18

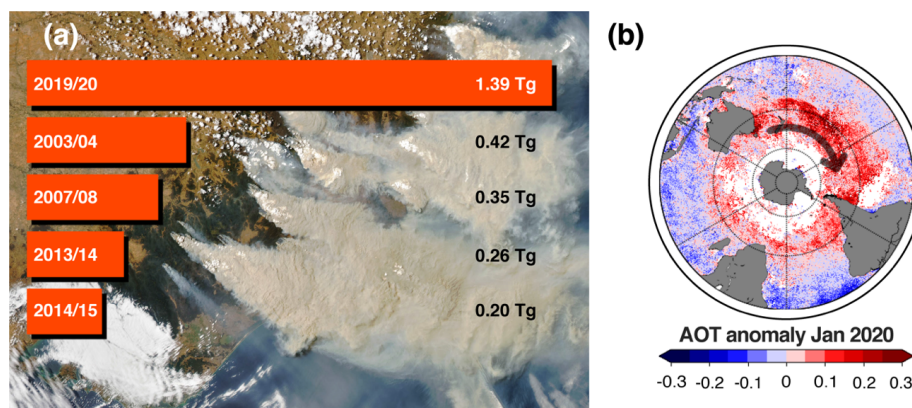

19 **Abstract.** More than 1 Tg smoke aerosol was emitted into the atmosphere by the exceptional 2019-2020 Southeast Australian
20 wildfires. Triggered by the extreme fire heat, several deep pyroconvective events carried the smoke directly into the
21 stratosphere. Once there, smoke aerosol remained airborne considerably longer than in lower atmospheric layers. The thick
22 plumes traveled eastward thereby being distributed across the high and mid-latitude Southern Hemisphere enhancing the
23 atmospheric opacity. Due to the increased atmospheric lifetime of the smoke plume its radiative effect increased compared to
24 smoke that remains lower altitudes. Global models describing aerosol-climate impacts show significant uncertainties regarding
25 the emission height of aerosols from intense wildfires. Here, we demonstrate by combination of aerosol-climate modeling and
26 lidar observations the importance of the representation of those high-altitude fire smoke layers for estimating the atmospheric
27 energy budget. In this observation-based approach, the Australian wildfire emissions by pyroconvection are explicitly
28 prescribed to the lower stratosphere in different scenarios. The 2019-2020 Australian fires caused a significant top-of-
29 atmosphere hemispheric instantaneous direct radiative forcing signal that reached a magnitude comparable to the radiative
30 forcing induced by anthropogenic absorbing aerosol. Up to +0.50 W m⁻² instantaneous direct radiative forcing was modeled
31 at top of the atmosphere, averaged for the Southern Hemisphere for January to March 2020 under all-sky conditions. While at
32 the surface, an instantaneous solar radiative forcing of up to -0.81 W m⁻² was found for clear-sky conditions, depending on the
33 model configuration. Since extreme wildfires are expected to occur more frequently in the rapidly changing climate, our
34 findings suggest that deep wildfire plumes must be adequately considered in climate projections in order to obtain reasonable
35 estimates of atmospheric energy budget changes.

36

1 Introduction

2 During the record Australian 2019-2020 wildfire season, the aerosol load increased substantially over large parts of mid and
3 high latitudes of the Southern Hemisphere due to the massive amounts of smoke aerosol injected into the stratosphere. The
4 austral summer of 2019-2020 is remembered as Australia's Black Summer due to the unprecedented intensity and scale of
5 wildfires. The devastating impact on local nature and life was particularly evident in the significant destruction of habitat for
6 hundreds of endemic species (Ward et al., 2020; Wintle et al., 2020). In addition, there is another aspect through the interactions
7 of the fire plume with large-scale weather (Kablick et al., 2020; Khaykin et al., 2020) that make the Black Summer fires a
8 distinct example to study the climate impacts of stratospheric smoke injection. Between September 2019 and January 2020,
9 almost twice the area burnt compared to any previous record fire in Australia, emitting unprecedented amounts of smoke
10 aerosol (Boer et al., 2020; Morgan et al., 2020) (Fig. 1a). Peaking between 29 December 2019 and 4 January 2020, the fires
11 caused a significant input of aerosol into the stratosphere. Several intense pyroconvective towers carried this aerosol directly
12 up to 14–16 km height in the lower stratosphere (Kablick et al., 2020; Ohneiser et al., 2020; Boone et al., 2020). The mass of
13 smoke emitted into the stratosphere by these fires has been estimated to range from 0.6 Tg (Khaykin et al., 2020) to 2.1 Tg
14 (Hirsch and Koren, 2021). Within days, the smoke was distributed zonally across the southern mid and high latitudes, where
15 satellite measurements by NASA's Moderate Resolution Imaging Spectroradiometer (MODIS) (Hirsch and Koren, 2021),
16 Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) data (Kablick et al., 2020) and ground-based
17 lidar measurements at the southern tip of South America clearly showed the elevated smoke layer (Ohneiser et al., 2020).
18 Satellite observations and global aerosol-climate model results show that this had significant effects on the radiation budget
19 (Hirsch and Koren, 2021; Yu et al, 2021). For the stratospheric smoke from the Australian wildfires, Hirsch and Koren (2021)
20 have derived an enhancement of outgoing solar radiation of 1.1 W m^{-2} in the latitude belt between 20°S and 60°S from NASA's
21 Clouds and the Earth's Radiant Energy System (CERES) satellite data. From model results and considering also the fast
22 adjustment from stratospheric warming, Yu et al. (2021) obtained an estimate for global annual average effective radiative
23 forcing of -0.03 W m^{-2} at top of atmosphere (TOA) and -0.32 W m^{-2} at the surface due to the smoke event.
24

27 **Figure 1.** (a) Biomass burning plumes in the Canberra region in Southeast Australia as seen from NASA's Aqua satellite on
28 4 January 2020 (<https://aqua.nasa.gov>). Overlaid is a ranking of carbon aerosol emissions accumulated for the annual Southeast
29 Australian bushfire seasons (September to March) based on Global Fire Assimilation System (GFAS) data (Kaiser et al., 2012).
30 (b) Anomaly in monthly mean AOT (630 nm) for January 2020 compared to the long-term January mean (1982 to 2019), as
31 observed by NOAA's AVHRR instrument (Zhao et al., 2017) (missing data depicted white).
32

