**Abstract.** Based on radiosonde observations from the spring and summer of 2016–2017, we verified the existence of an anomalous warm atmospheric layer, and quantified the heat contribution of suspended dust over the Tarim Basin (TB) in Northwest China. The atmospheric layer was identified between 300 and 500 hPa over the TB, with 2.53 and 1.39 K average intensities in spring and summer, respectively. The Taklimakan Desert (TD), i.e., the world’s second largest moving desert, is contained in the TB, emits large amounts of dust particles, which remain suspended over the TB. Using Cloud–Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) data, we found that dust can be lifted as high as the upper atmospheric layer, i.e., between 3.0 and 5.5 km above mean sea level, over the TB. Consequently, suspended dust can exert a maximum heating effect of approximately +0.45 and +0.25 K in spring and summer, respectively. The heat contributions of dust to the anomalous warm atmospheric layer over the TB in spring and summer were 13.77 and 10.25%, respectively. In view of the topographical feature, the TB is adjacent to the Tibetan Plateau (TP), which acts as an elevated heat source in spring and summer. The warm atmospheric layer over the TB seems a northward extension of Tibet heat source, the concept of which is proposed in this study. Such a northward “extension” of the elevated heating by the Tibetan Plateau may be a controlling factor of the regional climate, especially in the western section of the “Silk Road Economic Belt” and therefore, requires further investigations.

**Keywords:** Suspended dust; Heat source; Northward extension; Tibetan Plateau; Tarim Basin

# 1 Introduction

The Tarim Basin (TB), is situated north of the Tibetan Plateau (TP), covers an area of  $5.3 \times 10^5 \text{ km}^2$ , and contains the Taklimakan Desert (TD), which occupies the main part of the TB and is a major dust source in Asia (Gong et al., 2003; Wang et al., 2005). Based on Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) data, Liu et al. (2019) identified high emissions of dust particles from the TD; these dust particles can remain suspended over the TB for a long time (Huang et al., 2008; Ge et al., 2014; Cheng et al., 2020). Therefore, it is important to investigate the distribution of suspended dust and its impact on the Earth's climate system.

Dust is a heat-absorbing aerosol that heats the atmosphere (Yang et al., 2009; Yang et al., 2021a, 2021b, 2021c); it can change the vertical radiation distribution in the atmosphere and affect the regional and global climate (Huang et al., 2011; Sun and Zhao, 2020). When dust is suspended, it heats the atmospheric layers containing it (Huang et al., 2006a, 2006b; Huang et al., 2015; Liu et al., 2014; Jia et al., 2018; Xie et al., 2013; Su et al., 2020). The radiative forcing of dust over the TB and its contribution to climate change in Central Asia are scientific topics that require further clarification, and it is necessary to quantify the heating induced by dust in the upper atmosphere over the TB.

Previous studies that investigated the radiative effect of suspended dust over the TB were mainly based on satellite observations and numerical models. Using CALIPSO data, Huang et al. (2009) found that dust induced significant radiative forcing and heating over part of the TB. Gu et al. (2006, 2016) and Law et al. (2006), based on numerical results, elucidated the impact of dust on air temperature in the upper layers; nevertheless, regarding this aspect, in situ observations are sparse.

In this study, we used ground-based and radiosonde observations, as well as

reanalysis and satellite data, from the spring and summer of 2016–2017 for investigating the vertical air-temperature distribution and the three-dimensional structure of suspended dust over the TB, while quantifying the heating effect of suspended dust on the atmosphere. Based on our findings, we propose the concept of northward extension of the Tibetan heat source.

The rest of the paper is organized as follows: section 2 describes the data and methodology used in the study. Section 3 presents the main results and discussion. Conclusions are given in section 4.

## **2 Data and methodology**

### **2.1 Radiosonde observations**

We used radiosonde observations from six radiosonde stations situated in the TB for the spring and summer of 2016–2017 (Fig. 1), namely Kashi (KS), Akesu (AKS), Kuerle (KEL), Ruoqiang (RQ), Minfeng (MF), and Hetian (HT); from these data, we deduced the air-temperature profiles, which were measured twice per day (08:00 and 20:00 UTC+8). The observations were automatic and continuous, with 1 min temporal resolution, and the original data were processed into averages with 25 hPa interval. We also used in situ observations from six meteorological stations (i.e., KS, AKS, KEL, RQ, MF, and HT) for classifying and statistically describing events with dusty conditions.

