 10^7 H^{2/0.241} \text{ g hr}^{-1} \quad (1)$$

269 where *H* represents the plume height in km. By calculating the *MER* from *H*, any uncertainty associated with *H*  
 270 propagates in the resulting *MER* calculation. Furthermore, there is also an uncertainty associated with the nature of  
 271 the relationship, being an empirical one and based on a relatively small number of eruptions of variable magnitude  
 272 (Mastin et al., 2009). In order to take this into consideration, for all the ensemble members, the *MER* is perturbed for  
 273 a factor between 0.33 and 3, while we use 1 for the control run (Mass Eruption Rate Factor, *MERF*; Harvey et al.,  
 274 2018; Prata et al. 2019; Table 1).

#### 275 *Distal Final Ash Fraction (DFAF)*

The *MER* calculated with the Mastin et al. (2009) relationship (Eq. 1) estimates the total mass released during an eruption. However, the particle size distribution (PSD) of the erupted particles includes both larger particles ( $>1$  mm) that are usually removed from the column in the first phases of an eruption and an additional finer fraction that may leave the column due to aggregation processes. Particles larger than  $100\text{ }\mu\text{m}$  are removed rapidly, without travelling long distances, and as result, only a fraction of fine particles  $<100\text{ }\mu\text{m}$  is transported at long distances. Details of the true PSD are often unknown. Here, the default LVAAC PSD is used in each simulation (Table 1 in Witham et al., 2019), and aggregation processes are not modelled in the NAME simulations for this study. To account for this, the model assumes that most of the ash falls out close to the volcano, with only a small percentage of it reaching the distal plume. The NAME default value for this percentage (distal fine ash fraction, DFAF, Dacre et al., 2011), used here for the control run, is 5 %; however, the real value is uncertain and varies with each eruption (Witham et al., 2019). Consequently, the uncertainty associated with DFAF can be very high (Grant et al., 2012). Recent studies challenged the 5 % assumption by reaching contrasting conclusions: either 5 % is too high for most of the eruptions (Gouhier et al., 2019). Or it is too low, severely underestimating mass loadings (Cashman and Rust, 2020). For our prior ensemble, the range used is 0.5–20 % (Table 1).

#### *Ash density*

The default LVAAC value for particle density is  $2300\text{ kg m}^{-3}$  (Witham et al., 2019) and particle shape is assumed to be spherical in the NAME simulations. At the time of writing, no specific ash density or shape information is available for the 2019 Raikoke eruption. Density was selected as parameter to perturb as it may help in representing uncertainty attributed to ash aggregation and particle shape (e.g., Harvey et al., 2018). The range used is  $1350\text{--}2500\text{ kg m}^{-3}$ , while we use the default  $2300\text{ kg m}^{-3}$  for the control run (Table 1).

#### *Source duration*

The overall duration of the intense phase of the Raikoke eruption is relatively well constrained, with KVERT reporting a strong explosive eruption beginning about 1805 UTC on 21 June and a weaker explosive event reported at 0540 UTC on 22 June. However, ash emission continued, possibly until around 0800 UTC on 22 June, when KVERT reported a gas–steam plume with some ash content (Crafford et al., 2019). As uncertainty in the duration of ash emission may lead to uncertainty in both the location and timing of the modelled ash cloud (e.g., Prata et al., 2019), we considered a duration range of 9–15 hours for *ENS01* and 12 hours for the control run (Table 1). In the simulations, eruption source parameters are assumed constant throughout the release duration, although this is unlikely to be true for the Raikoke eruption.

#### **4.1.2 Driving Meteorology**

In this study, NAME was driven by the operational forecasts from the Met Office Global and Regional Ensemble Prediction System (MOGREPS). The global forecasts have 17 ensemble members plus a control member. The horizontal resolution is approximately 20 km in the mid-latitudes and there are 70 vertical levels with the lid at

approximately 80 km. Each forecast is run out for 7 days and they are initialised 4 times per day at 00, 06, 12 and 18 UTC (Bowler et al., 2008). At the time of the Raikoke eruption, MOGREPS-G used an on-line inflation factor calculation to calibrate the spread of the ensemble in space and time and a stochastic physics scheme to account for model uncertainty (Flowerdew and Bowler, 2011; Flowerdew and Bowler, 2013). The MOGREPS-G forecasts used in this study were initialized at 1200 UTC 21 June 2019.