1 Australia's Black Summer is among a recent series of extreme wildfires, including fires in the Western United States and
2 Canada (2017, 2018), Siberia (2019, 2020) and the Eastern Mediterranean (2021) that has renewed scientific attention
3 particularly to wildfires with strong fire-induced convection and self-lifting. Triggered by the intense fire heat, the
4 pyroconvection can grow to pyrocumulonimbus (pyroCb) clouds which are the primary pathway of smoke injection into the
5 upper troposphere and lower stratosphere (Fromm et al., 2010; Fromm et al., 2019), with radiation-induced self-lifting causing
6 plumes to continue to rise (Boers et al., 2010). Also due to such events, biomass burning smoke contributes considerably to
7 the global aerosol composition, affecting the Earth's energy balance through aerosol-radiation and tropospheric aerosol-cloud
8 interactions (Bowman et al., 2009; Streets et al. 2009; Boucher et al., 2013). Such extreme wildfires and associated deep
9 pyroconvection, for which injection of biomass burning smoke into the stratosphere has been observed, can have similar effects
10 as aerosol from volcanic eruptions (Peterson et al., 2018). An important component is black carbon aerosol, which is considered
11 to be the strongest warming short-lived radiative forcing agent. In addition, less-absorbing organic carbon and precursors for
12 sulfate aerosol are emitted. Depending on its radiative properties and the underlying surface reflectivity, the climate impact of
13 biomass burning aerosol can vary regionally (Jiang et al., 2016; Bellouin et al., 2020; Brown et al., 2021) as well as with
14 transport altitude (Ban-Weiss et al., 2012). During strong pyroCb events, radiative effects can be enhanced due to long
15 stratospheric lifetime of aerosol. While the high-altitude injection of wildfire plumes is yet insufficiently represented in
16 aerosol-climate models (Paugam et al., 2016), the recent accumulation of extreme wildfires and their potentially increased
17 occurrence with climate change (Jolly et al., 2015; Abazoglou et al., 2019; Dowdy et al., 2019; Kirchmeier-Young et al., 2019)
18 call for greater attention in global climate modeling.

19 In order to clarify the role of smoke injection of wildfire pyroconvection in the aerosol-climate modeling context, here we use
20 the aerosol-climate model ECHAM6.3-HAM2.3 (Zhang et al., 2012; Tegen et al., 2019). Specifically, we aim to show the
21 importance of considering these most extreme fire events in determining the global energy budget, while they are not
22 adequately reflected in today's climate simulations. The fire emission fluxes in the model are prescribed from the Global Fire
23 Assimilation System (GFAS; Kaiser et al., 2012), and the injection height of Australian fire smoke is set to the tropopause
24 level for the known pyroCb events and varied accordingly in sensitivity experiments. The modeled transport patterns are
25 evaluated with active and passive ground-based and spaceborne remote sensing, providing the basis for analyzing the radiative
26 impact of the carbonaceous smoke aerosol. Finally, we discuss implications and perspectives for climate models to capture
27 extreme wildfires and their effects in a changing climate.

28 **2 Observations and modeling**

29 The analysis of the 2019-2020 Australian fire season in this study is based on global aerosol-climate simulations. An important
30 part of the modeling is concerned with finding a configuration that best represents the pyroconvective fires. Since the typical
31 horizontal resolution of global climate models is too coarse to explicitly resolve convection, observed pyroCb events are
32 explicitly prescribed and the injection height of the wildfire plume is varied in terms of sensitivity experiments. Their results
33 are compared to the original settings for biomass burning emissions as well as evaluated with ground-based and spaceborne
34 remote sensing observations to show how realistically these can be represented if the injection heights for pyroCbs are
35 considered accordingly. The model results are then used to investigate the impact of pyroconvective smoke injection on plume
36 transport and radiative effects for January to March 2020.

37 **2.1 AERONET sun photometer measurements**

38 Information on column aerosol properties including aerosol optical thickness (AOT) at specific wavelengths and corresponding
39 information on effective aerosol size are available from quality-controlled measurements by the global sunphotometer network
40 AEROSOL ROBOTIC NETWORK (AERONET (Holben et al., 1998; Giles et al., 2019); <http://aeronet.gsfc.nasa.gov>). These data are

1 widely used for aerosol studies including evaluation of aerosol model results. In this study we use level 1.5 or, where available,
2 level 2 cloud-screened, 6-hour averages of AOT measurements. AERONET AOT values at 550 nm are extrapolated from the
3 measured values at 500 nm making use of the Angstrom exponent for each observation, which in turn is computed from the
4 ratio of observed AOT values at 500 nm and 675 nm, respectively. AOT measurements are compared to model results by
5 linearly interpolating model values to the times and locations of the measurements of the respective AERONET stations: Punta
6 Arenas, Chile (53.14°S, 70.89°W), Amsterdam Island (37.80°S, 77.57°E), Marambio (64.24°S, 56.63°W), Vechernaya Hill
7 (67.66°S, 46.16°E) and South Pole (90.00°S, 70.30°E).

8 **2.2 Ground-based lidar remote sensing**

9 The lidar observations at Punta Arenas (53.14°S, 70.89°W; 9 m above sea level), Chile, were conducted in the framework of
10 the long-term DACAPO-PESO campaign (Dynamics, Aerosol, Cloud And Precipitation Observations in the Pristine
11 Environment of the Southern Ocean; <https://dacapo.tropos.de>). Main goal of DACAPO-PESO is the investigation of aerosol–
12 cloud interaction processes in rather pristine, unpolluted marine conditions. The POLLY instrument (POrtabLle Lidar sYstem;
13 Engelmann et al., 2016) was operated at the University of Magallanes (UMAG) at Punta Arenas from November 2018 until
14 October 2021. The lidar has 13 channels and continuously measures elastic and Raman backscatter signals at the laser
15 wavelengths of 355, 532, and 1064 nm and respective Raman backscattering wavelengths of 387 and 607 nm for nitrogen
16 Raman scattering and 407 nm for water vapor Raman scattering (Baars et al., 2016; Baars et al., 2019). At the laser wavelengths
17 of 355 nm and 532 nm, particle extinction coefficients, the respective extinction-to-backscatter ratio (i.e. lidar ratio), and the
18 linear depolarization ratio are determined. Moreover, height profiles of the particle backscatter coefficient can be derived at
19 these wavelengths and, additionally, at 1064 nm. The mixing ratio of water vapor to dry air is obtained from measurements in
20 the UV. Auxiliary meteorological data, in particular temperature and pressure profiles, are required in the lidar data analysis
21 in order to calculate and correct for atmospheric molecular backscatter and extinction. To this end, GDAS1 (Global Data
22 Assimilation System 1) temperature and pressure profiles with 1° horizontal resolution from the National Weather Service’s
23 National Center for Environmental Prediction (GDAS et al., 2020) were used.

