9 **Abstract.** We analyze Aura Microwave Limb Sounder (MLS) monthly zonal mean time series of ClO and HOCl
10 between 50°S and 50°N to estimate upper stratospheric trends in these chlorine species from 2005 through 2020.
11 We compare these observations to those from the Whole Atmosphere Community Climate Model version 6
12 (WACCM6), run under the specified dynamics configuration. The model sampling follows the MLS coverage in
13 space and local time. We use version 5 MLS ClO zonal mean daytime profiles and similarly binned daytime ClO
14 model profiles from 32 to 1.5 hPa. For MLS HOCl, we use the version 5 offline product derived from daily zonal
15 mean radiances rather than averaged Level 2 profiles; MLS HOCl is scientifically useful between 10 and 2 hPa,
16 and the HOCl monthly zonal means are separated into day and night for comparison to WACCM6. We find good
17 agreement (mostly within ~10%) between the climatological MLS ClO daytime distributions and the model ClO
18 climatology for 2005–2020. The model HOCl climatology, however, underestimates the MLS HOCl climatology
19 by about 30%. This could well be caused by a combination of fairly large systematic uncertainties in both the
20 model-assumed rate constant for the formation of HOCl and the MLS HOCl retrievals themselves.

21 The model daytime ClO trends versus latitude and pressure agree quite well with those from MLS. MLS-
22 derived near-global upper stratospheric daytime trends between 7 and 2 hPa are $-0.73 \pm 0.40 \text{ \%yr}^{-1}$ for ClO and $-$
23 $0.39 \pm 0.35 \text{ \%yr}^{-1}$ for HOCl, with 2σ uncertainty estimates used here. The corresponding model decreases are
24 somewhat faster than observed (although the difference is not statistically significant), with trend values of
25 $-0.85 \pm 0.45 \text{ \%yr}^{-1}$ for ClO and $-0.64 \pm 0.37 \text{ \%yr}^{-1}$ for HOCl. Both data and model results point to a faster trend
26 in ClO than in HOCl. The MLS ClO trends are consistent with past estimates of upper stratospheric ClO trends
27 from satellite and ground-based microwave data. As discussed in the past, trends in other species (in particular,
28 positive trends in CH₄ and H₂O) can lead to a ClO decrease that is faster than the decrease in total inorganic

29 chlorine. Regarding trends in HOCl, positive trends in HO₂ can lead to a faster rate of formation for HOCl as a
30 function of time, which partially offsets the decreasing trend in active chlorine.

31 The decreasing trends in upper stratospheric ClO and HOCl provide additional confirmation of the
32 effectiveness of the Montreal Protocol and its amendments, which have led to the early stages of an expected
33 long-term ozone recovery from the effects of ozone-depleting substances.

34 **1 Introduction**

35 Changes in the gaseous chlorine content of the atmosphere have been scrutinized since the late 1970s, when
36 prescient warnings (Molina and Rowland, 1974) were made regarding likely threats to the Earth's stratospheric
37 ozone (O₃) layer from the decomposition of various chlorofluorocarbons (CFCs) emitted at the surface by human
38 industrial activities. These threats carried human health implications as a result of increased ultraviolet (UV)
39 radiation at the surface, which would follow from reductions in UV absorption by stratospheric ozone. Various
40 measurements of the abundances of different chlorine species in the stratosphere followed these early years of
41 concern regarding expected declines in global ozone. Early balloon-borne observations of chlorine monoxide
42 (ClO) radicals in the upper stratosphere (Anderson et al., 1977; Waters et al., 1981) confirmed the predicted
43 importance of gas-phase reactions (involving ClO, Cl, O₃, and O) on upper stratospheric ozone abundances. Since
44 the 1987 Montreal Protocol and its subsequent amendments, established to strongly reduce worldwide surface
45 emissions of halogenated compounds harmful to the ozone layer, both the tropospheric and stratospheric chlorine
46 budgets have been carefully studied and monitored by the atmospheric science community. This was motivated
47 by enhanced concerns regarding ozone decreases in the lower stratosphere, after the discovery of the seasonal
48 appearance of an ozone hole over Antarctica (Farman et al., 1985).

49 Studies of interannual and longer-term changes in stratospheric chlorine species were carried out by ground-
50 based (column) measurements of HCl and ClONO₂ at infrared wavelengths (Rinsland et al., 2003; Kohlhepp et
51 al., 2011; Mahieu et al., 2014). Near-global stratospheric chlorine changes have also been tracked by satellite
52 measurements of HCl. Indeed, this chlorine reservoir species at high altitude (near 50 km) accounts for the vast
53 majority of Cl_y (total inorganic chlorine), based on past measurements of the stratospheric chlorine budget by
54 Zander et al. (1992) and Nassar et al. (2006). Froidevaux et al. (2006) also discussed model results regarding the
55 contribution of upper stratospheric HCl to Cl_y and described measurable decreases in HCl (and by inference, in
56 Cl_y) from mid-2004 to early 2006, based on changes in Aura MLS profiles. The rather fast rise in chlorine from
57 the 1980s to the late 1990s (with increases of more than 55%) was followed by a slower rate of decrease, as

58 expected from model calculations. Stratospheric chlorine follows the overall tropospheric trends with about a 5-
59 year delay, which accounts for photolysis, transport, and mixing of tropospheric compounds into the stratosphere
60 (as discussed by Anderson et al., 2000, Waugh et al., 2001, and others).

61 Changes in chlorine source gases at the surface, as well as changes in stratospheric chlorine species, have been
62 updated and documented regularly in quadrennial reports (see WMO, 2018). Based on such analyses, stratospheric
63 HCl has been decreasing over the past two decades by about $0.5\text{--}1\% \text{yr}^{-1}$. This includes results from ground-based
64 infrared measurements, as well as from near-global upper stratospheric HCl measurements by the Atmospheric
65 Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS) (see Bernath and Fernando, 2018). These
66 results are consistent with surface total chlorine trends, based on in situ sampling of a large number of source
67 species by ground-based networks (Engel and Rigby et al., 2018), so that there is a good corroboration of the
68 effectiveness of the Montreal Protocol and its amendments, except for some recent departures from expectations
69 for the evolution of CFC-11 (Montzka et al., 2018). Ground-based microwave measurements of stratospheric ClO
70 profiles over the past two decades have also made valuable contributions to these long-term chlorine composition
71 records. This includes trend results for upper stratospheric ClO over Hawaii (Solomon et al., 2006; Connor et al.,
72 2013) as well as for the more variable lower stratosphere over Antarctica (Nedoluha et al., 2016). These findings
73 corroborate the longer-term decreasing trends in HCl (and Cl_y), although dynamical variability on timescales of
74 5–7 years complicates trend detection (e.g., for HCl) in the lower stratosphere (Mahieu et al., 2014; Strahan et al.,
75 2020); this variability and its causes are still under investigation in the community.

76 Here, we provide an analysis of upper stratospheric trends in near-global ClO and hypochlorous acid (HOCl).
77 These two chlorine species have been measured by the Aura Microwave Limb Sounder (MLS) globally on a near-
78 daily basis since its launch in 2004. An analysis of their trends falls within the general theme of confirming that
79 the Montreal Protocol has been able to significantly reduce the threat of stratospheric chlorine to global ozone.
80 The MLS measurements of upper stratospheric ClO and HOCl have taken on a larger role, in light of the fact that
81 MLS lost the capability of obtaining trend-quality data on upper stratospheric HCl after a hardware issue in early
82 2006 (see Livesey et al., 2020). The lower stratospheric HCl measurements have continued through the use of
83 radiances from an adjacent MLS measurement band (see also the lower stratospheric MLS HCl comparisons to
84 model results by Froidevaux et al., 2019). In Section 2, we describe the observations, model simulations, and
85 methods of analysis for this work. Section 3 focuses on the trend results for ClO and HOCl, while Section 4
86 provides a discussion in the context of broader trends in upper stratospheric species. Our conclusions are
87 summarized in Section 5.

88 **2 Observations, model simulations, and analysis methods**

89 In this work, we analyze temporal changes in upper stratospheric ClO and HOCl abundances, based on continuous
90 MLS observations of both species from 2005 through 2020. We compare these observational results to those from
91 a state-of-the-art chemistry climate model for the same time period.