#### 4.1.3 NAME internal model parameters

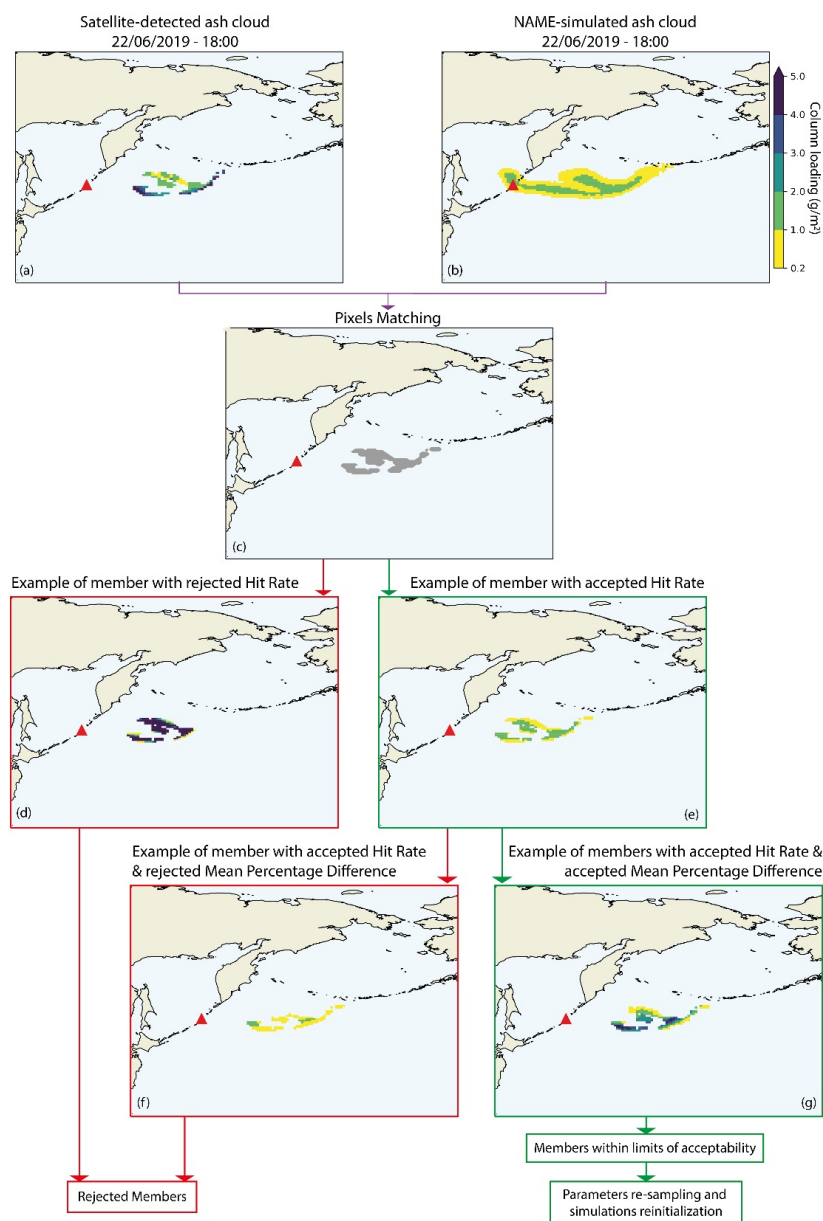

Previous studies have demonstrated how the NAME internal model parameters used for representing the free tropospheric turbulence can significantly impact the model output as they affect the vertical thickness of the simulated cloud and the overall motion of particles (Dacre et al., 2015; Harvey et al., 2018; Prata et al., 2019). To represent uncertainty in free tropospheric turbulence, we perturb the standard deviation ( $\sigma$ ) and Lagrangian timescales ( $\tau$ ) of the horizontal and vertical velocity components in NAME, by sampling them from a uniform distribution using the same ranges specified in Harvey et al. (2018) and Prata et al. (2019), with the horizontal component of  $\sigma$  sampled on a logarithmic scale. The horizontal and vertical components of these parameters are varied in proportion to each other. Similarly,  $\sigma$  of the horizontal velocity for unresolved mesoscale motions is also varied using the same range as in Harvey et al. (2018) and Prata et al. (2019) and sampled from a uniform distribution. For the control run, we use the default NAME values (Table 1). For both the control run and the ensembles, these values are fixed in time.

#### 4.2 Particle filter verification metrics

Each simulation is either discarded or retained based on its level of agreement with the satellite retrievals. We restrict the comparison only to the area covered by both NAME simulated ash cloud and by detectable ash in the satellite observations. The comparison is performed based on two verification metrics: Hit Rate (*HR*) and Mean Percentage Difference (*MPD*).

##### 4.2.1 Step 1: Identifying matching pixels

Most satellite retrievals are unable to detect column loadings less than  $0.2 \text{ g m}^{-2}$  (Prata and Prata, 2012). Consequently, before comparing the Himawari data and NAME output (Fig. 3a and 3b), we apply a minimum threshold of  $0.2 \text{ g m}^{-2}$  to the NAME-simulated ash column loading to align with the minimum detection limit of the satellite observations. The Himawari observations are then regridded over the NAME horizontal grid, to facilitate inter comparisons. Finally, we identify the grid boxes in which both the NAME output and the satellite retrievals detect ash as ‘matching pixels’ (Fig. 3c). For each ensemble member, we then calculate the Hit Rate and Mean Percentage Difference based on all matching pixels.

338

339 **Figure 3:** Ash column loading at 1800 UTC on 22 June 2019, (a) as detected by the satellite, (b) NAME simulation of one  
 340 ensemble member in NAME, and (c) after pixel-matching (grey pixels represent a match between satellite and simulation).  
 341 Examples of ensemble members rejected depending on values of Hit Rate and Mean Percentage Difference (red boxes) are  
 342 shown in panels (d) and (f). Examples of accepted ensemble members depending on values of Hit Rate and Mean Percentage  
 343 Difference (green boxes) are shown in panels (e) and (g). All panels except (c) use the colour scale shown in (b). The red  
 344 triangle in each panel shows the location of Raikoke.

#### 345 4.2.2 Step 2: Calculating Hit Rate

346 The Hit Rate, *HR*, is a widely used categorical metric applied to many meteorological phenomena for forecast  
 347 verification, representing the proportion of observed events that are successfully forecast by a simulation. The *HR* can  
 348 be used to discriminate “yes events” and “no events”, often by specifying a threshold to separate “yes” and “no”  
 349 (Joliffe and Stephenson, 2012). Similarly, *HR* has also been used to provide information on how ash forecast model  
 350 outputs compare to observations in terms of binary *ash yes/ash no* events (e.g., Stefanescu et al, 2014; Marti and  
 351 Folch, 2018). In such cases, a grid box would represent a hit if both simulation and observation detected ash above a  
 352 threshold of  $>0.2 \text{ g m}^{-2}$ .