### **2.2 Reanalysis data**

We also used The Fifth-Generation European Centre for Medium-Range Weather Forecasts (ECMWF) Reanalysis (ERA-5) and Modern-Era Retrospective Analysis for Research and Applications, Version 2 (MERRA-2) reanalysis data for the spring and summer of 2016–2017 are used. The ERA-5 reanalysis data in this study have a  $0.5^{\circ}\times 0.5^{\circ}$  latitude/longitude spatial resolution and 37 pressure levels in the vertical direction. The

95 MERRA-2 data are collected on a regular latitude-by-longitude grid of  $0.500 \times 0.625^\circ$   
with 42 pressure levels in the vertical direction. The temporal resolutions of air  
temperature from the two sets of reanalysis are one month. The ERA-5 data are the latest  
global atmospheric reanalysis produced by the ECMWF based on the Integrated  
Forecasting System (IFS) Cy41r2 (Hersbach et al., 2020). Notably, ERA-5 data were  
100 generated from an ECMWF IFS spectral model and did not yet assimilate the impact of  
aerosols on meteorology (Simmons, 2006). Therefore, if the effects of aerosols are not  
considered in the reanalysis model, the modeling error will be underestimated, which  
could somehow reflect the error induced by dust aerosols in the reanalysis field. The  
MERRA-2 data are an update of NASA's previous satellite reanalysis system and include  
105 additional observations and improvements on the Goddard Earth Observing System,  
Version 5 (GEOS-5) Earth-system model. The MREEA-2 data are different from the  
ERA-5 data, since aerosols and their interactions with weather and climate have been  
considered (Randles et al., 2017).

### 2.3 Satellite data

110 Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) was  
launched on April 28, 2006, for studying the impact of clouds and aerosols on the Earth's  
radiation budget and climate. The CALIPSO satellite includes the following three  
instruments: the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP), the  
Imaging Infrared Radiometer (IIR), and the Wide Field Camera (WFC). In this study, the  
115 CALIPSO Level 1B and Level 2 Vertical Feature Mask (VFM) datasets (i.e., aerosol  
profile), containing the half-orbit (i.e., day or night) of calibrated and geolocated single-  
shot (i.e., highest resolution) lidar profiles, were used for detecting dust events. The  
CALIPSO Level 1B product provides profiles of the total attenuated backscatter at 532

and 1064 nm; the feature classification from CALIPSO Level 2 VFM was used for  
120 distinguishing the types of aerosols. The seasonally averaged CALIPSO Level 2 VFM  
product was used for identifying the top height of the dust profile.

#### **2.4 Method for distinguishing the anomalous warm atmospheric layer**

First, based on the radiosonde air-temperature observations from each station in the  
TB in the spring and summer of 2016–2017, we fitted the air temperature using the  
125 following equation:

$$T_F = aH + b, \quad (1)$$

where  $T_F$  is the fitted air-temperature in °C,  $a$  is the mean slope,  $H$  is the altitude in hPa,  
and  $b$  is a constant. Second, according to eq. (1), the fitted air-temperature profile was  
calculated from the altitude data. Table 1 presents the fitting equations for each station.

130 The air-temperature difference  $\Delta T$  was calculated by comparing the radiosonde  
observations with the fitted air temperature:

$$\Delta T = T_O - T_F, \quad (2)$$

where  $T_O$  is the radiosonde air temperature and  $T_F$  is the fitted air temperature based on  
eq. (1). This method serves as a good indicator of anomalous air-temperature variations:  
135 Positive and negative  $\Delta T$  values indicate that the atmosphere is heating and cooling,  
respectively, while the absolute values indicate the warming/cooling intensity.