92 **2.1 Observations**

93 The primary datasets used in this analysis come from 16 full years (2005 through 2020) of global measurements
94 performed by Aura MLS. The MLS antenna scans the atmospheric limb as the Aura satellite orbits the Earth in a
95 near-polar sun-synchronous orbit; the instrument measures thermal emission (day and night), using microwave
96 radiometers operating at frequencies near 118, 190, 240, and 640 GHz, as well as a 2.5 THz module to measure
97 OH (during the early part of the mission only). MLS has been providing a variety of daily vertical stratospheric
98 temperature and composition profiles (~3500 profiles per day per product), with some measurements extending
99 down to the upper tropospheric region, and some into the upper mesosphere or higher. We rely here mainly on
100 the upper stratospheric MLS measurements of ClO and HOCl, obtained from 640-GHz radiometer data.
101 Specifically, ClO and HOCl emissions are obtained from lines centered at 649.5 and 635.9 GHz, respectively;
102 Waters et al. (2006) have provided an overview of the MLS instrument and its measurements, along with some
103 sample spectra, and Read et al. (2006) have described the simulated forward model and related spectra. The MLS
104 retrievals use an optimal estimation approach (Rodgers, 2000), with MLS-specific details provided by Livesey et
105 al. (2006); there is no assumption of atmospheric homogeneity along the line of sight (see Livesey and Read,
106 2000), and the MLS retrievals make use of the instrument's views (which are all along the line of sight) during
107 multiple consecutive MLS antenna scans of the Earth's limb. Data users interested in MLS data quality and
108 characterization, estimated errors, and related information, should consult Livesey et al. (2020), the latest update
109 to the MLS data quality document.

110 In this work, we use the latest data version from MLS, namely version 5.0 (or v5). The single-profile precision
111 (1σ random uncertainty) is ~0.1 ppbv for the ClO retrievals in the region between 32 and 1.5 hPa that we focus
112 on here; the vertical resolution of the ClO measurements is about 3–4 km. For our analyses of daytime MLS ClO
113 monthly zonal means in 5° latitude bins, the more relevant precision for averaged upper stratospheric values drops
114 to about 0.5–5%. In addition, the methodology used by the MLS team to assess the aggregate effects of simulated
115 errors in various input parameters on the measurement retrievals (see Livesey et al., 2020) leads to systematic
116 uncertainties of order 0.02–0.1 ppbv for upper stratospheric ClO, which translates to about 5–100% for ClO,

117 depending on whether one considers the peaks of the distributions (for the smaller uncertainty values) or regions
118 away from these peaks. The standard MLS data quality screening methodology (see the above reference) has been
119 applied to all Level 2 ClO profiles, prior to averaging into monthly zonal means.

120 For the MLS HOCl data, we have used an offline retrieval product that shows similar results as the averaged
121 Level 2 profiles, but with somewhat smaller variability. This product is created offline (i.e., after the daily
122 processing of incoming MLS data) by averaging daily Level 1 spectra before performing the retrievals of mean
123 daily profiles, which are then averaged for this work into either day or night monthly zonal means. The offline
124 retrieval technique follows the overall MLS retrieval methodology described by Livesey et al. (2006), except it is
125 a one-dimensional type of retrieval (as it is not used for line-of-sight ‘chunks’ of profiles like the Level 2
126 ‘tomographic’ approach). Moreover, the radiances that are used as part of the averages correspond to profiles for
127 which the temperature and ozone retrievals in Level 2 have passed the standard retrieval criteria for good quality
128 data. This methodology is the same as that used for the MLS offline retrievals of BrO and HO₂, which are also
129 considered to be MLS “noisy products”, based on their single-profile precision values (see Millán et al., 2012,
130 2015, for BrO and HO₂, respectively). These averaged offline products can be more stable and scientifically useful
131 over a wider vertical range than averages of the MLS Level 2 standard products (although the wider vertical range
132 only holds for HO₂). Also, the latitude grid spacing for the MLS offline HOCl product (as for the other offline
133 products mentioned above) is 10°, rather than the 5° used for ClO and other standard MLS retrieval products. We
134 have used the precision and accuracy HOCl estimates from the standard Level 2 MLS product, as we expect
135 similar uncertainties (or possibly better) for the offline HOCl product. The MLS HOCl precision for (day or night)
136 10° monthly zonal means is typically less than 5-10 pptv (or roughly 5–20%). Systematic uncertainties are
137 estimated to be 40–80 pptv for HOCl, or about 25–100%. The more limited useful vertical range for MLS HOCl
138 is 10 to 2 hPa, and the HOCl profiles have a vertical resolution of 5–6 km. The reader is referred to Livesey et al.
139 (2020) for more detailed information regarding the MLS HOCl standard product.

140 We also make use of upper stratospheric data from ACE-FTS, which was launched in 2003 as part of the
141 Canadian SCISAT mission. The instrument uses the solar occultation technique and gathers measurements in the
142 infrared region (at 750–4400 cm⁻¹, with a spectral resolution of 0.02 cm⁻¹). The ACE-FTS sampling is skewed
143 towards middle to high latitudes, with many fewer profiles per day (per species) than obtained from MLS (30
144 from ACE-FTS versus ~3500 from MLS). ACE-FTS has provided a wealth of constituent profile measurements
145 over basically the same period as Aura MLS (see the overview by Bernath et al., 2017); we use some ACE-FTS
146 trend results to obtain a broader description and understanding of chlorine species trends in the upper stratosphere.
147 We have used ACE-FTS data version 4.1 in the analyses presented here; see Boone et al. (2020) and references

148 therein for detailed information on the ACE-FTS retrievals. We have removed the largest outliers in the ACE-
149 FTS data by using the prescription regarding data flags from Sheese et al. (2019), although this data screening
150 makes essentially no difference to the near-global upper stratospheric data averages and related trend results in
151 this work.

152 **2.2 Model simulations**

153 The model used here is the Whole Atmosphere Community Climate Model version 6 (WACCM6), a
154 component of the Community Earth System Model 2 (CESM2), configured to use specified dynamics as described
155 by Gettelman et al. (2019). These authors showed that this chemistry climate model reproduces many modes of
156 variability, as well as trends, in the middle atmosphere. WACCM6 is the “high-top” version of the Community
157 Atmosphere Model, version 6 (CAM6; Danabasoglu et al., 2019). CAM6 includes updated representations of
158 boundary layer processes, shallow convection, liquid cloud macrophysics, and two-moment cloud microphysics
159 with prognostic cloud mass and concentration. This version of CAM6 uses a finite volume dynamical core (Lin,
160 2004). The horizontal resolution is 0.95° latitude x 1.25° longitude. The model has 88 levels with a vertical range
161 from the surface to the lower thermosphere. The vertical resolution in the lower stratosphere ranges from 1.2 km
162 near the tropopause to ~2 km near the stratopause.

163 The WACCM6 model represents chemical processes from the troposphere into the lower thermosphere. The
164 chemical scheme includes the O_x, NO_x, HO_x, ClO_x, and BrO_x chemical families, along with CH₄ and its
165 degradation products. This scheme also includes primary non-methane hydrocarbons and related oxygenated
166 organic compounds. The chemical processes have evolved from previous versions and are summarized in detail
167 by Emmons et al. (2020). Reaction rates follow the JPL 2015 recommendations (Burkholder et al., 2015). The
168 chemical scheme also includes a new detailed representation of secondary organic aerosols (SOAs), based on the
169 “simple Volatility Basis Set” approach (Tilmes et al., 2019). WACCM includes a total of 231 species and 583
170 chemical reactions broken down into 150 photolysis reactions, 403 gas-phase reactions, 13 tropospheric, and 17
171 stratospheric heterogeneous reactions. The photolytic reactions are based on both inline chemical modules and a
172 lookup table approach (Kinnison et al., 2007).

173 The model scenario used here is based on historical forcings (and recent updates) from the Climate Model
174 Intercomparison Project – Phase 6 (Meinshausen et al., 2017); any reference to “model” in this work refers to this
175 WACCM6 scenario (unless otherwise noted, in particular, for a sensitivity study). The forcings include
176 greenhouse gases (CH₄, N₂O, and CO₂) and organic halogens (CH₃Cl, CH₃CCl₃, CCl₄, CFC-11, CFC-12, CFC-
177 113, CFC-114, CFC-115, HCFC-22, HCFC-141b, HCFC-142b, CH₃Br, halon-1211, halon-1301, halon-2402,

178 CHBr₃, and CH₂Br₂). CMIP6 specification of NO_x emissions from medium energy electrons (MEEs), solar proton
179 events (SPEs), and galactic cosmic rays (GCRs) is also included. The 11-year solar cycle variability is taken from
180 the Naval Research Laboratory's (NRL) solar variability model, referred to as the NRL Solar Spectral Irradiance
181 version 2 (NRLSSI2; Coddington et al., 2016). The volcanic SO₂ emissions (used in the sulfate aerosol density
182 calculation) are derived for each volcanic eruption using the Neely and Schmidt (2016) database updated through
183 the year 2020. This work uses the specified dynamics (SD) option (Lamarque et al., 2012), where reanalysis
184 temperature, zonal and meridional winds, surface stress, surface pressure, and surface latent and sensible heat are
185 used to nudge the model state, thus affecting parameterizations controlling boundary layer exchanges, advective
186 and convective transport, and the hydrological cycle. This model's dynamical constraints, including the Quasi-
187 Biennial Oscillation (QBO), arise from meteorological fields provided by the Modern-Era Retrospective analysis
188 for Research and Applications Version 2 (MERRA-2; Gelaro et al., 2017), and the nudging approach is described
189 by Kunz et al. (2011). The model meteorological fields are nudged from the surface to 50 km; above 60 km, these
190 fields are fully interactive, with a linear transition in between. The model nudging time constant is 50 hours.
191 Model results are obtained from a simulation that, originally, started in 1980 and ended in 2014 (Gettelman et al.,
192 2019); it was later augmented with runs through 2020. After 2014, the greenhouse gas and organic halogen inputs
193 follow the CMIP6 SSP2-45 scenario that projects inputs beyond 2014 (O'Neill et al., 2016; Riahi et al., 2017;
194 Meinshausen et al., 2020), the SPEs are derived from the Geostationary Observational Environmental Satellites
195 (GOES) proton fluxes (Jackman et al., 2008), and the MEEs and GCRs are based on the CMIP6 pre-industrial
196 control.