353 Here, we calculate the Hit Rate as the percentage of matching pixels for which the simulated value lies within one  
 354 standard deviation of the corresponding mean satellite-detected ash column loading. The standard deviation is  
 355 provided by the retrieval algorithm as a measurement of the error for the retrieved ash values in each grid box (Sect.  
 356 2.1). Hence, we both directly compare the ash column loadings between simulation and observations for each  
 357 individual matching pixel, and we complement this by considering the error associated with the satellite observations.

358 Once we have identified the total number of hits in each member, the *HR* can be calculated:

$$359 \quad HR = \frac{HITS}{Matching\ Pixels} \times 100 \quad (2)$$

360 At this point, members that have an *HR* below a specific threshold are discarded (Fig. 3d) and the remaining members  
 361 (Fig. 3e) are then verified further by testing against the observations using Mean Percentage Difference.

#### 362 4.2.3 Step 3: Calculating the Mean Percentage Difference

363 The final step in the evaluation process determines, for the members retained following the *HR* verification, how much  
 364 the NAME-simulated ash column loading values differ from the satellite-detected ones on a grid box basis. The  
 365 percentage difference magnitude (*PD*) for each matching pixel is the difference between the simulated and observed  
 366 column loadings, divided by the mean of the two values and expressed in terms of percentage.

367 Then, the mean of the *PDs* over all grid boxes (*MPD*) for each ensemble member is calculated. Ensemble members  
 368 with *MPD* below a threshold (Fig. 3g) are retained and used to form our posterior. Those above the threshold are  
 369 rejected (Fig. 3f).

#### 370 4.2.4 HR and MPD Thresholds

371 Both *HR* and *MPD* are sensitive to the total number of satellite grid boxes containing detectable ash. Therefore, when  
 372 there are only a few satellite grid boxes available, fixed *HR* and *MPD* thresholds may retain too few ensemble members  
 373 to form posterior pdfs. To avoid this, the acceptability thresholds for *HR* and *MPD* are adjusted dynamically during  
 374 the verification to ensure that a minimum of 50 ensemble members are retained (i.e., 5 % of total number of ensemble

members). This dynamic adjustment is carried out by initially setting the *HR* threshold to 95% and the *MPD* threshold to the minimum *MPD* value. Ensemble members are evaluated against these thresholds, and the thresholds adjusted (by increasing the *MDP* value up to the median value, and by decreasing the *HR* value, in 5 % increments) until at least 50 members lie within the limits of acceptability.

This dynamic thresholding method, therefore, guarantees that the members within limits of acceptability are always retained using the “best” threshold available for both *HR* and *MPD*, for a given time (Table 2). Only for *T1*, when 32 grid boxes containing detectable ash are available, were both thresholds varied substantially and fewer than 50 members were retained. Thereafter, a *HR* of 95% was maintained at each verification cycle. *MPD* values had to be varied more to retain at least 50 members but were always within the range 20–50 % of the minimum *MPD*.

Ensemble	Verification Time	Num. of grid boxes	Posterior members WLoA <sup>1</sup>	Prior members WLoA <sup>2</sup>	H.R. threshold (%)	M.P.D. threshold (%)
01	T1: 22/06/19 06:00	32	22	22	64	152
02	T2: 22/06/19 12:00	107	53	0	95	60
03	T3: 22/06/19 18:00	138	90	7	95	65
04	T4: 23/06/19 00:00	65	176	30	95	68
05	T5: 23/06/19 06:00	71	108	33	95	78
06	T6: 23/06/19 12:00	55	66	20	95	56
07	T7: 23/06/19 18:00	41	60	58	95	71
08	T8: 24/06/19 00:00	70	59	181	95	99
09	T9: 24/06/19 06:00	66	52	35	95	54
10	T10: 24/06/19 12:00	31	62	53	95	57
11	T11: 24/06/19 18:00	18	118	13	95	29

**Table 2: number of members within limits of acceptability (WLoA), and *HR* and *MPD* thresholds for each ensemble at each verification time.**

<sup>1</sup>total number of retained ensemble members for a given time. Parameters for Ensemble 01 (prior ensemble) were sampled from uniform distributions. Parameters for each subsequent ensemble (posterior ensemble) were sampled from posterior pdfs obtained from the retained members of the previous ensemble, verified at the previous verification time. Threshold values for *HR* (higher is better) and *MPD* (lower is better) used at each verification time are shown in the last two columns.

<sup>2</sup>total number of ensemble members that would be retained from the prior ensemble, *ENS01*, if the verification was run at each verification time, using the same *HR* and *MPD* thresholds for which each posterior ensemble has been evaluated.