#### **2.5. Method for estimating the dust effect on the air temperature**

In the analysis, the dust effect on temperature was estimated based on the  
observation minus reanalysis (OMR) method proposed by Ding et al. (2013, 2016), which  
140 assumes that differences between observations and reanalysis models reflect the impact  
of unresolved processes. In this sense, investigating the differences between the  
observations and ERA-5 reanalysis data can provide an opportunity to reveal the heating

effect of dust aerosols.

$$OMR = T_O - T_R, \quad (3)$$

145 where  $T_O$  is the radiosonde air temperature and  $T_R$  is the ERA-5 air temperature, which does not include the impact of dust aerosols and assimilates only limited upper-atmosphere observations (Simmons, 2006); hence, this method is a good indicator of dust heating. The signs and magnitudes of the OMR values have the same meanings as those of  $\Delta T$ .

## 150 **3 Results and discussion**

### **3.1 Anomalous warm layer over the TB**

In the troposphere, air temperature (hereinafter referred to simply as temperature) generally decreases linearly with increasing altitude; however, temperature exhibited an anomalous lapse rate over the TB. Figures. 2a–f present profiles of the temperature difference ( $\Delta T$ ) between the radiosonde observations ( $T_O$ ) and the fitted air temperature ( $T_F$ )(see Section 2) at the KS, AKS, KEL, HT, MF, and RQ stations in the spring and summer of 2016–2017. A relatively warm layer is observed between 700 and 300 hPa in the spring and summer over the TB (shading in Figs. 2a–f); however, the temperature differences exhibit obvious discrepancies among the stations. According to the locations  
160 of the six observational stations (Fig. 1), we divided the TB into northern (i.e., KS, AKS, and KEL) and southern (i.e., HT, MF, and RQ). In the northern TB, although the height of the warm layer was consistent between the two seasons, the warming in spring was more intense than the one in summer. Conversely, in the southern TB, the warming in summer extended to altitudes beyond the ones it reached in spring, with more pronounced  
165 warming at altitudes higher than 400 hPa.

In this study, we focused mainly on temperature anomalies at 500–300 hPa altitude.

The mean  $\Delta T$  values between 500 and 300 hPa at each station in spring and summer are shown in Figs. 3a and b, respectively. In spring, the  $\Delta T$  values at each station were positive and ranged from 2.29 to 2.73 K, with 2.53 K mean; in summer, the  $\Delta T$  values were smaller than those in spring, varying from 1.21 to 1.57 K, with 1.39 K mean. Overall, an anomalous warm layer was identified between 500 and 300 hPa over the TB.

### 3.2 Distribution of dust aerosols in the warm layer over the TB

Dust aerosols are the principal particulate type in the atmosphere over the TB (Cheng et al., 2020). The distribution of dust aerosols is key for evaluating their radiative forcing. We analyzed the vertical distribution and variation of dust based on the CALIPSO Level 1B and 2 VFM datasets over the TB, and determined the distribution of the top height of the dust profile over the TB.

The CALIPSO product, which documents aerosols over bright surfaces and beneath thin clouds in clear skies (Vaughan et al., 2004; Winker et al., 2006), was used for identifying dust aerosols. We used the total attenuated backscatter coefficient at 532 nm for classifying particles from CALIPSO and identifying dust aerosols. To identify dust aerosols, values of 0.0008–0.0480  $\text{km}^{-1} \text{sr}^{-1}$  were chosen as the thresholds for the total attenuated backscatter (Liu et al., 2015; Jia et al., 2015). The left panels of Fig. 4 show the CALIPSO orbit–altitude cross-section of the 532-nm total attenuated backscattering coefficient on July 4, 5, 25, and 27, 2016, along the CALIPSO trajectory presented in Fig. 1. The gray shading in Fig. 4 indicates the topography, while the deep blue area denotes the absence of a signal owing to clouds, which the laser could not penetrate. As shown in Fig. 4 (left panels), the total attenuated backscatter ranged from 0.002–0.005  $\text{km}^{-1} \text{sr}^{-1}$ . Based on the thresholds for identifying dust aerosols, July 4 and 5, 2016, were two severely dusty days. Meanwhile, the dust layer was also evident in clear days; however,

its range and intensity were reduced compared with dusty days.