24 **2.3 Spaceborne remote sensing**

25 Observations with the Advanced Very High Resolution Radiometer (AVHRR) onboard the National Oceanic and Atmospheric
26 Administration (NOAA) operational satellites are available for almost four decades. For the present study, we use version 3
27 of the AOT product (Zhao et al., 2017). It provides daily mean AOT at 0.63 μm for cloud-free pixels over none-glint water
28 surfaces with a horizontal resolution of 0.1°.

29 Lidar observations from the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP, Winker et al., 2013) instrument are
30 used to retrieve the extinction coefficient at 532 nm and 1064 nm. We use the level 2 version 4 aerosol profile product which
31 is averaged over 5 km segments along the near nadir-view ground track (05kmAPro product). The cloud-aerosol discrimination
32 (CAD) score is used to include only those columns in which at least one aerosol retrieval was successfully performed, using a
33 threshold of < -20 CAD scores. This level of quality screening is the same as that described in Winker et al. (2013). However,
34 despite the use of the highest quality data, CALIOP is known to frequently fail to detect thin aerosol layers in the upper
35 troposphere. As a result of its low sensitivity the mean fraction of aerosol detected by CALIOP is 44% lower than the aerosol-
36 climate model ECHAM-HAM (Watson-Parris et al., 2018). Despite this bias, the substantial increase in aerosols resulting
37 from the Australian wildfires is evidently detected by CALIOP. While sampling and detection biases occur on individual
38 profiles the trends in the extinction profiles offer some useful constraints for the ECHAM-HAM model.

1 2.4 Aerosol-climate simulations

2 2.4.1 Model description and setup

3 The simulations for this study were made with the global state-of-the-art aerosol-climate model ECHAM6.3-HAM2.3 (Tegen
4 et al., 2019). This model uses the aerosol microphysics model M7 (Vignati et al., 2004) to predict the evolution of black carbon
5 (BC), organic carbon (OC), sulphate, sea salt and mineral dust. The mass and number concentrations of the aerosols are
6 influenced by emission, loss processes, particle microphysics and atmospheric chemistry. The particles can interact with
7 radiation and clouds. Anthropogenic and biomass burning emissions of aerosols are prescribed. Daily data from the Global
8 Fire Assimilation System (GFAS; Kaiser et al., 2012) based on fire radiative power observations by the MODIS instruments
9 aboard NASA's Terra and Aqua satellites are used for the biomass burning related aerosol emissions of BC, OC, sulphate and
10 dimethyl sulphide. In its original version, 75% of the biomass burning aerosol mass is injected in the planetary boundary layer
11 (PBL), 17% in the first layer above the PBL and 8% in the second layer above the PBL (see Sect. 2.4.2 for the setup of
12 sensitivity experiments on fire injection height).

13 The ECHAM6.3-HAM2.3 simulations were performed for the time period November 2019 to March 2020, using T63
14 horizontal resolution (approximately $1.875^\circ \times 1.875^\circ$) and 47 levels in the vertical from the ground to 0.01 hPa (~80 km). The
15 dynamics in all simulations was nudged towards ECMWF ERA5 reanalysis data (Hersbach et al., 2020). Sea surface
16 temperatures and sea-ice concentrations were prescribed as lower boundary conditions using AMIP data (Giorgetta et al.,
17 2012). Concentrations of long-lived greenhouse gases were specified following the Representative Concentration Pathway
18 (RCP) 4.5 scenario. Output was written every 6 hours. The simulated aerosol properties include AOT and vertical profiles of
19 extinction at 550 nm wavelength.

20

21 2.4.2 Sensitivity experiments on wildfire smoke injection

22 Wildfire injection heights are usually parameterized in coarser-scale models by schemes of various complexity (Paugam et al.,
23 2016), but these do not necessarily represent the deep pyroconvection that is observed during very intense wildfires (Remy et
24 al., 2017; Haairig et al., 2018; Ohneiser et al., 2020). In order to reconstruct the elevated smoke injection due to pyroconvection
25 and to explore the impacts on plume transport and climate radiative effects of the 2019-2020 Australian fire plume, we adapted
26 the high-altitude smoke injection height by pyroconvection for the days 29 – 31 December 2019 and 4 January 2020 (pyroCb
27 days) in the model, on which strong pyroconvective activities were reported in the Southeastern Australian region affected by
28 the fire (Kablick et al., 2020). Since no direct information was available on the actual pyroconvective injection heights, these
29 were varied in the model in sensitivity experiments and verified with the range of above-mentioned remote sensing
30 observations, in particular with the lidar measurements over Punta Arenas in Chile.

31 For the four pyroCb days (29 – 31 December 2019 and 4 January 2020), the smoke injection from Southeastern Australia was
32 set to the model layers above and below the tropopause as in the scenarios listed in the following: 'TP+1': 100% smoke
33 injection into the model layer above the tropopause; 'TP': 100% smoke injection into the model layer containing the
34 tropopause, 'TP-1', 100% smoke injection into the model layer below the tropopause; 'TPI_8020': as TP+1 but only 80% of
35 the emitted smoke injected above and 20% distributed below the tropopause; 'TPI_5050': as TP+1, but only 50% of the
36 emitted smoke injected above and 50% distributed below the tropopause; and '14km': smoke injection into 14 km height as
37 suggested from spaceborne lidar measurements by the CALIOP instrument (Hirsch and Koren, 2021).

38 In addition, a reference simulation with the original biomass burning injection was carried out, which hereafter is referred to
39 as *BASE* case. To estimate the input of fire aerosol to the stratosphere from the pyroconvective fires, a model run was also
40 performed in which the Southeastern Australian wildfire emissions were set to zero for the pyroCb days (referred to as case
41 *NoEmiss*). Further experiments include model runs with and without interactive aerosol-radiation interaction in order to

1 quantify the radiative forcing of the fire plume aerosol and to test the hypothesis that self-lifting due to radiative heating has
2 significantly influenced the smoke plume evolution. The different model experiments are summarized in Table 1.

3

4 **Table 1.** Overview of scenarios simulated with ECHAM6.3-HAM2.3 using different assumptions for the emission height of
5 the emitted biomass burning aerosol over Southeastern Australia.