#### 4.3 Posterior resampling

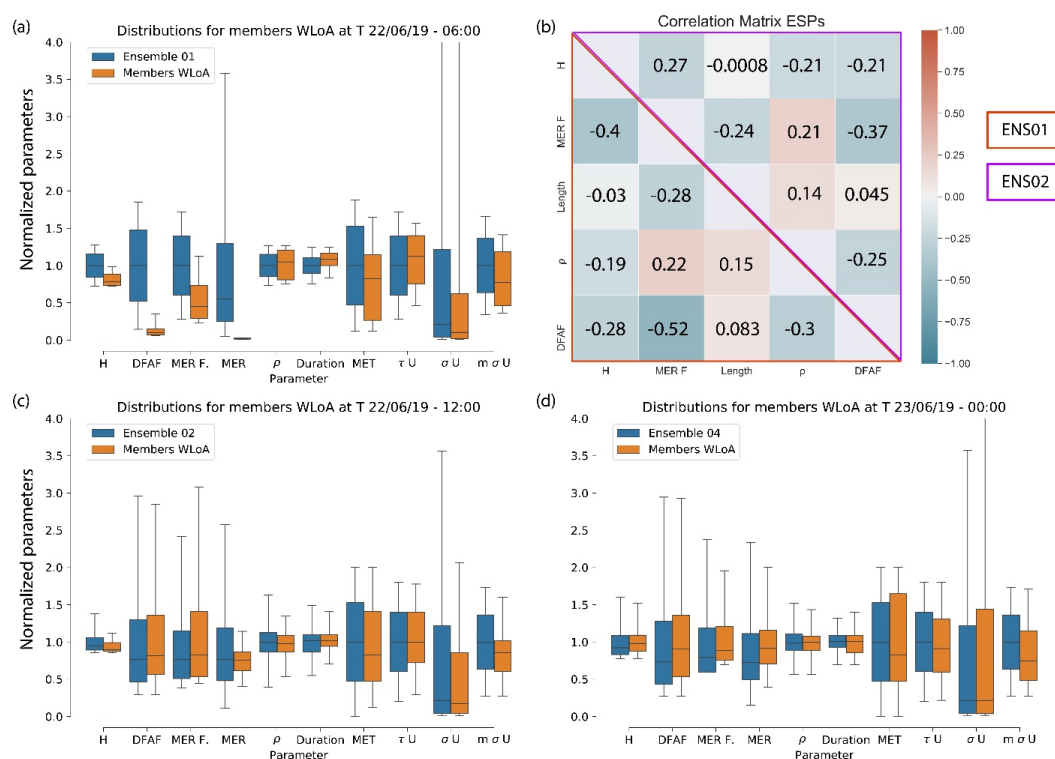

The comparison of the prior and posterior pdfs for each parameter allows us to identify the range of parameters that represent a good approximation of those generating the observed volcanic ash cloud at the verification time. Fig. 4 shows this comparison for *ENS01*, *ENS02* and *ENS04*; each ensemble was verified using observations at *T1*, *T2* and *T4* respectively (Table 2). For *ENS01* (Fig. 4a), most of the posterior ESP pdfs from the retained simulations are highly skewed. In particular, this can be seen for *H*, *DFAF* and *MERF*. *H* is used to calculate the mass eruption rate (shown

in Fig. 4 but not explicitly perturbed), that is then perturbed further by *DFAF* and *MERF*. Therefore, these ESPs significantly influence both the vertical and horizontal structure of the modelled ash cloud and ash concentrations. However, *ENS02* (Fig. 4c) and *ENS04* (Fig. 4d), which use the particle filter described above, show how as more ensembles are run and evaluated forward in time with new observations, the parameter ranges of each posterior ensemble gradually reduce. Additionally, the differences between posterior pdfs and the prior pdfs decrease and the ESPs become increasingly constrained.

Although this evolution is evident for many of the ESPs, the input model parameters ( $\tau U$ ,  $\sigma U$  and  $m\sigma U$ ) do not show a similar behaviour among the different ensembles. This suggests that the Raikoke simulations are not sensitive to these internal parameters.