CALIPSO data revealed that vertically extended dust layers were widespread throughout the TB with peak lidar returns between 2.5 and 5.5 km above mean sea level due to strong convective activity during dusty as well as clear days (Cheng et al., 2020);  
195 this is consistent with other studies (Huang et al., 2009; Liu et al., 2015). The right panels of Fig. 4 also show that thick dust plumes were present over the entire TB. Moreover, the geographic setting of the TB, which is surrounded by high mountains, generates atmospheric circulation that favors the formation of long-lasting suspended dust (Tsunematsu et al., 2005).

200 Figure 5a presents the frequencies of dust events observed by ground stations in the spring and summer of 2016–2017 throughout the TB. The frequencies of dust events at the MF, HT, RQ, KS, KEL, and AKS stations were 55.43, 50.00, 53.26, 33.70, 22.83, and 34.24% in spring and 60.33, 42.93, 50.54, 2.72, 4.89, and 17.39% in summer, respectively. Therefore, the frequencies of dust events in the southern TB were obviously higher than  
205 those in the northern TB. Here, dust events include dust storms and cases of blowing and floating dust; of these dust events, cases of floating dust constitute the majority, accounting for more than 50% in the southern TB (Fig. 5b). These results are consistent with the findings of Zhou et al. (2020). This is because when cold air streams with different intensities intrude the TB, the wind fields converge strongly and rise in the areas  
210 of the HT and MF stations; hence, these areas experience dusty weather more frequently than the other areas (Han et al., 2005).

Information on the dust-top height (DTH) can elucidate the vertical structure of dust. The DTH is defined as the height above the surface elevation and exhibits significant seasonal variations over the TB, as shown in Figs. 5c–d, where the blank area represents

215 the default observed value. Over the TB, DTH in spring was higher than that in summer,  
with 3.0–5.5 km range. We note that the variations here resemble those of the boundary-  
layer height (BLH) (Luo et al., 2017). A previous study suggested that the BLH is  
essential for determining the vertical distribution of dust in the TB (Li et al. 2021). In  
contrast to urban districts (Ding et al. 2016; Huang et al. 2018), the BLH in the TD was  
220 especially high, i.e., higher than 5 km, according to sounding data obtained from a month-  
long intensive field campaign conducted in July 2016 (Wang et al., 2019).

According to the above, spring and summer are the seasons when dusty weather  
occurs more frequently in the TB, especially in its southern part, while dust can be  
suspended in the upper layer for a long time. As an important component of absorbing  
225 aerosols, dust aerosols constitute an elevated heat source in the atmosphere (Lau et al.,  
2006), and we reveal the contribution of suspended dust to the anomalous warm layer  
over the TB based on in situ observations in the following.

### 3.3 Spatial and temporal features of the heating effect of dust aerosols

Previous studies reported that the dust emitted from the TD has anomalously strong  
230 optical absorption properties, and thus, pronounced heating ability (Ge et al., 2010; Huang  
et al., 2015). Based on the OMR method (see Section 2), we estimated the effects of dust  
aerosols on the temperature; for this, we used radiosonde observations and ERA-5)  
reanalysis data. The ERA-5 reanalysis data likely involve a certain amount of errors;  
however, they are widely used and are considered to be reliable (Hersbach et al., 2020).

235 In this study, we focused mainly on temperature anomalies at 500–300 hPa altitude.  
Figure 6 presents the vertical profiles of the temperature difference between the  
radiosonde observations and ERA-5 data at 500–300 hPa altitude in the spring and  
summer of 2016–2017. As mentioned in Section 2, the effect of aerosols on the

temperature can somehow infer by calculating the OMR value. As shown in Fig. 6, dust  
240 can heat the atmosphere between 500 and 300 hPa over the TB in spring and summer;  
however, there are clear temporal and spatial variations.

In spring, all stations recorded heating between 500 and 300 hPa with 0.30 K mean  
OMR value. The initial height of the warm layer in summer was higher than that in spring,  
particularly at the HT and MF stations. The average OMR values indicated that the warm  
245 layer was between 400 and 300 hPa, with 0.13 K mean intensity. Results showed that the  
heating intensity in summer was significantly weaker than that in spring. In the southern  
TB, the average OMR values of the warm layer in spring and summer were 0.31 and 0.17  
K, respectively; in the northern TB, the average OMR values of the heating layer in spring  
and summer were 0.28 and 0.12 K, respectively. Therefore, the heating intensity in the  
250 southern TB was stronger than that in the northern TB.