Scenario	Description
<i>BASE</i>	Standard emission height as prescribed in the ECHAM-HAM model for wildfires (75% in PBL, 17% in the first layer and 8% in the second layer above PBL)
<i>NoEmiss</i>	Wildfire smoke emission set to zero for the pyroCb days 29 – 31 December 2019 and 1 April 2020 in Southeastern Australia
<i>TP+1</i>	Wildfire smoke emission from Southeastern Australia injected into the model layer above the tropopause for the pyroCb days
<i>TP</i>	As <i>TP+1</i> , but smoke injection into the model layer containing the tropopause
<i>TP-1</i>	As <i>TP+1</i> , but smoke injection into the model layer below the tropopause
<i>TP1_8020</i>	As <i>TP+1</i> , but only 80% of the emitted smoke injected above and 20% distributed below the tropopause
<i>TP1_5050</i>	As <i>TP+1</i> , but only 50% of the emitted smoke injected above and 50% distributed below the tropopause
<i>14km</i>	Wildfire smoke emission from Southeastern Australia injected into 14 km height for the pyroCb days as suggested from satellite lidar observations

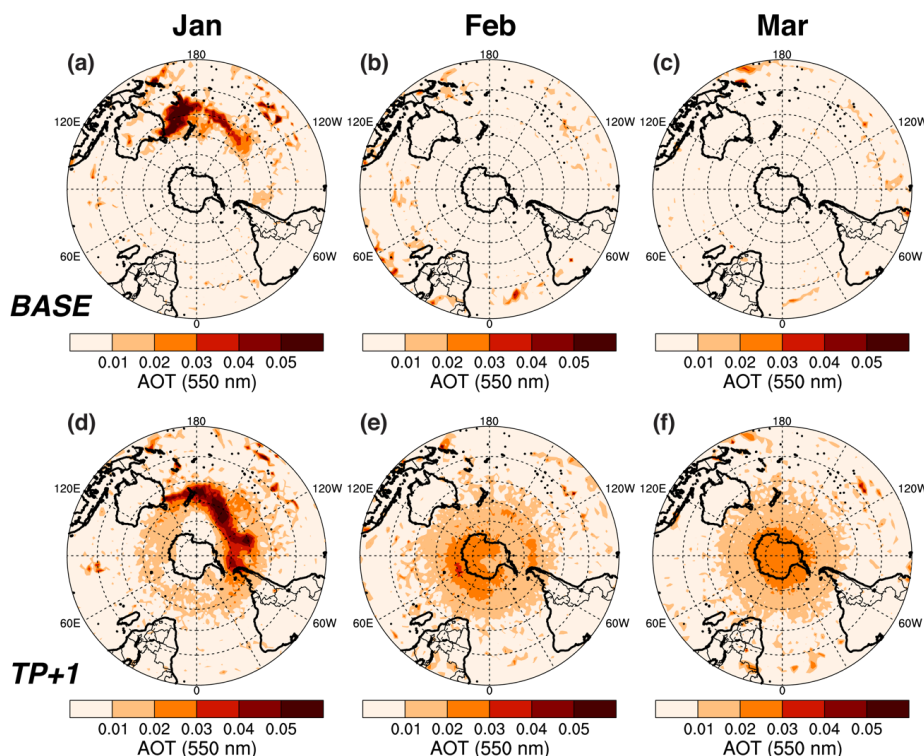

6

7 **3 Results**

8 **3.1 Smoke transport simulation and model evaluation**

9 According to satellite observations, the 2019-2020 Australian wildfire plume considerably increased the AOT of the usually
10 pristine Southern Hemisphere (Hirsch and Koren, 2021). Average aerosol optical thickness (AOT) derived from the Advanced
11 Very High Resolution Radiometer (AVHRR) satellite instrument between 20°S–60°S was significantly increased to 0.16 for
12 January 2020, which implies a 51% offset from the long-term mean (Fig. 1b). Ground-based observations for example at the
13 station Punta Arenas show that the January to March 2020 average AOT was 0.10, which is more than a factor 2 increase
14 compared to the year 2019 for at least half a year. One year later, in January 2021, the observed 500-nm AOT over Punta
15 Arenas was still increased with a monthly mean of 0.06 (50% increase relative to 2019).

Figure 2. Monthly mean simulated AOT differences for January to March 2020 for the cases *BASE - NoEmiss* (top panels) showing the contribution of smoke AOT for the case when no smoke injection by pyroconvection is prescribed in the model, and *TP+1 - NoEmiss* (bottom panels), showing the effect on AOT of smoke injection into the model layer above the tropopause for the pyroCb days 29 – 31 December 2019 and 4 January, 2020 in Southeastern Australia.

The emission and subsequent transport of this smoke plume are reproduced using the global aerosol-climate model ECHAM6.3-HAM2.3. The comparison of the modeled AOT of the *BASE* and *TP+1* experiments, respectively, and that of the *NoEmiss* experiment (see Fig. 2) provide an insight into the AOT distribution due to the wildfire smoke and illustrate the role of the smoke injection height. While monthly mean smoke AOT values as high as 0.26 and 0.22 are simulated for January just downwind of the fire region in Southeast Australia for the *BASE* and *TP+1* experiments, respectively, the results of the *BASE* experiment do not show increased smoke AOT eastward of 120°W in January and none in the later months. In contrast, the results of the *TP+1* model experiment in which the smoke aerosol was injected into the model layer above the tropopause for the four Southeastern Australian pyroCb days show persistently enhanced smoke AOT south of 30°S with AOT differences between 0.01 and 0.03 until at least March 2020. Also, a southward transport of the stratospheric smoke during the three months leading to maximum smoke AOT anomaly above Antarctica in March is evident. Similar smoke transport to Antarctica was reported by Jumelet et al. (2020) for the earlier major Australian fires in 2009. The effect of the stratospheric transport of the smoke plume on simulated monthly mean AOT from the Australian wildfires is shown in Fig. 2d–f. For the simulations that consider an explicit prescription of the aerosol injection into the upper troposphere or lower stratosphere, the model shows significantly enhanced AOT in large parts of the Southern Hemisphere. These model results indicate, in agreement with observations (Khaykin et al., 2020; Ohneiser et al., 2020), that elevated levels of wildfire smoke were sustained over several months and markedly impacted the radiative conditions in the Southern Hemisphere.