197 In terms of sampling, the flexibility of WACCM allows for a choice of profiles for local time and spatial
198 coincidences as close as possible to each MLS profile, using the roughly 1° × 1° model bin that includes a given
199 data location for a model local time that falls within 15 minutes of the MLS local time, and binned according to
200 day or night criteria. The model's daily zonal mean profiles (sampled following the MLS locations and local
201 times) are interpolated (as a function of $\log(p)$, where p is pressure) to the MLS retrieval grid points; for ClO and
202 HOCl, this grid is defined by a stratospheric subset of $p(n) = 1000 \times 10^{-n/6}$, in units of hPa, where n is the pressure
203 level index.

204 **2.3 Analysis methods**

205 We have used solar zenith angles less than 90° or larger than 100° to separate daytime from nighttime values,
206 respectively, for both MLS and model profiles; after this selection, monthly zonal means were created.

207 In terms of trend analyses, we follow the approach for MLS data and model trends discussed by Froidevaux et
208 al. (2019), namely a multivariate linear regression (MLR) method, in order to fit the monthly zonal mean time
209 series from both MLS and the model. We refer the reader to Appendix (A3) of the above reference for more details
210 regarding the regression model, which includes commonly used functional terms, namely a linear trend and a
211 constant term, cosine and sine functions with annual and semi-annual periodicities, as well as functions describing
212 variations arising from the QBO and the El Niño / southern oscillation (ENSO); ENSO plays a large role (in
213 comparison to the QBO) only in the lower stratosphere (e.g., Randel and Thompson, 2011). Here, we also include
214 a fitted component that follows variations in solar radio flux (at 10.7 cm), F10.7, based on the Canadian solar
215 measurements described by Tapping (2013). For the trend uncertainty estimates, as mentioned also by Froidevaux
216 et al. (2019), we use a block bootstrap resampling method (Efron and Tibshirani, 1993), as done by Bourassa et
217 al. (2014), Mahieu et al. (2014), and others, in trend analyses of atmospheric composition. Basically, for every
218 fitted time series from MLS and the model, we analyze many (thousands of) resamplings of the fit residuals, with
219 year-long blocks of values replaced by values from randomly chosen years; (twice the) standard deviations in
220 these random distributions provide (2σ) uncertainty values. Such results are typically very similar to the 95%
221 confidence level (which would be arrived at by using the 2.5 and 97.5 percentile limits of the distributions). We
222 have found that such trend uncertainty calculations generally lead to significantly larger error bars than methods
223 that neglect the autocorrelation of the residuals, and even than some methods that include simple correction factors
224 for this autocorrelation (see more details in a later section).

225 **3 Results**

226 **3.1 ClO**

227 We first provide in Fig. 1 an overview of daytime ClO climatological values for January and July (averages
228 for 2005 through 2020) in the 50°S–50°N latitude region, and a comparison to the model results. As a consequence
229 of the photochemical balance between Cl and ClO radicals in the upper stratosphere, the largest ClO abundances
230 occur at pressure levels near 2 to 3 hPa; in the mid- to lower stratosphere, the availability of reactive chlorine is
231 limited by the conversion of ClO and NO₂ to ClONO₂. The observed ClO daytime distributions during January
232 and July are well reproduced by the model results (top and middle panels in Fig. 1, respectively), with ratios
233 between model and data between 0.9 and 1.1 for most latitudes at pressures less than 10 hPa (bottom panels in
234 Fig. 1); in this region, the systematic uncertainty estimates for MLS ClO are about 0.02 to 0.03 ppbv (see Livesey
235 et al., 2020), or of order 5–10%. Near 20–30 hPa, the model ClO values in the winter hemisphere mid- to high

236 latitudes are lower than observed by ~30%, although there is not much available ClO (in a climatological average
237 sense) in this region, and the systematic uncertainty estimates for MLS ClO are of order 0.1 ppbv, which can be
238 as much as 50–100%. Besides these features (and equally good model/data agreement during other months of the
239 year, not shown), we note that the model reproduces the seasonal changes in the peak ClO abundance patterns,
240 which are tied to other seasonal changes. Indeed, it has been shown in the past that seasonal and longer-term
241 variations in the CH₄ and H₂O distributions play a primary role in the chlorine partitioning between upper
242 stratospheric HCl and ClO (see Solomon and Garcia, 1984; Siskind et al., 1998; Froidevaux et al., 2000).

243 Sample time series for the MLS ClO daytime data are shown in Fig. 2, along with the model series, and
244 regression fits (see Sect. 2) to both data and model series. Residual series are shown in the bottom panel of Fig. 2,
245 for the fits to MLS and to the model, and also for the model minus MLS series, after taking out the average model
246 bias versus the data. In this latitude/pressure bin (35–40°N/2.2 hPa), there is a slight model underestimate of the
247 observed time series, but the modelled temporal decrease (reflected in the relevant fitted line) follows the slope
248 of the observed tendency fairly closely. The root mean square (rms) residual values for this panel, and in general,
249 are close to 5–7%, although the WACCM time series actually fit the MLS data better than the regression fits do,
250 as the rms residuals for (de-biased) WACCM versus MLS data are typically between 3 and 5%. These ClO results
251 are further quantified in Fig. 3, where we show excellent agreement between the modeled and observed trends
252 versus latitude at different pressures, in terms of the magnitude and morphology. These results demonstrate
253 statistically significant decreasing ClO trends of about -0.5 to -1% yr⁻¹ in the region between about 30 and 1 hPa
254 from 2005 to 2020, with very good agreement between the measurements and the WACCM6 simulations. Fig. 3
255 also shows that there is no significant difference between modelled and measured ClO trends, given the size of
256 the uncertainties (displayed in these plots as 2σ error bars), as obtained from the statistics of block bootstrap
257 resampling of the fitted residuals (see Sect. 2.3). This good agreement between modelled and measured ClO trends
258 can also be viewed in the pressure/latitude contour plots of Fig. 4; the trend differences (model minus data trends)
259 shown in the bottom panel are usually less than 0.1 to 0.2%yr⁻¹. We note (from Figs. 3 and 4) that there is some
260 asymmetry in the stratospheric ClO trends between the two hemispheres, with stronger decreases at northern than
261 at southern midlatitudes, and with a somewhat more pronounced effect in the lower stratosphere. However, these
262 asymmetries do not carry much statistical significance. These tendencies are opposite to what has been observed
263 in HCl column trends (see Strahan et al., 2020), which show stronger declines in the south than in the north. Lower
264 stratospheric ClO trends are likely to also be related to trends in CH₄ and H₂O, although we do not pursue this
265 quantitatively here, other than through the WACCM results, which show a similar but slightly stronger
266 interhemispheric asymmetry in lower stratospheric ClO trend than in the MLS data. At 32 hPa, we note that there

267 is evidence for low frequency (multi-year) MLS and model ClO variations with poorer regression fits to both data
268 and model (although not shown here and not the focus of this work); this complexity is a likely reason for the
269 larger trend discrepancies (WACCM versus data) in this region. Further investigations of interhemispheric
270 asymmetries in lower stratospheric trends (and related age of air issues) are probably best pursued through detailed
271 studies of longer-lived species than ClO.

272 In Fig. 5, we give the near-global (50°S to 50°N) ClO profile trend results, based on our analyses of monthly
273 zonal mean daytime profile time series for this region as a whole. We obtain very similar trend values if we
274 average results from separate latitude bins, or if we deseasonalize time series from different (narrower) latitude
275 bins prior to the regression. However, we feel it is appropriate to apply the regression analysis to the whole 50°S
276 to 50°N region to describe the resulting uncertainties in these near-global trends in a consistent way, and
277 (particularly) to compare overall ClO trends to those in other species, as we do in a subsequent section. We see
278 from Fig. 5 that measured near-global ClO trends are of order -0.7 to -0.8yr^{-1} in the 15–1.5 hPa range, with
279 values closer to -1yr^{-1} near 20 to 30 hPa. Model ClO trends are typically slightly more negative than observed
280 trends, with an average upper stratospheric value closer to -0.9yr^{-1} (for pressures less than about 15 hPa). In
281 summary, we find very good agreement in the derived ClO trends between the model and the MLS data for 2005–
282 2020, and the differences are not statistically significant.