Although the heating effect of suspended dust over the TB was confirmed through  
the in-situ observations, we were unable to evaluate it in its entirety due to the limited  
number of stations. To address this issue, we used the MERRA-2 reanalysis data to  
supplement the observation data. The main reasons for this were the following: First, one  
255 of the advantages of the MERRA-2 data is the assimilation of aerosol observations,  
thereby providing a multidecadal reanalysis in which aerosol and meteorological  
observations are jointly assimilated within a global data-assimilation system (Gelaro et  
al., 2017); more importantly, MERRA-2 considers the interactions of aerosols with  
weather and climate (Randles et al., 2017). Then, Fig 7a shows the relationship between  
260 radiosonde temperature observations and MERRA-2 data at 500–300 hPa altitude in the  
spring and summer of 2016–2017. The linear fitting slopes between the radiosonde  
temperature observations and MERRA-2 reanalysis data were 0.993 and 0.995 in 2016

and 2017, respectively, with coefficients of determination ( $R^2$ ) equal to 0.997. In addition, we calculated the mean square error (MSE) between the radiosonde observations and MERRA-2 data for each layer between 500 and 300 hPa in 2016–2017 (Fig. 7b). We used the MSE for measuring the deviation of the two data sets and found that the MSE of each layer was between 0.06 and 0.10. Therefore, it is feasible to use MERRA2 data as observations for analyzing the heating effect of suspended dust over the entire TB.

Figures 7c–d show the distributions of the OMR values averaged over 500 and 300 hPa in the spring and summer of 2016–2017. The mean OMR values between 500 and 300 hPa were relatively high in the southern TD both in spring and summer, which is consistent with the dust occurrence frequency (Figs. 5a–b). Accordingly, the heating intensity by dust was greater in spring (with approximately +0.45 K maximum) than in summer (with approximately +0.25 K maximum). In summary, dust aerosols can exert a heating effect and are responsible for the atmospheric warming between 500 and 300 hPa over almost the entire TB. The results demonstrate clearly that dust can heat the upper atmosphere over the TB; suspended dust serves as a critical “bridge”. This is a unique atmospheric phenomenon in China.

Combined with Figs. 2 and 6, Table 2 shows the contribution of suspended dust to the abnormal heating layer at 500–300 hPa altitude over the TB, with 13.77 and 10.25% average contributions in spring and summer, respectively. It is clear that the dust radiative forcing contributes heat to the warm layer over the TB. In fact, we found that the water vapor at 4–7 km altitude (i.e., almost at the same height as that of the dust layer) was nearly saturated during the daytime over the TB (not shown). The water vapor would absorb solar radiation and heat the atmosphere; hence, it may be an important heat contributor to the warm layer over the TB. Furthermore, the radiative properties of the

surface, atmospheric trace gases, and clouds also influence the aerosol–radiation interactions (IPCC, 2013). Therefore, the warm layer over the TB is likely a result of multiple factors. There are still many unknown issues that warrant further research.

#### 290 **3.4 Concept of the northward extension of the Tibetan heat source**

The above results show that there is a suspended dust layer over the TB in spring and summer (Figs. 4 and 5), which changes the temperature stratification (Fig. 6), and a heating layer appears between 300 and 500 hPa with approximately +0.45 and +0.25 K maximums in spring and summer, respectively, covering almost the entire basin (Figs. 295 7c–d). Topographically, the TB is adjacent to the TP (Fig. 1), which acts as an elevated heat source in spring and summer (Duan et al., 2013; Wonsick et al., 2014). The warm atmospheric layer over the TB seems a northward extension of the Tibetan heat source; therefore, we propose the concept of the northward extension of the Tibetan heat source, as illustrated in Fig. 8. Considering the important roles of TP and TB in affecting the 300 climate along the Silk Road Economic Belt (Liu et al., 2020; Zhao et al., 2020), more attention is required regarding the impact of the northward extension of the Tibetan heat source on the regional climate. Moreover, the northward extension of the Tibetan heat source can be attributed to the extreme weather conditions. In recent years, heavy precipitation events have occurred frequently in Xinjiang, e.g., the KS, AKS, and HT 305 stations recorded an extreme precipitation event, lasting for more than 100 h from May 15 to 21, 2018, during which precipitation broke the annual historical extremum in many places, while seriously endangering the local economy and people’s lives. The northward extension of the Tibetan heat source and its thermal effect on regional precipitation anomalies in spring and summer require further analysis. Therefore, a comprehensive 310 study of the influence of the northward extension of the Tibetan heat source on regional

weather and climate is necessary.