Figure 3. Scatter plots of observed versus simulated monthly mean 550-nm AOT at southern mid and high-latitude AERONET stations for January to March 2020. The error bars represent the standard deviation based on daily values. Compared are model results for the cases (a) BASE, (b) TP+1, and (c) TP-1. The stations are color-coded respectively: Punta Arenas, Chile (53.14°S, 70.89°W), blue triangle; Amsterdam Island (37.80°S, 77.57°E), light blue circles; Antarctic Stations Marambio (64.24°S, 56.63°W) and Vechernaya Hill (67.66°S, 46.16°E), purple pentagons; South Pole (90.00°S), light purple hexagons.

10 To evaluate the representation of smoke emission height during the pyroCb days, the model results for the different sensitivity
11 cases representing different injection heights are compared to sunphotometer measurements of mid- and high-latitude
12 AERONET stations in the Southern Hemisphere (Holben et al., 1998) for the months January to March 2020 (Fig. 3), and with
13 ground-based lidar measurement from the PollyXT instrument at Punta Arenas for several days January 2020 (Fig. 4).
14 Particularly for the AERONET stations located in Antarctica the observed AOT was enhanced in early 2020 compared to
15 previous years. The agreement of model results with AOT measured at five AERONET stations is clearly better for the cases
16 TP+1 and TP-1 with prescribed fire injection heights compared to the BASE case using the original model configuration with
17 75% wildfire emissions within the planetary boundary layer and 25% into the two model layers above (Fig. 3). All model
18 results show a negative bias compared to the observations, indicating that the modeled effects of the smoke will underestimate
19 the actual load and solar absorption of stratospheric smoke (see also Sect. 3.2). In the BASE case the bias is larger than for the
20 other cases representing smoke injection into the upper troposphere and lower stratosphere, and the correlation is also lower,
21 at least compared to the TP+1, TP, TP-1 and TP1_8020 cases (Table 2). The results for TP+1, TP, TP-1, TP1_8020 and 14km
22 agree similarly well with the observations, with less agreement for the TP1_5050 case. The two cases BASE and TP1_5050
23 therefore represent the observations worst, while no clear best fit is apparent for the other setups.
24 The Australian wildfire smoke was observed in early 2020 above Punta Arenas with a ground-based lidar. Pronounced smoke
25 layers arrived first on 8 January and were clearly above the local tropopause (Fig. 5), which is also consistent with the
26 CALIPSO satellite lidar observations. The altitude of the observed smoke plumes steadily increased and reached top heights
27 of 26–27 km at the end of January. For four observations in January and February 2020 (Fig. 4), the exceptionally thick smoke
28 plume is also reflected in the measured extinction coefficients. These remarkable values in terms of structure and magnitude

1 **Table 2.** Statistical key figures for the comparison of measured and simulated AOTs for the different model cases at the
 2 AERONET sun photometer stations Punta Arenas, Chile (53.14°S, 70.89°W), Amsterdam Island (37.80°S, 77.57°E), Antarctic
 3 Stations Marambio (64.24°S, 56.63°W), Vechernaya Hill (67.66°S, 46.16°E), and South Pole (90.00°S). The numbers in bold

6

7

8 can only be captured by the model with stratospheric Australian fire injection heights. Although the grid-cell to point-
 9 measurement comparison remains uncertain in detail, again a tendency for an underestimation of the stratospheric smoke is
 10 apparent. When using the model with original injection height (*BASE* case), none of the structures in the stratosphere can be
 11 simulated, giving the clear evidence that the deep pyroconvection in the wildfire hotspots in Southeast Australia did emit
 12 smoke well above the usually assumed injection heights (Remy et al., 2017; Val Martin et al., 2018). The model results also
 13 indicate the role of absorptive aerosol heating for the vertical transport of the smoke layer. In the lidar profiles, a continuous
 14 rise of the smoke layer is visible, with plume center heights increasing from 15 km to 23 km (Figs. 4, 5). The radiatively-
 15 induced self-lifting of smoke can only be reproduced if aerosol-radiation interactions are considered in the simulations that
 16 finally lead to a considerable absorptive heating and associated buoyancy production.

17

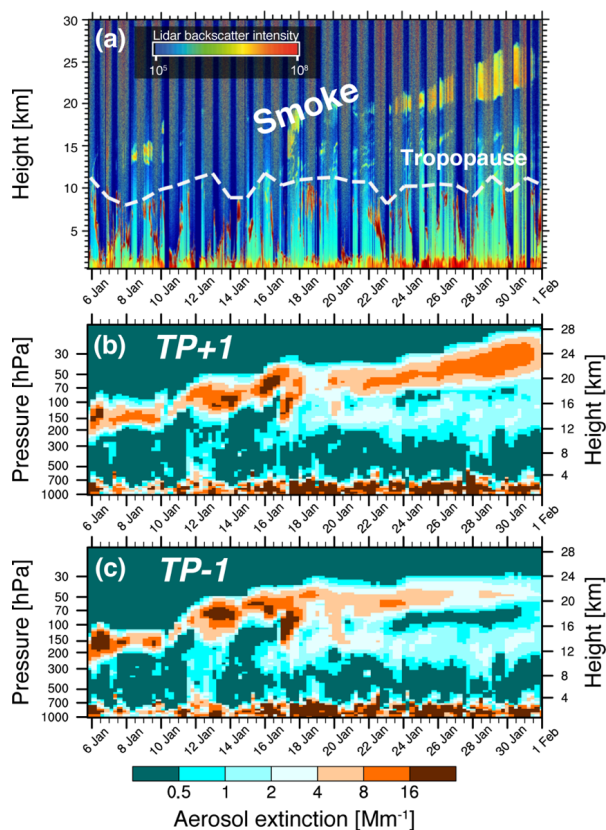

18

19

20 **Figure 4.** Comparison of modeled and observed profiles of aerosol extinction coefficients at the field site in Punta Arenas for
 21 9, 12, and 26 January and 16 February 2020. Error bars indicate the estimated lidar measurement uncertainties of 30%, values
 22 below the lidar detection limit are omitted from the graph. See Table 1 for details of the different simulations.

23

24

1

2 **Figure 5.** Comparison of the pattern of the temporal evolution of stratospheric smoke observed by lidar measurements and
3 model results at Punta Arenas, Chile for January 2020. (a) Time-height curtain plot of aerosol attenuated backscatter coefficient
4 from the PollyXT lidar at Punta Arenas in southern Chile (53.14°S, 70.89°W). (b, c) Simulated aerosol extinction for the model
5 results for the cases *TP+1* and *TP-1*, respectively.