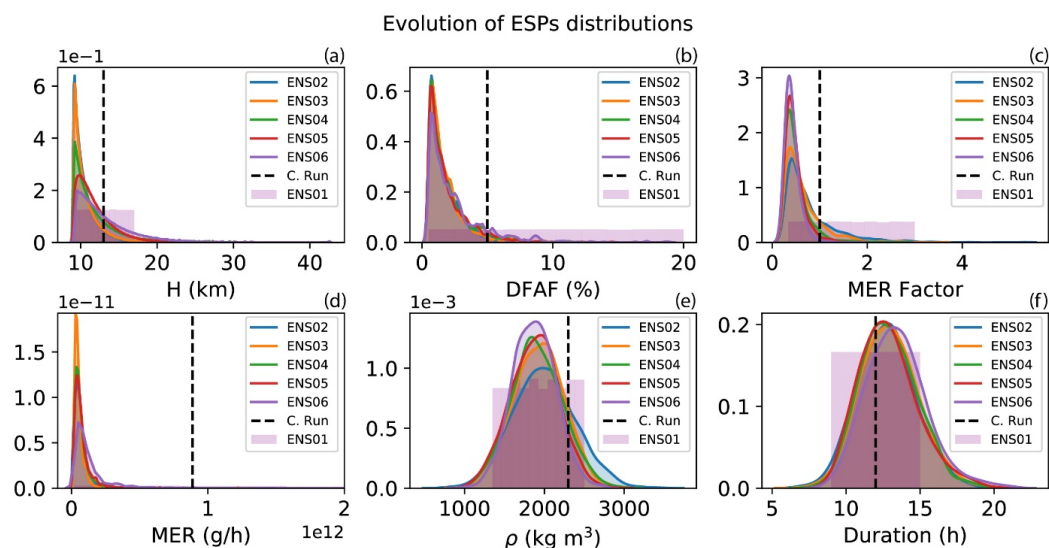

**Figure 4: Evolution of parameters distributions for (a) members Within Limits of Acceptability (WLoA) for Ensemble 01, (b) comparison of correlation matrixes between ENS01 ESPs in the members WLoA (lower matrix, red triangle) and ESPs posterior pdfs for ENS02 (upper matrix, purple triangle), and (c) distributions for members WLoA for Ensemble 02 and (d) Ensemble 04.  $\rho$ ,  $\tau U$ ,  $\sigma U$  and  $m\sigma U$  represent density, horizontal Lagrangian timescale for free tropospheric turbulence, standard deviation of horizontal velocity for free tropospheric turbulence, and Standard deviation of horizontal velocity for unresolved mesoscale motions. In (a), (c) and (d), Mass eruption rate (*MER*) is plotted to show its variation, although it is not explicitly perturbed in any of the ensembles. Each parameter in the box plots is normalized by dividing each individual value from the ensemble members by the mean of that entire parameter range from the selected ensemble.**

418 This constraining behaviour is the result of the refinement of each posterior ensemble, achieved by repeatedly refitting  
 419 the parameters sets of the retained simulations at each verification time, and resampling posterior ensemble parameters  
 420 from the newly fitted posterior pdfs. For the prior ensemble, the LHS is performed independently for each parameter.  
 421 However, eruption source parameters are likely to be correlated, especially the plume height, distal fine ash fraction  
 422 and mass eruption rate factor, which are used to estimate and perturb the mass eruption rate. Thus, before the  
 423 resampling process, the input parameter ranges from the retained members are used to generate both posterior pdfs  
 424 reflecting the distribution of each ESP and a correlation matrix for the ESPs (Fig. 4b). Then, using a Cholesky  
 425 decomposition of the correlation matrix, a correlation structure is enforced to a new LHS design (Fig. 4b). Finally,  
 426 each ESP is sampled from the newly generated posterior pdfs in the updated LHS design, maintaining the dependency  
 427 among the parameters. In contrast, model input parameters and driving meteorology are treated independently and  
 428 their posterior pdfs are sampled again from uniform pdfs, using the same ranges as for the prior ensemble (Table 1).

429 For the majority of the ESPs in *ENS02*, this resampling strategy modifies the ESPs distributions away from the initial  
 430 uniform distribution of the prior ensemble to a distribution that is highly skewed towards the lower end of the initial  
 431 range (Fig. 5). Then, as the posterior pdfs are refined by moving forward in time with new observations, the pdfs for  
 432 several of the ESPs tend toward normal distributions (Fig. 5).

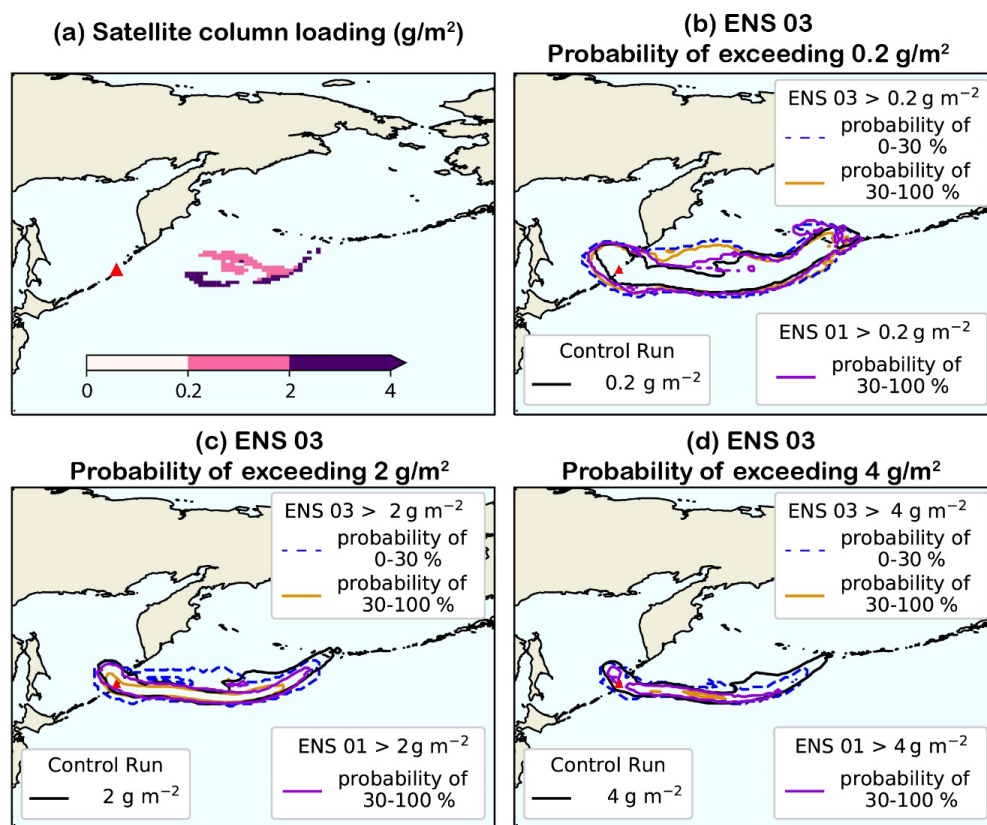

434 Figure 5: Evolution of ESPs distributions for ENS01 (purple shading), ENS02 (blue shading), ENS03 (orange shading),  
 435 ENS04 (green shading), ENS05 (red shading) and ENS06 (dark purple shading). Each panel shows: (a) plume height ( $H$ ),  
 436 (b) distal fine ash fraction ( $DFAF$ ), (c) mass eruption rate factor ( $MERF$ ), (d) mass eruption rate ( $MER$ ), (e) ash density ( $\rho$ ),  
 437 and (f) eruption duration. For ENS01, each parameter is sampled from a uniform distribution. For ENS02–06, each  
 438 parameter is sampled from posterior pdfs following a fit of the members WLoA and considering the interaction among the  
 439 parameters. Mass eruption rate ( $MER$ ) is plotted to show its evolution, although it is not explicitly perturbed in any of the  
 440 ensembles. Dashed black lines in each plot represent the parameter value used for the control run.