283 3.2 HOCl

284 We now show results for HOCl, using the same approach as for ClO. The MLS HOCl offline product (see
285 Sect. 2.1) yields climatological fields displayed in Fig. 6 for January and July, over the 10 to 2 hPa region, where
286 the MLS HOCl data are deemed to be scientifically useful (see Livesey et al., 2020); this vertical range also holds
287 for the offline product. We observe peak HOCl January (daytime) values of about 160 pptv near 5 hPa at mid- to
288 high latitudes in the Southern Hemisphere, with slightly larger July peak values in the Northern Hemisphere (near
289 45°N). These patterns are also seen in the model HOCl (daytime) distributions, albeit with a shift to smaller
290 abundances; as seen from the model/MLS ratios in the bottom panels of Fig. 6, model HOCl values are typically
291 about 30% smaller than the mean measurements from MLS. This model-measurement difference is also seen in
292 the nighttime HOCl climatology, as shown in the supplementary material (Fig. S1). A small upward shift in the
293 altitude of peak nighttime HOCl abundances is seen in the MLS data, in comparison to the daytime case (Fig. 6),
294 as well as in the model values. Such a diurnal shift in the distribution of HOCl was also noted in the global satellite
295 measurements of HOCl made by the Michelson Interferometer for Passive Atmospheric Sounding (MIPAS)
296 aboard Envisat (von Clarmann et al., 2006; 2012). We note here that the MLS HOCl measurements have fairly

297 large systematic uncertainties (2σ estimated systematic errors of 30–100%, see Livesey et al., 2020), which could
298 thus largely explain the model/data differences. We also note that slightly smoother profiles would be obtained
299 by applying the MLS averaging kernels to the model profiles, since the MLS HOCl vertical resolution is 5–6 km;
300 doing so would lead to an even larger model underestimate of the MLS HOCl profiles.

301 Another consideration to factor into the model uncertainties for HOCl has to do with the uncertainties in the
302 rate constant for HOCl formation ($k_{\text{HO}_2+\text{ClO}}$). While the model used here conforms to the JPL Evaluation 18
303 (Burkholder et al., 2015) rate constant for this reaction, a more recent rate constant determination by Ward and
304 Rowley (2016) leads to significantly faster HOCl formation. Model simulations were performed to compare
305 annual mean HOCl abundances (50°S – 50°N) based on these different choices of $k_{\text{HO}_2+\text{ClO}}$, as shown in Fig. 7 (a);
306 the percent differences (in panel (b)) indicate that 25–45% larger HOCl abundances are obtained with the faster
307 rate constant, depending on altitude. The issue of a fairly poorly determined HOCl formation rate constant has
308 persisted for a number of years, affecting comparisons of balloon-borne HOCl profiles and model results
309 (Kovalenko et al., 2007), as well as analyses of MIPAS HOCl observations (von Clarmann et al., 2009; 2012).
310 Kovalenko et al. (2007) pointed out the need for a faster rate constant to improve agreement between modelled
311 and measured HOCl, such as the rate constant measured by Stimpfle et al. (1979), in comparison to the current
312 (at the time) value from the JPL Evaluation of Chemical Kinetics and Photochemical Data (Sander et al., 2006);
313 this position was supported by the MIPAS measurements of HOCl and other species over Antarctica (von
314 Clarmann et al., 2009). Using a temperature of 240 K, appropriate for the region of interest here, in previous
315 temperature-dependent laboratory studies leads to five different rate constant values that have oscillated over time.
316 Specifically, the values from Stimpfle et al. (1979), Nikolaisen et al. (2000), Knight et al. (2000), Hickson et al.
317 (2007), and Ward and Rowley (2016), respectively, yield 11.3, 10.3, 6.6, 8.6, and 12.5 (all in units of 10^{-12} cm^3
318 $\text{molecule}^{-1} \text{ s}^{-1}$), leading to an average of 9.7 with a (1σ) scatter of 2.1, or a range of about 3, if all five estimates
319 are included. For comparison, the latest JPL Evaluation (Burkholder et al., 2019) gives an HOCl formation rate
320 constant of $8.7 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, although that particular report did not take into account the work from
321 Ward and Rowley (2016). However, making use of the Superconducting Submillimeter-Wave Limb-Emission
322 Sounder (SMILES) HOCl, ClO, and HO₂ data versus time of day, Kuribayashi et al. (2014) obtained a seemingly
323 well-constrained estimate of $k_{\text{HO}_2+\text{ClO}}$ for a limited temperature and pressure range ($7.75 \pm 0.25 \times 10^{-12} \text{ cm}^3$
324 $\text{molecule}^{-1} \text{ s}^{-1}$ at 245 K in the upper stratosphere). This leads to a value of $\sim 8.3 \times 10^{-12}$ at 240 K (as inferred using
325 an average temperature dependence), consistent with, but slightly smaller than, the latest evaluation’s
326 recommendation mentioned above. To summarize, we find that the differences between MLS and model values
327 could well stem from a combination of uncertainties in both the MLS data and the model, and it is not possible to

328 definitively attribute the discrepancy to one or the other data set. This discussion does not include other uncertainty
329 sources (e.g., the photochemical loss rate of HOCl), as we believe that they are smaller in magnitude.

330 The MIPAS HOCl measurements were taken at about 10am/pm local time during 2002–2004; the SMILES
331 HOCl data cover the full diurnal cycle, but only for part of 2009–2010. The ACE-FTS solar occultation (i.e.,
332 sunrise/sunset) measurements have recently included retrievals of stratospheric HOCl profiles (up to about
333 38 km), as discussed by Bernath et al. (2021). The various satellite measurements of near-global HOCl
334 distributions are not easily compared, given their different local times and the non-negligible diurnal changes in
335 HOCl (see SPARC, 2017). Upper stratospheric peak HOCl values from ACE-FTS, MIPAS, Aura MLS, and
336 SMILES range from about 150 to 200 pptv, with MIPAS providing the largest values, as summarized by Bernath
337 et al. (2021). Khosravi et al. (2013) provided a more detailed intercomparison of HOCl measurements from
338 MIPAS, SMILES, and MLS in the upper stratosphere, with the help of model simulations of the diurnal cycle
339 (and ClO intercomparisons were also discussed). Good agreement was obtained, overall, versus the expected
340 HOCl diurnal variations, despite the noise in some of the data sets (with SMILES HOCl producing the least noisy
341 data). In SPARC (2017), HOCl monthly zonal mean distributions from MIPAS, SMILES, and MLS were
342 intercompared, albeit not for the same range of years (see also the recent update by Hegglin et al., 2021). Nighttime
343 values were used, as this time period exhibits somewhat smaller changes versus local time than the daytime data.
344 The MLS HOCl data were shown to be on the low side (by 20 to 30%) of both the MIPAS and SMILES results,
345 with the SMILES values lying between the MLS and MIPAS values; a low bias in MLS HOCl was also seen in
346 the comparisons presented by Khosravi et al. (2013). However, those studies used v3 HOCl data from the standard
347 MLS product. Mean differences between v3 HOCl and v5 HOCl are of order 5–10%, with the v5 data on the low
348 side of v3. More to the point, the offline HOCl retrievals yield larger values, by about 25%, than the monthly
349 zonal means from the standard v5 product, as can be seen from a comparison of Fig. 6 for the offline MLS HOCl
350 climatology versus Fig. S2 for the standard MLS HOCl product. The HOCl offline data values are thus about 20%
351 larger than the v3 MLS standard product values, so that much of the MLS low bias versus MIPAS and SMILES
352 is mitigated by using the offline MLS HOCl product. It follows from the above comments that the WACCM6
353 values will also significantly underestimate the HOCl abundances from MIPAS and SMILES. Based on the above
354 references discussing past satellite data intercomparisons for HOCl, the (2σ) systematic uncertainties for non-
355 MLS HOCl data sets are likely larger than 10–15%. The MLS v5 HOCl uncertainties are in the 40–80 pptv range
356 (see Livesey et al., 2020), or at least ~25% (and significantly more in the lower part of the upper stratosphere); it
357 is reasonable to expect that the offline MLS HOCl product will be affected by very similar systematic uncertainties

358 as the MLS standard product. In summary, we cannot expect much better agreement between the various HOCl
359 data sets than the (roughly) 20% level of agreement implied here.