6

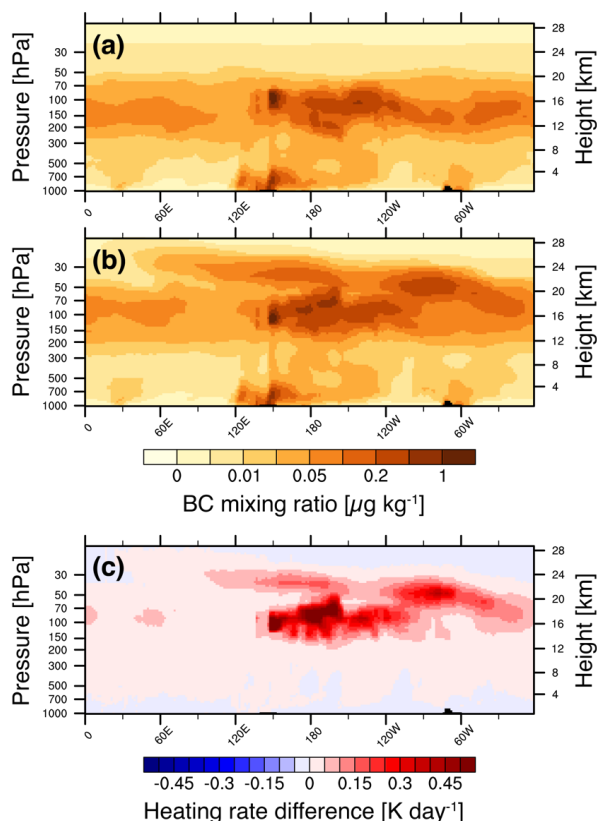

7

8 Figure 5 qualitatively compares the development of the smoke extinction profile for the cases *TP+1* and *TP-1* with the aerosol
9 backscatter measurements at Punta Arenas, where the rise of the smoke plume center to 24 km by 31 January is particularly
10 well matched for the *TP+1* case. For the other model scenarios, the plume is lifted to lower heights of 20–21 km by the end of
11 January. But even for the case *TP-1* for which the smoke was injected below the tropopause the smoke has lifted into the
12 stratosphere in the model. This result underlines the importance of a correct representation of fire injection heights, especially
13 for intense wildfires, which is essential to realistically assess the radiative effects of smoke plumes.

14 The role of the self-lifting of the smoke caused by the radiative heating of the absorbing BC aerosol in the smoke is also
15 illustrated by the vertical distribution of modeled BC mixing ratios (shown for case *TP1_8020* in Fig. 6) averaged for January
16 2020 at 35°S latitude where the fires occurred. The BC mixing ratios for a model simulation where the aerosol is not interacting
17 with radiation and thus do not heat the smoke containing atmospheric layers the smoke BC remains below 20 km height, while
18 ascending to 24 km for radiatively interactive aerosol in the model (Fig. 6a, b). The monthly heating rate increase caused by
19 the wildfire smoke leading to the self-lifting of the smoke plume is computed as the difference between the *TP1_8020* and the
20 *NoEmiss* scenarios (Fig. 6c). This heating rate reached monthly mean values up to 1.7 K day⁻¹ in January 2020.

21

22

1

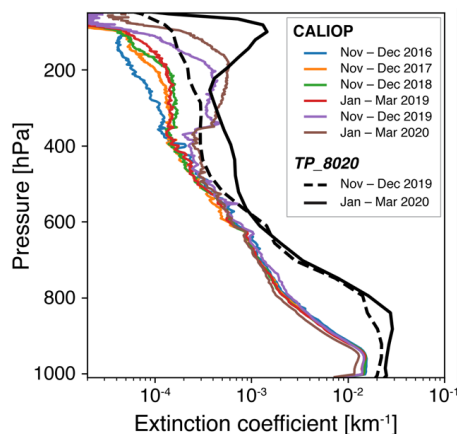

2

3 **Figure 6.** Longitude-height distributions of modeled black carbon aerosol mixing ratios at latitude 35°S for January 2020 for
 4 the case *TPI_8020* with injection of 80% Southeastern Australian smoke on the days with pyroconvective activity (pyroCb
 5 days) into the layer above the tropopause and 20% distributed in the troposphere. BC mixing ratios simulated (a) without and
 6 (b) with aerosol interacting with the radiation in the model. (c) Change in radiative heating rate caused by the absorption of
 7 solar radiation by the Australian wildfire smoke from the pyroCb days, computed as the difference between the cases
 8 *TPI_8020* and *NoEmiss*.

9

10 Evidence that the 2019-2020 Australian wildfires caused significantly increased upper tropospheric/lower stratospheric aerosol
 11 loading throughout the Southern Hemisphere is also shown by the CALIOP satellite lidar observations in Figure 7. The
 12 2019/2020 extinction profiles averaged over the Southern Hemisphere are considerably enhanced in the altitude range above
 13 200 hPa (~12 km) than those of the previous seasons in 2016 to 2018. Comparing the model results with the CALIOP
 14 observations, it can be seen that our approach of prescribing pyroconvective smoke injection also reproduces well the vertical
 15 distribution of Australian wildfire aerosol across the Southern Hemisphere, as shown in example of scenario *TPI_8020*.
 16 Discrepancies at altitudes above 400 hPa are likely related to the CALIOP sampling bias discussed in Sect. 2.3 while at lower
 17 atmospheric layers the model is believed to overestimate the boundary layer aerosol other than smoke.

18

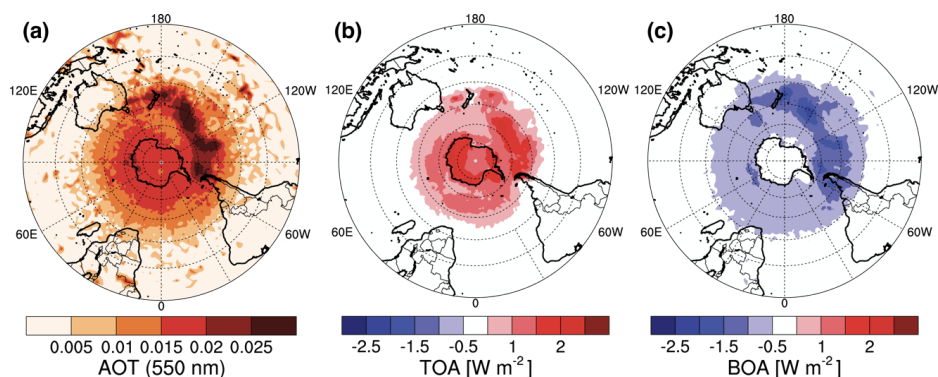

1

2 **Figure 7.** Mean vertical profile of the 532-nm retrieved extinction coefficient from CALIOP (colored lines) for several selected
3 periods within 2016 – 2020 and the 2019-2020 results from the ECHAM6.3-HAM2.3 model for the *TP1_8020* case, averaged
4 over the Southern Hemisphere.