## 441 5 Discussion

442 The particle filtering data assimilation technique described in Sect.4 demonstrates how a series of ensembles of  
443 volcanic ash simulations can be successfully constrained based on the level of agreement between the simulation  
444 output and satellite retrievals. Each ensemble is verified forward in time with new retrievals. Compared to the  
445 parameter ranges used for the prior ensemble (Table 1), the range of eruption source parameters used to produce  
446 simulated ash clouds that represent a good approximation to the observed volcanic ash cloud reduces as the posterior  
447 ensembles become more constrained by the satellite retrievals.

448 The effects of the refinement on the posterior ensemble can be observed in probability of exceedance maps, given  
449 here for three different thresholds of ash column loadings,  $0.2 \text{ g m}^{-2}$  (Fig. 6b),  $2 \text{ g m}^{-2}$  (Fig. 6c) and  $4 \text{ g m}^{-2}$  (Fig. 6d).  
450 The satellite retrieval at 1800 UTC 22/06/2019 detects two distinct regions where ash loadings exceed  $0.2 \text{ g m}^{-2}$  and  $2$   
451  $\text{g m}^{-2}$  (Fig. 6a). The posterior ensemble (*ENS03* – brown contour) agrees with the control run (black contour) and the  
452 prior ensemble (*ENS01* – purple contour) on regions where loadings  $> 0.2 \text{ g m}^{-2}$  are likely (30–60 %) and very likely  
453 (60–100 %; not plotted in Fig. 6). The simulated ash cloud regions are more extensive than the area of satellite–  
454 detected ash. However, this overestimation is greater for both the prior ensemble (purple contour) and the control run  
455 (black contour) than for the posterior ensemble (brown contour) (Fig. 6b) and is largest for column loadings  $> 2 \text{ g m}^{-2}$   
456 (Fig. 6c) and  $4 \text{ g m}^{-2}$  (Fig. 6d). The refined ensemble shows a much–reduced region with a 30–100 % probability of  
457 exceeding these loadings, showing better agreement with the observations especially when considering loadings  $> 2$   
458  $\text{g m}^{-2}$  detected by the satellite (Fig. 6a). Thus, by accounting for uncertainties, a wider region where those loadings are  
459 less likely (up to 30%, dashed blue contour) has been shown instead, for all the considered thresholds (Fig. 6).

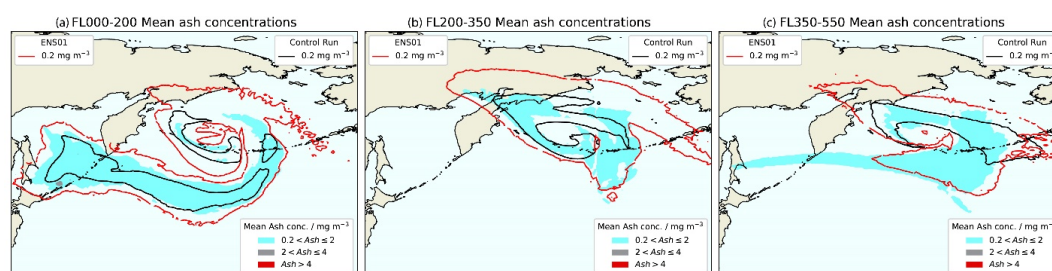

460

461 Figure 6: (a) Satellite-detected column loading at  $T3$  (22/06/2019 1800 UTC) shown in filled contours, and probability of  
 462 exceedance maps for  $ENS03$  at  $T3$  for column loading thresholds of (b)  $0.2 \text{ g m}^{-2}$ , (c)  $2 \text{ g m}^{-2}$  (d)  $4 \text{ g m}^{-2}$  shown with dashed  
 463 blue contours (the region within the blue line is a probability region up to 30 %) and brown contour (30 % probability  
 464 region – the region within the brown line goes from 30 % up to 100 %). The black contour in panels (b), (c) and (d) show  
 465 the relevant column loading threshold for the control run. The purple contours show the 30 % probability region for  $ENS01$   
 466 of exceeding the relevant column loading threshold (the region within the purple dashed line goes from 30 % up to 100 %).  
 467 For generating the purple contours, members from the prior ensemble were retained by verifying  $ENS01$  with observations  
 468 at  $T3$  (a) and using the same  $HR$  and  $MPD$  thresholds for which  $ENS03$  has been evaluated (Table 2) to ensure a fair  
 469 comparison between the prior and posterior ensembles.