360 Turning to the derived trends in HOCl, these will not be affected much (in units of $\% \text{yr}^{-1}$) by mean differences
361 between measured and modeled climatological values. As was done earlier for the ClO time series, we show
362 sample daytime HOCl time series, fits, and residuals in Fig. 8. We observe from such time series that, apart from
363 the absolute value difference between MLS and model HOCl, the measured seasonal cycle is well reproduced by
364 the model; less photochemical destruction of upper stratospheric HOCl during the winter months accounts for the
365 wintertime high values in the region shown (top panel). The residuals in this example (and in general) are larger,
366 by at least a factor of two, than those for ClO, and the correlation coefficients for the fits and for model versus
367 data are poorer, especially when comparing regression fits to the data and (de-biased) model fits to the data; the
368 poorer fits arise because the MLS HOCl data set is noisier (even for monthly zonal means) than is ClO. Thus, in
369 the case of HOCl, the regression fits to the model give the best results, in terms of correlation coefficients between
370 the regression fits to the MLS or model series, as well as for the de-biased model curves in comparison to the data,
371 and regarding root mean square residuals (as derived from data such as the curves in the bottom panel of Fig. 8).
372 The derived trends for HOCl are shown in Fig. S3 as a function of latitude, from 2.2 to 10 hPa. Many of the MLS-
373 derived trends at specific pressures and latitudes are not statistically different from a zero-trend value, while the
374 model-derived trends are typically negative (with values that are more negative than the measured trends) and
375 statistically different from zero. Figure 9 provides a summary of the results for MLS and model HOCl trends, with
376 day and night data shown separately, after multiple regression is applied to the averaged 50°S – 50°N time series.
377 For MLS data between 3 and 7 hPa, we obtain statistically significant decreasing near-global HOCl trends, both
378 day and night. These results provide an unambiguous indication of decreasing upper stratospheric trends in HOCl,
379 given that negative trend center values occur at all retrieval levels. There is no statistically significant difference
380 between the nighttime and daytime results for either the MLS data or the model. The average model HOCl trend
381 ($-0.6\% \text{yr}^{-1}$) is more negative than the average MLS result ($-0.4\% \text{yr}^{-1}$), although this is not a statistically significant
382 difference, given the (2σ) error bars shown in Fig. 9, and the fact that the MLS HOCl vertical resolution is about
383 6 km, so there are really only about 3 independent retrieval levels in the pressure range displayed in Fig. 9 (and
384 any error reduction for averaged results over all pressures would be by a factor of $\sqrt{3}$, or 1.7, at best). However,
385 the nighttime model and data trends at 2 hPa agree better than the daytime results, with the nighttime MLS trends
386 exhibiting a more homogeneous behavior versus pressure than the daytime MLS trends. This is likely caused by
387 the larger MLS signal for nighttime HOCl (see the climatological values in Fig. S1 versus the daytime values in
388 Fig. 6); the nighttime MLS trend errors are also smaller than the corresponding daytime errors.

389 We show in Fig. 10 a summary of the trend profiles for ClO and HOCl, both based on daytime results. We
390 mentioned above that the nighttime HOCl results agree well with those from daytime HOCl, and display better
391 agreement versus the model nighttime results at 2 hPa. For ClO, we have also checked that nighttime trends over
392 a limited pressure range (from 1.5 to 3.2 hPa) agree with the daytime trends (not shown), but nighttime ClO values
393 are typically much smaller than those during the day at pressures larger than 4 hPa, where we found that no robust
394 nighttime ClO trends can be obtained from the MLS data. Figure 10 demonstrates that both of these chlorine
395 species have decreased over much of the globe during the past 16 years, with the ClO trends being more negative
396 (by $\sim 0.35\% \text{yr}^{-1}$) than the trends in HOCl, both in the model and the observational results. Limiting results to an
397 average over the uppermost stratosphere (between 2.2 and 6.8 hPa for both species), the (daytime) MLS-derived
398 near-global upper stratospheric trends are $-0.73 \pm 0.40\% \text{yr}^{-1}$ for ClO and $-0.39 \pm 0.35\% \text{yr}^{-1}$ for HOCl. The (2σ)
399 error bars here are the root mean square value applicable to this vertical range, with no reduction in error bars for
400 the broader region; we would rather use a somewhat more conservative uncertainty than one that is too
401 “optimistic” (such as an error reduction by a factor of two for ClO, which assumes uncorrelated errors between
402 pressure levels). The corresponding model trends for this vertical range are $-0.85 \pm 0.45\% \text{yr}^{-1}$ for ClO and -0.64
403 $\pm 0.37\% \text{yr}^{-1}$ for HOCl. Even if the HOCl trends are not significantly different from the ClO trends at any given
404 level, when averaged, these differences do become more significant.

405 In terms of the time series variability and the regression fits, the largest components are, by far, the annual and
406 semi-annual terms (with their relative impacts somewhat dependent on latitude and pressure). For both the
407 observed and modeled near-global cases shown in Fig. 10, about 70–80% of the explained variance arises from
408 these two terms. The ENSO and solar terms typically account for less than a few percent of the explained variance,
409 and the same is true for short-period (less than 6-month) terms. The QBO signal is generally the largest component
410 that remains, if one considers near-global deseasonalized percent anomaly time series, as seen in Fig. 11 for ClO
411 and HOCl at two upper stratospheric pressure levels. The data and model fits generally behave in similar ways,
412 although there can be some small differences between the two. The correlation coefficients between observed
413 HOCl and ClO anomaly time series are of order 0.6–0.7 in the upper stratosphere (with values close to 0.8 if one
414 smooths out some of the short-term variability in the time series first). The model ClO anomalies track the
415 observed anomalies quite well (with correlation coefficients close to 0.8). We provide the percent residuals
416 associated with Fig. 11 in Fig. S4; these tend to be about twice as large for HOCl (of order $\pm 10\%$) as those for
417 ClO (of order $\pm 5\%$).

418

419 4 Discussion

420 We now review our estimated trends in the context of past results, and we discuss potential reasons for different
421 trends in various chlorine species in the upper stratosphere, including the slower decrease in upper stratospheric
422 HOCl in comparison to the ClO decrease. As a reminder of the relative importance of the main inorganic chlorine
423 species in the upper stratosphere, we display in Fig. 12 the percent contribution to total inorganic chlorine (Cl_y)
424 over the 10 to 1 hPa range, based on the climatological (daytime) model results over 50°S – 50°N for the time
425 period analyzed here. The Cl_y abundance includes all species contributions from HCl, ClO, HOCl, and ClONO_2 ,
426 which are shown in the plot, as well as very minor contributions from Cl, Cl_2 , Cl_2O_2 , OCIO, and BrCl. The “Sum”
427 curve shown on the right side of this figure is just the sum from the four main species whose contributions are
428 plotted; this does not quite equal 100% because of the very small (daytime) relative contributions from the latter
429 five species. HCl is clearly the dominant reservoir in the upper stratosphere, as it makes up about 80 to 95% of
430 total inorganic chlorine in this region (see also Froidevaux et al., 2006), while ClO makes up about 5 to 15% of
431 the total, with minor contributions from ClONO_2 and HOCl, both at the few percent level for most of this region.

432 While published trends in chlorine species can be compared, there will always be some differences in the
433 results, given the different measurement locations, coverage, and time periods being considered. We note that the
434 surface maximum in total chlorine was reached in 1992–1993; following the fast initial decrease in methyl
435 chloroform (CH_3CCl_3), tropospheric chlorine declined at a slower rate (O’Doherty et al., 2004). There is also
436 evidence for slightly slower decreases in the ACE-FTS upper stratospheric HCl time series after about 2010
437 (Bernath and Fernando, 2018; Bernath et al., 2020), in comparison to the rate of decline over the 2004–2010
438 period. In terms of the MLS ClO results discussed here, the upper stratospheric trend (for 2005–2020) of
439 $-0.73 \pm 0.40 \text{ \%yr}^{-1}$ can be compared to other estimated trends in upper stratospheric ClO. Jones et al. (2011)
440 reported upper stratospheric ClO trends of $-0.7 \pm 0.8 \text{ \%yr}^{-1}$ for 2001 through 2008, based on a combination of
441 Odin Sub-Millimetre Radiometer (SMR) and Aura MLS data over the tropics; the estimated uncertainty in this
442 satellite-based ClO trend is quite large, but the trend estimate is consistent with our result covering a longer time
443 period. Solomon et al. (2006) displayed the rise and decline of upper stratospheric ClO abundances in the 1982 to
444 2004 time period, based on microwave ground-based profile data from Hawaii. However, the fairly large ClO
445 trend (-1.5 \%yr^{-1}) initially obtained by these authors for 1995–2004 was superseded by analyses of an improved
446 data set over a longer time period using a new methodology (Connor et al., 2013), which led to a ClO trend
447 estimate (at about 4 hPa) of $-0.65 \pm 0.15 (2\sigma) \text{ \%yr}^{-1}$ over the 1995–2012 period. Thus, we find good consistency

448 between our MLS results and previous trend estimates for ClO, especially given the differences in measurement
449 coverage and time periods considered.

450 For the HOCl trends, we are aware of only one prior result, a recent trend estimate based on ACE-FTS HOCl
451 data by Bernath et al. (2021), who quote a marginally significant trend of -0.23 ± 0.22 (2σ) pptv yr⁻¹, which we
452 translate to about -0.19 ± 0.18 %yr⁻¹, given mean HOCl abundances (of 124 pptv) from their analysis of ACE-
453 FTS data at 30–39 km and 60°S–60°N from 2004–2020. This can be compared to our near-global MLS HOCl
454 trend estimate of -0.39 ± 0.35 %yr⁻¹ for a very similar time period; while these two estimates agree within the
455 fairly large uncertainty estimates, the MLS mean trend value represents twice as rapid a decrease as the mean
456 ACE-FTS trend result. At this time, the cause of these differences is not known, although these measurements are
457 among the more difficult for both instruments, and the two sampling patterns are quite different. We note that the
458 model upper stratospheric HOCl trend is faster (at -0.64 ± 0.37 %yr⁻¹) than the MLS-derived trend, and even
459 faster in comparison to the ACE-FTS result.