5 3.2 Estimates of direct radiative perturbation

6 Regionally varying climate forcing agents such as aerosols substantially modulate anthropogenic greenhouse forcing. We find
7 that the individual extreme Australian fire event caused a significant hemispheric direct instantaneous radiative forcing signal
8 (Fig. 8), with the highest value for the scenario *TP+I* of $+0.50 \text{ W m}^{-2}$ at TOA averaged for the Southern Hemisphere for
9 January to March 2020 under all-sky conditions due to the elevated smoke layers (Table 3). This would correspond to a global-
10 average TOA radiative forcing of $+0.25 \text{ W m}^{-2}$. In Table 3, the range of forcing estimates is given for all considered model
11 scenarios except the clearly unrealistic cases *BASE* and *TP1_5050*. This instantaneous forcing by the singular fire event is of
12 similar magnitude as the latest multi-model estimate of the global-average instantaneous forcing for all anthropogenic black
13 carbon with $+0.28$ ($0.13\text{--}0.37$) W m^{-2} (Thornhill et al., 2021). Previous studies, in contrast, found negative TOA radiative
14 forcing estimates of -1 W m^{-2} (Khaykin et al., 2020) for this event but only considered clear-sky situations in which the smoke
15 aerosols appear brighter over the dark ocean surface due to the dominant scattering effect (Bellouin et al., 2020). However,
16 the elevated Australian smoke layers that contain absorbing black carbon were located above clouds and to a large extent also
17 above the strongly reflecting snow and ice cover of the Antarctic. Over such bright surfaces, the balance between aerosol
18 scattering and absorption is shifted and smoke aerosol darkens the scene seen from TOA. At surface (bottom of atmosphere,
19 BOA), the clear-sky instantaneous solar radiative forcing was estimated to ranging from -0.68 to -0.81 W m^{-2} for the different
20 model scenarios. This corresponds to the short-term surface dimming caused by a large volcanic eruption (Schmidt et al.,
21 2018). On the other hand, according to the model, the smoke-containing air layer itself experienced significant absorptive
22 heating with maximum heating rates in January 2020 of 1.7 K day^{-1} for the *TP+I* case. While the effective TOA radiative
23 forcing is expected to be low due to stratospheric adjustment to the instantaneous forcing, these heating rate changes may have
24 the potential to trigger responses in the atmospheric dynamics (Boers et al., 2010; Khaykin et al., 2020).

25

1

2 **Figure 8.** AOT and solar radiative forcing of the 2019-2020 Australian wildfire smoke plume in the Southern Hemisphere.
 3 Model results of (a) AOT and (b, c) instantaneous shortwave radiative forcing of the elevated smoke aerosol layer, averaged
 4 over the months January to March 2020. All values are differences between model ECHAM6.3-HAM2.3 results with
 5 Australian wildfire smoke injection for the scenario *TP+I* and *NoEmiss*. The instantaneous radiative flux differences are shown
 6 for all-sky conditions at top (TOA; b) and bottom of the atmosphere (BOA; c).

7 Major uncertainties in the model estimates of aerosol radiative forcing are due to uncertainties in AOT; in particular related to
 8 aerosol absorption that is characterized by its single scattering albedo (SSA). In our model, at the height of maximum extinction
 9 of the smoke plume, the particle SSA lies between 0.82–0.85 at 550 nm, which is within the range of other aerosol models
 10 (Bellouin et al., 2020). Inversion results of multispectral lidar observations in the Northern Hemisphere from the strong 2017
 11 Canadian fires yield a SSA of 0.80 for the stratospheric smoke (Haarig et al., 2018). For the 2019-2020 Australian fires, first
 12 inversion results even point towards SSA values just below 0.8, as calculated using the method of Veselovskii et al. (2002).
 13 This would indicate an underestimation of absorption by the stratospheric Australian smoke in the model, which is supported
 14 by the comparison to observed extinction profiles (Fig. 4). Thus, together with the low bias of the modeled smoke AOT, we
 15 argue that our results illustrate a conservative estimate for the positive TOA forcing of this event.

16

17 **Table 3.** Solar instantaneous direct radiative forcing (W m^{-2}) of the elevated smoke plume during the 2019-2020 Australian
 18 wildfires. The estimates are calculated differences between the instantaneous shortwave irradiances of the model results
 19 including stratospheric smoke injection and the case *NoEmiss* without smoke emission from Southeastern Australia for the
 20 pyroCb days, averaged over the Southern Hemisphere. Ranges are given for the different configurations *TP+I*, *TP1_8020*,
 21 *TP*, *TP-I*, and *14km* (see Table 1). Shown are the differences for all-sky and clear-sky conditions at top and bottom of
 22 atmosphere (TOA, BOA) averaged for the months January to March (JFM) 2020.

	TOA all sky	TOA clear sky	BOA all sky	BOA clear sky
January 2020	+0.45 – +0.56	-0.02 – -0.05	-0.54 – -0.61	-0.86 – -0.97
February 2020	+0.40 – +0.57	+0.003 – +0.07	-0.42 – -0.51	-0.67 – -0.84
March 2020	+0.25 – +0.37	-0.01 – +0.07	-0.28 – -0.38	-0.46 – -0.63
JFM Average	+0.37 – +0.50	-0.02 – +0.02	-0.42 – -0.50	-0.68 – -0.81

1 4 Implications and perspectives

2 In order to determine the impact of biomass burning aerosol on the global energy budget, accurately estimating emission fluxes
3 and their injection height in the atmosphere is essential. State-of-the-science global aerosol-atmosphere models generally
4 consider biomass burning aerosol, but still show uncertainties in the spatio-temporal distribution. In particular, large emission
5 events like Australia's Black Summer wildfires of 2019–2020 are underrepresented.