470 By considering mean ash concentrations ( $\text{mg m}^{-3}$ ) at  $T10$  for  $ENS08$ , thus at 0000 UTC on 24 June 2019, for the three  
 471 “thick” Flight Layers, FL000–200 (Fig. 7a), FL200–350 (Fig. 7b) and FL350–550 (Fig. 7c), the control run seems to  
 472 underestimate the areas with concentrations exceeding  $0.2 \text{ mg m}^{-3}$  compared to the subset of retained members of both  
 473  $ENS01$  and  $ENS08$ . Contrary,  $ENS01$  forecasts concentrations exceeding  $0.2 \text{ mg m}^{-3}$  over larger regions compared to  
 474 the posterior ensemble. The overestimation increases considerably for FL200–350 but also for FL350–550, even with  
 475 the posterior ensemble forecasting an additional plume tail extending to the east of Raikoke (Fig. 7c). Indeed, the areas  
 476 forecasted by  $ENS08$  with concentrations  $> 0.2 \text{ mg m}^{-3}$  for both FL200–350 (Fig. 7b) and FL350–550 (Fig. 7c) are,

respectively, around 60 % and 30 % less extended than the ones forecasted by *ENS01*. In general, for all three flight levels, the area that a posterior ensemble would forecast with high ash concentrations is drastically reduced compared to the prior ensemble.

**Figure 7: Mean ash concentration values ( $\text{mg m}^{-3}$ ) for *ENS08* members for (a) FL000–200, (b) FL200–350 and (c) FL350–550 at 0000 UTC 24/06/2019. Each panel shows also the associated  $0.2 \text{ mg m}^{-3}$  ash concentration contour for both the control run (black contour) and *ENS01* (red contour).**

## 5.1 Application to aviation operations

The use of either probability exceedance maps (Fig. 6) or concentration maps (Fig. 7) condense the information given by the ensemble of VATDM simulations. However, multiple charts are still needed to cover all the relevant information, such as different flight levels, times and ash concentration thresholds. To reduce information overload from these numerous charts, which could impede fast decision-making during emergency response, they can be condensed further into a single chart using a risk matrix (Prata et al., 2019). Here we apply this risk-based approach to international flight routes in the vicinity of Raikoke using both the prior and posterior ensembles outlined in Sect.4.

### 5.1.1 Flight routes and dosage risk

To simulate potential aircraft encounters with volcanic ash, flight routes with minimised travel time were generated by solving a time-optimal control problem as described in Wells et al. (2021). Trans-Pacific flights were generated assuming a constant true airspeed of  $240 \text{ m s}^{-1}$  ( $\sim 864 \text{ km hr}^{-1}$ ) at a cruise altitude of FL380 (or 200 hPa) and using horizontal wind speeds extracted from the National Center for Atmospheric Research re-analysis data (Kalnay et al., 1996). Eastbound and westbound time-optimal routes from Sapporo (CTS) to Honolulu (HNL), Los Angeles (LAX) to Seoul (ICN) and San Francisco (SFO) to Shanghai (PVG) international airports were calculated for each day of the dispersion model output (i.e., at 24 hr intervals).

As in Prata et al. (2019), the along-flight ash dose,  $D$ , was defined as the ash concentration multiplied by the duration in that concentration (duration of exposure), integrated along an aircraft's flight path at cruise altitude (assumed to be FL350–550). This definition means that dose always increases monotonically along the route. All dose calculations assume that the modelled ash concentration fields at a given time step are fixed (i.e., do not change with time) as the aircraft flies from the origin to destination at its true airspeed (Prata et al., 2019).

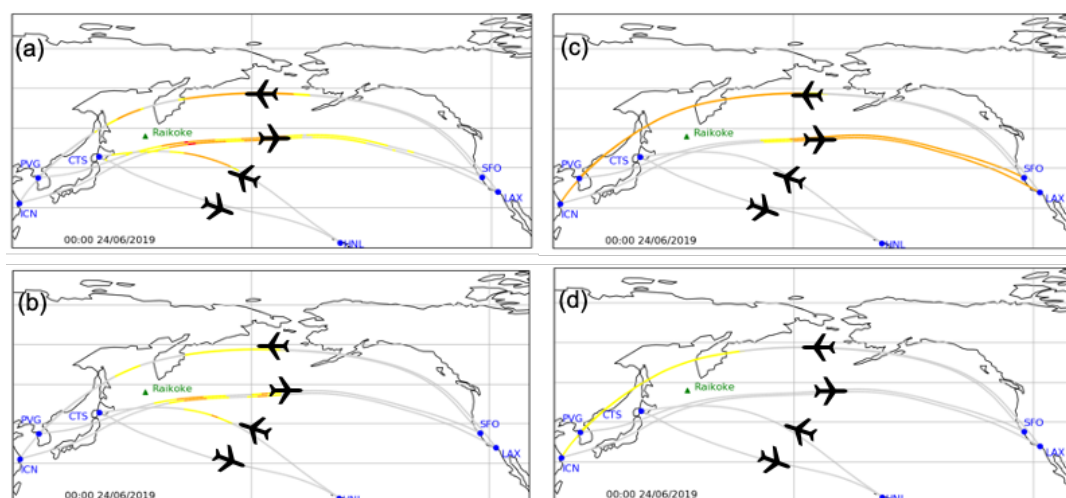

### 5.1.2 Risk based approach

505 The first step in determining the risk is to calculate the fraction of ensemble members that have concentrations above  
 506 specified impact thresholds for each of the three flight levels. In line with the current International Civil Aviation  
 507 Organisation (ICAO) guidance, the impact concentration thresholds used are  $0.2\text{--}2\text{ mg m}^{-3}$ ,  $2\text{--}4\text{ mg m}^{-3}$  and greater  
 508 than  $4\text{ mg m}^{-3}$ , for low, medium and high impact respectively. The risk of encountering ash is then determined by  
 509 combining the likelihood ranges (less likely, 0–10 %; likely, 10–90 %; very likely, 90–100 %) and the impact. The  
 510 risk of flying in a specific location and at a flight level is then assigned to be low, medium or high. The overall risk  
 511 presented is the maximum risk over the three flight levels. In Prata et al. (2019), each risk level has a set of actions  
 512 that may be implemented by the decision maker. These range from checking updated ash forecasts to considering  
 513 alternative routes and scheduling extra maintenance.