460 We now turn to some additional model results as well as other relevant measurements from MLS and ACE-
461 FTS, to discuss upper stratospheric trends in chlorine and related species in a broader context. Figure 13 shows
462 the derived average trends in various upper stratospheric chlorine species based on our regression analyses of
463 measured and modeled time series for monthly zonal means from 50°S to 50°N. The near-global upper
464 stratospheric trend values in Fig. 13 are obtained from trends like those in Fig. 10 for MLS ClO and HOCl, but
465 averaged from 6.8 to 2.2 hPa. Error bars represent typical 2σ estimates, calculated from the root mean square of
466 the 2σ estimates for pressures in the 6.8 to 2.2 hPa range; we prefer to use this more conservative error rather than
467 the standard error in the mean, which will typically be an underestimate, since errors from different pressure levels
468 are not completely uncorrelated. As mentioned earlier, no useful MLS-based estimate of HCl trends in the upper
469 stratosphere could be obtained after the related MLS hardware degradation in early 2006. MLS HCl measurements
470 are still scientifically useful in the lower stratosphere, even for trends (see the related model/data analysis by
471 Froidevaux et al., 2019), and certainly they accurately capture the larger seasonal, interannual, and winter polar
472 vortex HCl variations. To derive the trends based on ACE-FTS data shown in Fig. 13, we have used seasonally
473 averaged time series of v4.1 measurements, a methodology used in previous investigations of ACE-FTS trends to
474 lessen the impacts of that instrument’s sampling patterns (e.g., see Bernath and Fernando, 2018). We have applied
475 a simple linear fit to the deseasonalized anomalies from ACE-FTS seasonal means (from 50°S to 50°N), thus
476 using the same type of analysis as in the latter reference. In this approach, the auto-correlation of the residuals is
477 taken into account by following the methodology described by Tiao et al. (1990) and Weatherhead et al. (1998);

478 the auto-correlation is assumed to follow a first-order autoregressive model, and the trend error bars are multiplied
479 by a factor that depends on the autoregressive coefficient. We also point out that it would be more complicated to
480 apply the MLR approach used for the MLS and model time series to the ACE-FTS seasonal data, as the MLR
481 method we have used is based on monthly proxy values. A careful intercomparison of different approaches to
482 estimate error bars in various trends analyses is beyond the scope of this paper, although such an intercomparison
483 would be helpful.

484 We see in Fig. 13 (as was shown in Fig. 10) that the MLS ClO trend is more negative than the MLS HOCl
485 trend; this is also true for the model results in Fig. 13, and the model ClO trend is also more negative than the
486 model Cl_y and HCl trends (with respective values of $-0.66 \pm 0.30 \text{ \%yr}^{-1}$ and $-0.64 \text{ \%} \pm 0.30 \text{ \%yr}^{-1} (2\sigma)$). The
487 faster ClO decrease (versus Cl_y or HCl) seen in Fig. 13 is tied to the dependence of ClO on other species. More
488 specifically, the ClO abundance ([ClO]) is roughly proportional to $[\text{HCl}] [\text{H}_2\text{O}]^{1/2} / [\text{CH}_4]$ (see Froidevaux et al.,
489 2000). The model and observed trends in both H₂O and CH₄ agree well (see the bottom portion of Fig. 13). Here,
490 we have averaged all ACE-FTS (50°S–50°N) trends between 33 and 43 km, based on all sunrise and sunset
491 profiles combined. The MLS v5 H₂O trend of $0.13 \pm 0.15 (2\sigma) \text{ \%yr}^{-1}$ is close to the trend we obtain from ACE-
492 FTS data, at $0.18 \pm 0.15 \text{ \%yr}^{-1}$ (which is in reasonable agreement with the near-global mid-stratospheric H₂O trend
493 of 0.24 \%yr^{-1} provided in the broad overview of ACE-FTS trends by Bernath et al., 2020). Although the MLS v4
494 H₂O data suffered from a drift that led to trends that were too large, this drift has been largely mitigated in the v5
495 H₂O data used here (Livesey et al., 2021). The measured trend in CH₄, also obtained from ACE-FTS data, as well
496 as the model CH₄ trend (in very good agreement with the ACE-FTS trend), are significantly larger than the trends
497 in H₂O; more CH₄ will thus lead, in time, to less chlorine in the form of ClO, which means a faster rate of decrease
498 for ClO. The photochemical balance for HOCl, on the other hand, leads to [HOCl] being roughly proportional to
499 $k_{\text{HO}_2+\text{ClO}} [\text{ClO}] [\text{HO}_2] / (J_{\text{HOCl}} + k_{\text{HOCl}+\text{OH}} [\text{OH}] + k_{\text{HOCl}+\text{O}} [\text{O}])$, where J_{HOCl} is the photodissociation rate constant for
500 HOCl, and the rate constants indicate which HOCl production or destruction reaction we are referring to. In the
501 mid- to upper stratosphere, the J term clearly dominates (e.g., see Chance et al., 1989, and also, based on our
502 diagnostics for the WACCM run used here), and we would thus expect the trend in HOCl to be less negative than
503 the trend in ClO, given that the HO₂ trend is (slightly) positive (per Fig. 13). The MLS-derived trend for HO₂
504 comes from our analysis of the offline MLS HO₂ product (see Millán et al., 2015). As recommended for this
505 product, we performed our trend analysis using day minus night differences, that is, we constructed such monthly
506 zonal means from the set of day and night daily zonal means; the model and data HO₂ trends agree within the
507 error bars, although the MLS error bar is quite large. The model OH trend also points to a slight positive trend,
508 which likely stems from the increasing trends in H₂O. Algebraically, a percent change in HOCl will be driven by

509 the percent change in ClO added to the percent change in HO₂, so that the decreasing trend in HOCl is slowed,
510 relative to the ClO trend, by the increasing trend in HO₂. Using the modelled HO₂ trend in Fig. 13 (~0.2% yr⁻¹),
511 which is consistent with the observed HO₂ trend, one could expect the HOCl trend to lie ~0.2% closer to zero than
512 the ClO trend; this is consistent (within the error bars) with both the modelled and measured trend differences
513 between HOCl and ClO (these differences are ~0.2% and 0.3%, respectively, for the model and for the
514 measurements).

515 The ClONO₂ trends shown in Fig. 13 are less negative than the ClO trends; this likely stems from the slightly
516 positive trends in NO₂, which can mitigate the extent of the decrease in ClONO₂ (formed from ClO and NO₂). We
517 also note that the differences between the model and ACE-FTS HCl trends are somewhat larger than those between
518 the model and MLS ClO, although the error bars in Fig. 13 indicate that none of these differences are statistically
519 significant. It has been shown that the better sampling from emission-type measurements can provide more
520 reliable trend estimates than in the case of sparser sampling (e.g., from occultation-type data; see Millán et al.,
521 2016). We expect that sampling differences between ACE-FTS and MLS (or the model) contribute part of the
522 trend differences versus MLS (or the model). In this regard, error bars in the ACE-FTS trends are likely to be
523 smaller than the errors that would be obtained from a more fully sampled dataset with less data averaging (and
524 thus, with more spatio-temporal variability).

525 While this is less pertinent to the chlorine species trends, we find it interesting that the N₂O trends in Fig. 13
526 appear to be much larger than the trends in NO and NO₂, two radicals that are the products of N₂O destruction in
527 the upper stratosphere; MLS, ACE-FTS, and the model results all point to upper stratospheric trends slightly larger
528 than 1% yr⁻¹, albeit with comparable 2σ uncertainties. Some of this difference might be caused by the strong
529 latitude dependence of the N₂O trends, coupled with large trend uncertainties in a region with rapidly decreasing
530 abundances with height; the N₂O trends from ACE-FTS at lower altitudes yield small positive values that are
531 more consistent with the NO_x trends shown here, and also with tropospheric N₂O trends (see also Bernath et al.,
532 2020). We note also that the MLS N₂O trends likely constitute lower limits, given that there are some unmitigated
533 negative drifts in the version 5 MLS N₂O time series in the lower stratosphere, even after the improvements versus
534 the v4 data (Livesey et al., 2021). Finally, there are also temperature-related effects that could potentially modify
535 the partitioning of chlorine species over the long-term. However, since the average upper stratospheric
536 temperature decrease over the past 16 years is less than 1K (e.g., Steiner et al., 2020), the temperature dependence
537 issue for this time period should not lead to a significant perturbation of chlorine species trends and chlorine
538 partitioning in this region. For the ClO or HOCl photochemical balance in particular, the strongest temperature-
539 dependence (by far) is from the Cl + CH₄ reaction, but even this would lead to a fairly small (15-30%) perturbation

540 (for the cooling rate implied above) in comparison to the impact of the CH₄ trend, or versus the trends in the
541 chlorine species themselves.