6 A key uncertainty is the vertical injection of fire smoke into the atmosphere that may ultimately cause misrepresentation of
7 the plume evolution. The results of this study show that using fire emission data from the GFAS dataset and injecting the
8 smoke into the tropopause region for pyroCb events gives results that are reasonable, although still somewhat underestimated
9 in the present study.

10 The substantial increase in stratospheric AOT in the Southern Hemisphere, and thus the perturbation of the radiative balance,
11 from the southeastern Australian wildfire smoke from just four days of pyroconvection events is remarkable. The local sub-
12 grid scale nature of fire plume rising challenges the representation in models beyond the 1-km scale, but especially in global
13 models that do not resolve convection (Paugam et al., 2016; Veira et al., 2015). In these coarse models, the vertical distribution
14 of fire emissions is based on climatological profiles (Val Martin et al., 2018) or prescribed by injection heights estimated from
15 satellite retrievals of fire radiative power (Remy et al., 2017). While this is appropriate for the majority of vegetation fires, the
16 vertical transport during deep pyroconvective events with potentially far-reaching effects is most likely underestimated due to
17 the obstruction of satellite observations by dense pyroCb clouds (Remy et al., 2017). Adequate plume-rise parameterizations
18 exist particularly for mesoscale chemistry-transport models, but have not found their way into climate modeling on a wider
19 scale yet (Paugam et al., 2016; Val Martin et al., 2018; Veira et al., 2015).

20 Consequently, aerosol-climate models underestimate the wildfire aerosol impacts on the energy balance, as the vertical location
21 of the smoke relative to clouds is fundamental to its radiative impact. To solve this, adjustments are needed in the representation
22 of biomass burning injection. By implementing a more realistic emission scenario based on aerosol-profiling observations but
23 still using the emission fluxes from the standard GFAS database, we enhance the ability of our model to capture the extreme
24 2019-2020 Australian pyroCb event and can thus showcase the potential of global aerosol-climate models to realistically
25 reproduce the spatio-temporal evolution of smoke plumes of intense wildfires. This further allows for an improved estimate
26 on aerosol impacts on radiation and clouds. Ultimately, these improvements are essential to any estimate on the Earth's energy
27 balance and climate state. In this respect, it is particularly important to make climate models capable of dealing with
28 exceptional outliers of wildfires, which are anticipated to increase in frequency and severity worldwide in response to
29 anthropogenic climate warming (Jolly et al., 2015; Abatzoglou et al, 2019; Wotton et al, 2017). The increased risk of serious
30 wildfires is related to extreme heat and drier conditions, as well as record-low snow cover in boreal regions (Box et al., 2019;
31 Dowdy et al., 2019). More frequent and intense fire weather extremes will also increase the likelihood of deep pyroconvection
32 (Dowdy et al., 2019).

33 In essence, biomass burning emissions are an important source of aerosol particles, and individual wildfires are shown to have
34 more widespread effects than previously assumed. An as-accurate-as-possible description, therefore, is key to successfully
35 estimate aerosol climate effects, and future climate projections will clearly benefit from an improved aerosol representation in
36 Earth system models.

37

1 *Code availability.* The ECHAM-HAMMOZ code is maintained and made available to the scientific community under
2 <https://redmine.hammoz.ethz.ch>. The availability is regulated under the HAMMOZ Software Licence Agreement that can be
3 downloaded from https://redmine.hammoz.ethz.ch/attachments/download/291/License_ECHAM-HAMMOZ_June2012.pdf.

4 *Data availability.* The ECHAM6.3-HAM2.3 model output, on which the figures are based, and the analyzed lidar profiles are
5 accessible at Zenodo from <https://zenodo.org/deposit/5571545> (Heinold et al., 2021) The ground-based Polly lidar data time
6 series is visualized at polly.tropos.de and will become publicly available via the data portal of the European Aerosols, Clouds
7 and Trace gases Research Infrastructure (ACTRIS) when its implementation phase is completed. Until then, raw data is
8 available on request via polly@tropos.de. AERONET data can be obtained with the Aerosol Robotic Network download tool
9 https://aeronet.gsfc.nasa.gov/cgi-bin/webtool_opera_v2_new. The Aerosol Optical Thickness CDR used in this study was
10 acquired from NOAA's National Climatic Data Center (<http://www.ncdc.noaa.gov>).

11 *Author contribution.* BH and IT conceived the idea and led the study. BH and AK performed the model development and ran
12 the simulations. NS provided the LIDAR simulator for ECHAM6.3-HAM2.3. IT, FS, KS, AK and BH focused on the analysis
13 and interpretation of model results. RS analyzed NASA's AVHRR AOT climatology data, and DV researched the Earth history
14 context. KO, HB and BB performed the lidar analysis and interpretation. BH, IT, KS, FS and RS wrote the paper with
15 contributions from all co-authors. All authors participated in the revision and editing of the paper.

16 *Competing interests.* The authors declare no competing interests.

17 *Acknowledgements.* The authors thank Johannes Quaas and Albert Ansmann for sharing their comments on an earlier version
18 of the manuscript. We also would like to thank the whole DACAPO-PESO team for ensuring the continuous operation of all
19 the different instruments at Punta Arenas. Special thanks to Patric Seifert, Martin Radenz, Cristofer Jimenez and Ronny
20 Engelmann for taking care of the lidar, measurements and ensuring high-quality data operation at the cost of spending many
21 lifetime hours in an airplane. Igor Veselovskii is acknowledged for computing lidar inversion products. The AVHRR Aerosol
22 Optical Thickness Climate Data Record (CDR) was originally developed by Xuepeng Zhao and colleagues for NOAA's CDR
23 Program. We thank P. Goloub, V. E. Cachorro Revilla, P. Seifert, J. Butler, B. Holben, and A. Chaikovskiy for their efforts in
24 establishing and maintaining the AERONET sites Amsterdam Island, Marambio, Punta Arenas, South Pole, and Vechnaya
25 Hill. The ECHAM-HAMMOZ model is developed by a consortium composed of ETH Zürich, Max Planck Institute for
26 Meteorology, Forschungszentrum Jülich, the University of Oxford, the Finnish Meteorological Institute and the Leibniz
27 Institute for Tropospheric Research (TROPOS) and managed by the Center for Climate Systems Modelling (C2SM) at ETH
28 Zürich. We are grateful for computing time from the Deutsches Klimarechenzentrum (DKRZ). Computing resources at DKRZ
29 were granted under project number bb1004.