514 The risk can be visualised as a 2D map or projected on to flight tracks of interest (Fig. 8). Considering risk based on  
 515 ash concentrations at 0000 UTC on 24 June 2019, there are large portions of the flight tracks that encounter low and  
 516 mid-level risk, with a small region of high risk to the east of Raikoke when using the prior ensemble (Fig. 8a). Thus,  
 517 based on the prior ensemble output, flight operations could be expected to be severely disrupted at this time. However,  
 518 determining risk from the posterior ensemble (*ENS08*) removes the region of highest risk and, overall, the amount of  
 519 flight track potentially impacted and therefore requiring action from the flight operator is greatly reduced (Fig. 8b).

520 To account for the overall exposure of the aircraft to ash, the risk approach can also be applied to dose along a flight  
 521 track (Fig. 8). To do this the ash dose impact thresholds used are  $4.4\text{--}14.4\text{ g s m}^{-3}$ ,  $14.4\text{--}28.8\text{ g s m}^{-3}$  and greater than  
 522  $28.8\text{ g s m}^{-3}$  (Clarkson and Simpson, 2017; Prata et al., 2019). The likelihood ranges used are the same as those used  
 523 for the concentration approach. In this scenario the risk is only determined at cruising altitude, which is assumed to  
 524 be at FL350–550 (not the maximum over all flight levels). For the prior ensemble, the flight tracks to and from the  
 525 West Coast of North America encounter mid-level risk and could potentially require specific actions by the airlines  
 526 (e.g., more fuel and engine checks). Using this metric, flights between Honolulu and Sapporo do not reach doses that  
 527 reach the lowest level of risk (Fig. 8c). For the posterior ensemble (*ENS08*), only the route from SFO to PVG and ICN  
 528 reach sufficiently high doses to be highlighted by the risk approach. The other routes have very few ensemble members  
 529 where doses are above  $4.4\text{ g s m}^{-3}$  and therefore are not highlighted by the risk approach (Fig. 8d). This could greatly  
 530 reduce the need for an operator to implement any mitigation strategies.

**Figure 8: Concentration risk along time optimal flight routes at 0000 UTC on 24 June 2019 for (a) prior ensemble (b) *ENS08*. Ash dose risk along the same time optimal flight routes at 0000 UTC on 24 June 2019 for (c) prior ensemble (d) *ENS08*. Yellow shading indicates the lowest level of risk, orange shading indicates mid-level risk and red indicates the highest level of risk. Note that dose risk only considers risk at FL350–550, whereas concentration risk considers at all levels.**

## 6 Conclusions

This study presents a new particle filtering data assimilation methodology that combines VATDM simulations with satellite retrievals including their uncertainty estimates, to improve forecasts of volcanic ash cloud location and concentration. A prior ensemble is created by simultaneously varying nine parameters representing the meteorology, eruption source and internal parameters. Members from the prior ensemble are retained or discarded based on their level of agreement with the satellite retrievals. The retained simulations are then used to create a posterior ensemble. Each posterior ensemble is verified and filtered using satellite data at subsequent verification times.

The ESPs ranges in the constrained posterior ensembles are both smaller and skewed towards lower values than those used in the control run and prior ensemble. Therefore, a single ensemble designed with unconstrained parameters ranges (i.e., the prior ensemble) seems insufficient for estimating ESPs ranges that may approximate more accurately the observed volcanic ash cloud. This is not the case for internal model parameters which remain unconstrained by the data assimilation.

Communicating the risk of volcanic ash to aviation using risk maps and risk trajectories shows that the prior ensemble forecasts mid-level and highest risk for both ash concentration and dose thresholds for much of a set of representative flight tracks. Based on this information flight operations could be severely disrupted by the eruption. However, using the constrained posterior ensemble, the region of highest risk is removed, and the mid-level risk is reduced. Thus, using the refined posterior ensembles potentially reduces the need for the operator to implement any mitigation strategies and hence reduces disruption to airline operations.

554 This methodology is easily generalisable to other VATDMs and could be used to run a comparison with other models.  
555 Different remote sensing datasets could be used to assess its sensitivity to the observations used. Running multiple  
556 1000–members ensembles requires either a high computational power or can be subject to variable queuing times on  
557 computer clusters such as JASMIN. Future work could include code optimization, to make runtime and ensemble size  
558 more efficient, potentially allowing an operational application. Furthermore, the evaluation method is based on limits  
559 of acceptability; a future improvement could be to define a formal likelihood measure, and weight the behaviour of  
560 each simulation output with the observations for creating the posterior.

#### 561 **Data availability**

562 NAME simulation output for the prior ensemble (*ENS01*) and posterior ensembles 03 (*ENS03*) and 08 (*ENS08*) are  
563 available in the Lancaster University Research Directory at <https://doi.org/10.17635/lancaster/researchdata/491>. Raw  
564 data for all the posterior ensembles can be provided by the authors upon request.

#### 565 **Authors contributions**