542 We have provided above a few arguments that can help explain some of the differences in upper stratospheric
543 chlorine species trends summarized in Fig. 13. The full chemistry climate model takes all the (modelled) factors
544 into account, both regarding photochemical balance issues and any underlying dynamical factors, such as
545 variations and trends in long-lived tracers that can also impact shorter-lived species.

546 **4 Conclusions**

547 We have analyzed Aura MLS monthly zonal mean time series of ClO and HOCl between 50°S and 50°N to
548 estimate upper stratospheric trends in these chlorine species from 2005 through 2020. We compare these
549 observations to those from a state-of-the-art chemistry climate model, WACCM6, run under the specified
550 dynamics configuration, with MERRA-2 meteorological constraints, and sampled for the same time period; in
551 addition, the model sampling follows the MLS coverage in space and local time. We use version 5 MLS ClO
552 zonal mean (Level 3) daytime profiles (associated with solar zenith angles less than 90°) and, for comparison,
553 similarly binned daytime ClO model profiles. For MLS HOCl, we use the version 5 offline product derived from
554 daily zonal mean radiances (in 10° latitude bins) rather than averaged Level 2 profiles; MLS HOCl is scientifically
555 useful between 10 and 2 hPa, and HOCl monthly zonal means are separated into day and night averages (solar
556 zenith angles greater than 100° for night conditions), for comparison to similarly binned WACCM6 HOCl profiles.

557 We find good agreement (mostly within about 10%) between the climatological MLS daytime ClO
558 distributions and the corresponding model ClO climatology for 2005–2020. The model HOCl climatology,
559 however, underestimates the MLS HOCl climatology by about 30% (for both daytime and nighttime). This
560 discrepancy could well be caused by a combination of fairly large systematic uncertainties in both the model-
561 assumed rate constant for the formation of HOCl and the MLS HOCl retrievals themselves, although we note that
562 these model results would likely also underestimate other satellite measurements of HOCl. The model daytime
563 ClO trends versus latitude and pressure agree well with those from MLS ClO. Between 15 and 32 hPa, there are
564 indications of some interhemispheric asymmetry in the MLS ClO trends, with faster decreases at northern than at
565 southern midlatitudes, although this is not statistically significant; there is also evidence for low frequency (multi-
566 year) variability, especially at 32 hPa. Further investigations of interhemispheric asymmetries in lower
567 stratospheric trends (and related age of air issues) are probably best pursued through detailed studies of longer-
568 lived species than ClO.

569 MLS-derived near-global upper stratospheric daytime trends between 7 and 2 hPa are $-0.73 \pm 0.40 \text{ \%yr}^{-1}$ for
570 ClO and $-0.39 \pm 0.35 \text{ \%yr}^{-1}$ for HOCl, with 2σ uncertainty estimates used here. The corresponding near-global
571 upper stratospheric model trends are $-0.85 \pm 0.45 \text{ \%yr}^{-1}$ for ClO and $-0.64 \pm 0.37 \text{ \%yr}^{-1}$ for HOCl. Both data and
572 model results point to a slower trend for HOCl than for ClO. The MLS trends for ClO are generally consistent
573 with past estimates of upper stratospheric ClO trends, based on a combination of Odin/SMR and MLS data from
574 2001 to 2008 (Jones et al., 2011), and based on ground-based microwave results from Hawaii for 1995–2012
575 (Connor et al., 2013). The MLS HOCl trend represents a faster rate of change (by about a factor of two) than the
576 marginally significant trend ($-0.19 \pm 0.18 (2\sigma) \text{ \%yr}^{-1}$) that Bernath et al. (2021) obtained from a recent analysis
577 of ACE-FTS HOCl measurements from 2004 to 2020.

578 Our general overview (Fig. 13) shows decreasing near-global trends for all the measured upper stratospheric
579 chlorine species. Differences can arise as a result of the impact of trends in other gases that can affect the slowly
580 varying photochemical equilibrium for different species in this region. Notably, observed and modeled positive
581 trends in CH_4 will tend to steepen the decrease of active chlorine (ClO values) in comparison to trends in HCl or
582 Cl_y . Regarding trends in HOCl, positive trends in HO_2 can lead to a faster rate of formation for HOCl as a function
583 of time, which partially offsets the impact of decreases in ClO (also involved in HOCl production).

584 Lastly, the decreasing trends in upper stratospheric ClO and HOCl that are arrived at in this work provide
585 additional confirmation of the effectiveness of the Montreal Protocol and its amendments, which have led to the
586 early stages of an expected long-term ozone recovery from the effects of ozone-depleting substances (see WMO,
587 2018). Indeed, the known decreases in surface chlorine since the early 1990s, which are faithfully included in the
588 model results, have played a major role in the decreasing trends of ClO and HOCl over the 2005–2020 time period.

589

590

591 *Data availability.* The link <http://disc.sci.gsfc.nasa.gov/Aura/data-holdings/MLS> provides public access to Aura
592 MLS data used here; for the offline MLS HOCl product, the data are available upon request to Luis Millán
593 (luis.f.millan@jpl.nasa.gov). For the availability of ACE-FTS 4.1 data, see <http://www.ace.uwaterloo.ca/data.php>
594 (registration required at <https://database.scisat.ca/l2signup.php>). For solar flux data, the site
595 ftp://ftp.seismo.nrcan.gc.ca/spaceweather/solar_flux/monthly_averages/solflux_monthly_average.txt was used to
596 obtain monthly means of the Canadian F10.7 solar flux measurements; these series (see
597 <http://www.spaceweather.gc.ca>) were included in our regression fits. MERRA-2 data can be obtained from NASA
598 at https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/data_access/. Model results shown in this paper are available
599 online at:

600 [https://urldefense.us/v3/https://acomstaff.acom.ucar.edu/dkin/ACP_Froidevaux_2021/!!PvBDto6Hs4WbVuu7!Yk6MAjKksie5II_GsOOzm_FmoXFSt_0ExPIxMEA6hEUdqF6I4S72h5M3WBjsxoKwX1vZRj9wgz6b\\$.](https://urldefense.us/v3/https://acomstaff.acom.ucar.edu/dkin/ACP_Froidevaux_2021/!!PvBDto6Hs4WbVuu7!Yk6MAjKksie5II_GsOOzm_FmoXFSt_0ExPIxMEA6hEUdqF6I4S72h5M3WBjsxoKwX1vZRj9wgz6b$.)

602

603 *Author Contributions.* LF prepared this manuscript with contributions from all co-authors. DEK provided inputs
604 for running the necessary model runs, as well as properly averaged and formatted outputs from the model, along
605 with various contributions to the main text and Figures. MLS provided assistance in the validation and generation
606 of the MLS ClO data, along with comments on the manuscript. LFM provided the MLS HOCl offline products
607 and related expertise, along with comments on the manuscript. NJL provided leadership for MLS overall, along
608 with comments regarding the manuscript. WGR provided leadership for the MLS forward model and data
609 retrievals, along with measurement science expertise and related manuscript comments. CGB provided assistance
610 towards obtaining the model runs, as well as comments regarding the model description. JJO provided assistance
611 regarding the available laboratory data on the HOCl formation rate constant and its related uncertainties, along
612 with manuscript comments. RAF provided properly formatted and averaged MLS data sets for the various species
613 analyzed in this work.

614

615 *Competing Interests.* The authors declare that they have no conflict of interest.

616

617 *Acknowledgments.* We are thankful to the whole MLS team (past and present) for their contributions over the
618 years to the MLS instrument, data, processing, and database management; all this has contributed to making this
619 research work possible. We also gratefully acknowledge the work of the whole ACE-FTS team in producing and
620 sharing their updated data sets, as these were used here as part of the discussion and comparisons. F10.7 data
621 collection and dissemination are supported by the National Research Council of Canada, with the participation of
622 Natural Resources Canada and support by the Canadian Space Agency. D.E.K. was funded in part by NASA grant
623 (80NSSC20K0926). WACCM is a component of the CESM, supported by the National Science
624 Foundation (NSF). We would like to acknowledge high-performance computing support from Cheyenne
625 (doi:10.5065/D6RX99HX) provided by NCAR's Computational and Information Systems Laboratory, sponsored
626 by the NSF. Work at the Jet Propulsion Laboratory, California Institute of Technology, was performed under
627 contract with the National Aeronautics and Space Administration (80NM0018D0004). Copyright 2021. All rights
628 reserved. We also gratefully acknowledge the reviewers of this work for their comments and suggestions.

914
915

916 **Figure 1.** Climatological mean fields (over 2005 through 2020 for CIO (daytime data) from MLS and model results between
 917 50°S and 50°N and 32 to 1.5 hPa. Daytime averages (observed and simulated values) are based on values with solar zenith
 918 angles less than 90° only. (a) and (b) show the January MLS and model climatologies, respectively, while (c) gives the ratio
 919 (model values divided by MLS values) for that month; (d), (e), and (f) are the same as (a), (b), and (c), respectively, but for
 920 July instead of January. The model daily values (throughout this work) were sampled to provide the closest match in space
 921 and time to the MLS daily Level 2 data; model results were then binned in latitude and averaged over each month, and
 922 interpolated to the MLS pressure grid, in order to best match the averaging process of MLS monthly zonal mean data.

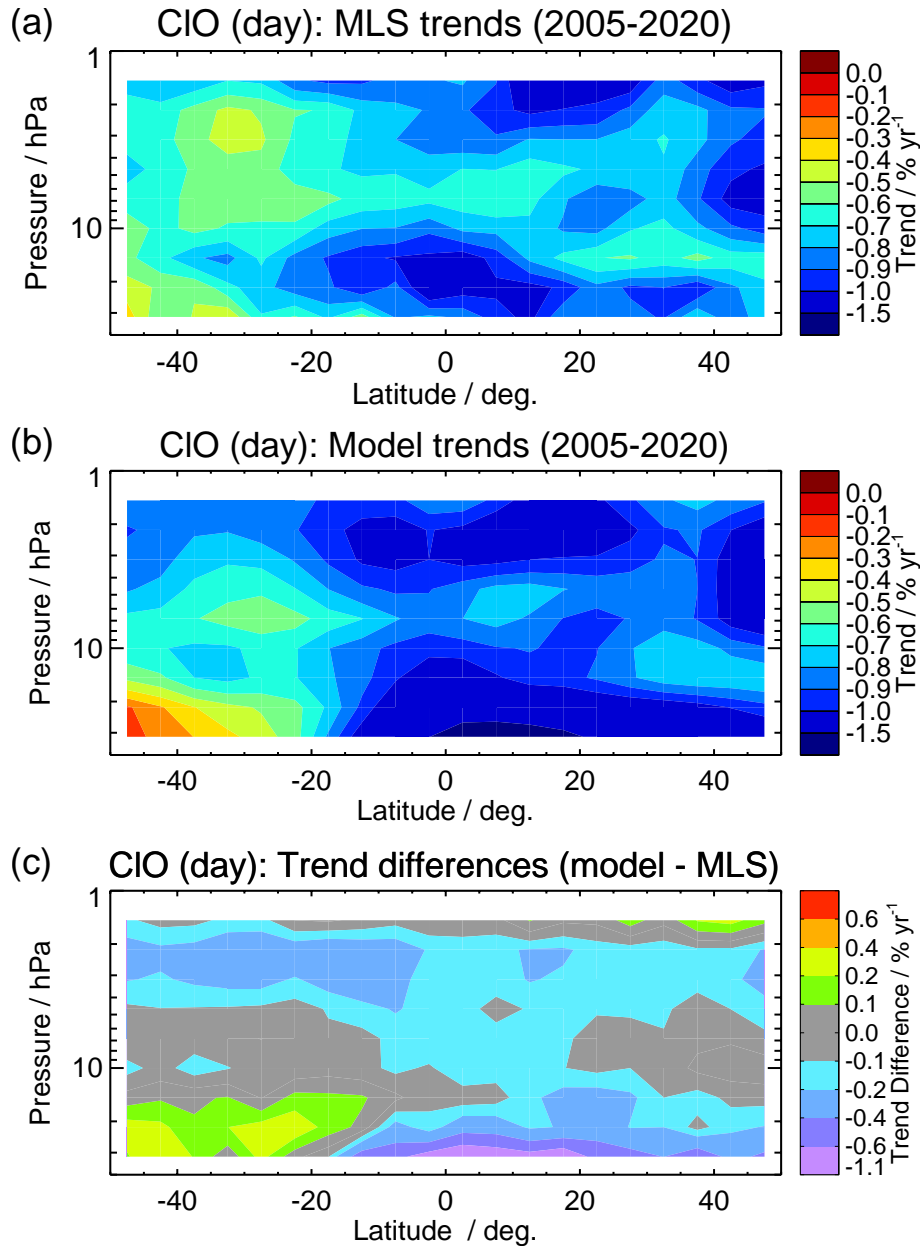

923
 924
 925
 926
 927
 928
 929

Figure 2. (a) Examples of MLS and model CIO (day) monthly zonal mean time series (2005 through 2020) for the 35°N–40°N latitude bin at 2.2 hPa. The MLS data (blue) are fitted by a regression model (grey), and the model series (red) is fitted by the same type of regression model (orange). The dark grey and orange lines are the linear components of the corresponding fits to the MLS and model curves, respectively. (b) Percent residuals, for the fit to MLS (fit minus MLS) in grey, for the fit to the model (fit minus model) in orange, and for the debiased model minus MLS time series in pink.

Figure 3. Linear trends in upper stratospheric CIO (2005 through 2020) at different pressure levels versus latitude, as obtained from multiple regression analyses applied to monthly zonal mean daytime series from MLS (blue) and the model (red). Error bars depict the uncertainties (2σ) for these trend results, based on block bootstrap analyses of the monthly residual series from the fits to the MLS and model series.

Figure 6. Same as Figure 1, except for climatological (2005–2020) HOCl daytime values from MLS and the model (see text for more details); the vertical range for useful MLS HOCl data (and for related trend analyses) is 10 to 2.2 hPa.

951

952 **Figure 7.** (a) Sensitivity of average (for 2014, 50°S to 50°N) model upper stratospheric HOCl profile (pptv) to the choice of

953 rate constant for the HOCl formation reaction between HO₂ and ClO. The JPL 15-10 Evaluation 18 rate constant choice gives

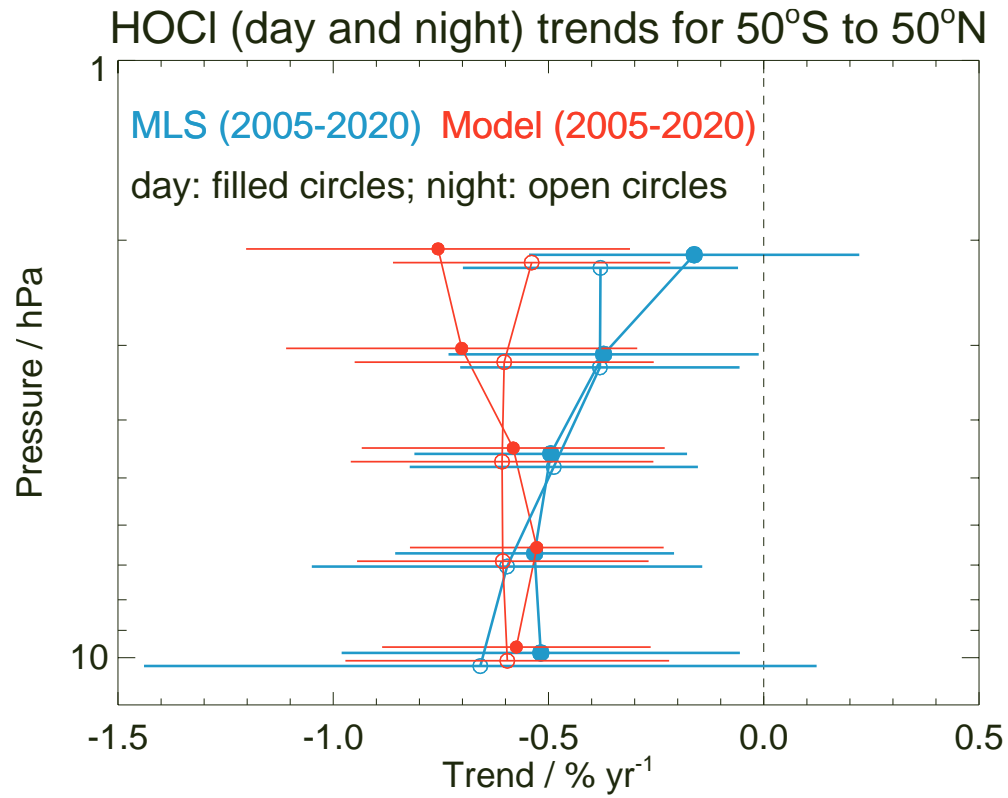

954 the purple average profile, whereas the larger rate constant derived by Ward and Rowley (2016) leads to the blue average

955 profile. (b) The percent difference (increase) between the two curves in panel (a) (blue minus purple).

Figure 12. Percent contributions of various species (daytime HCl, ClO, HOCl, and ClONO₂) to the upper stratospheric chlorine budget between 10 and 1 hPa, based on climatological (16-yr) daytime model results in the 50°S to 50°N latitude range. The sum of these contributions is shown in orange; there are also very small contributions in this pressure range from other species (Cl, Cl₂, Cl₂O₂, OClO, BrCl, which are not represented here).