## 4 Conclusions

Dust aerosols can warm the climate, but the net influence of dust aerosols on global climate is rather uncertain (Penner, 2019). Aerosol–radiation interactions require  
315 knowledge of the spectrally varying aerosol extinction coefficient, single scattering albedo, and phase function (McComiskey and Feingold, 2008; Loeb and Su, 2010; Kahn, 2012), which can, in principle, be estimated from the aerosol size distribution, shape, chemical composition, and mixing state (Sicard et al., 2014; Lacagnina et al., 2015; Li and Sokolik, 2018). This leads to large uncertainties in quantifying the dust radiative  
320 effect in models. In contrast to other studies (Gu et al., 2006, 2016; Law et al., 2006; Huang et al., 2009), this is the first in situ observational evidence on the heating effect of dust aerosols over the Tarim Basin (TB). Although we avoided these complex processes, it is undeniable that errors still exist. The main conclusions are as follows:

A relatively warm layer was observed between 700 and 300 hPa in spring and  
325 summer over the TB. We focused on the temperature anomalies at 500–300 hPa altitude, and found that, in spring, the  $\Delta T$  values at each station were positive, ranging between 2.29 and 2.73 K; in summer, the  $\Delta T$  values were smaller than those in spring, ranging between 1.21 and 1.57 K.

Dust can heat the layer between 500 and 300 hPa in spring and summer over the TB;  
330 this heating effect exhibits clear temporal and spatial variations. The heating intensity in summer (i.e., 0.13 K mean OMR value) was significantly weaker than that in spring (i.e., 0.30 K mean OMR value). In the southern TB, the average OMR values of the heating layer were 0.31 and 0.17 K in spring and summer, respectively; in the northern TB, the average OMR values of the heating layer were 0.28 and 0.12 K in spring and summer,

335 respectively. Dust radiative forcing was one of the heat contributors to the warm layer  
over the TB. Topographically, the TB is adjacent to the Tibetan Plateau, which acts as an  
elevated heat source in spring and summer. The warm atmospheric layer over the TB  
seems to be a northward extension of the Tibetan heat source. Therefore, in this study, we  
proposed the concept of the northward extension of the Tibetan heat source.

## Figure captions

575 Figure 1. Topographical map of the study domain and distribution of the stations in the Tarim Basin (TB). The contours of the terrain height are in km above mean sea level. The solid lines indicate the trajectory of the CALIPSO satellite over the TB on July 4 (20:22 UTC; black line), 5 (07:02 UTC; red line), 25 (20:40 UTC; blue line), and 27 (20:28 UTC; green line), 2016, of which, July 4 and 5 were  
580 characterized by dusty weather, while July 25 and 27 were clear days.

Figure 2. Temperature-difference ( $\Delta T$ ) profiles in the spring and summer of 2016–2017 at the (a) Kashi (KS), (b) Akesu (AKS), (c) Kuerle (KEL), (d) Hetian (HT), (e) Minfeng (MF), and (f) Ruoqiang (RQ) radiosonde stations. Shadings indicate the layer with positive  $\Delta T$ .

585 Figure 3. Average  $\Delta T$  between 500 and 300 hPa in (a) spring and (b) summer. Dots indicate the site locations, while different colors indicate different heating intensities.

Figure 4. The altitude–orbit cross-section of the 532-nm total attenuated backscattering intensity (left panels) and classified particles (right panels) on July (a1 and b1) 4, (a2 and b2) 5, (a3 and b3) 25, and (a4 and b4) 27, 2016, along the trajectory  
590 of the CALIPSO satellite over the Tibetan Plateau, as presented in Fig. 1. Gray shadings indicate the topography.

Figure 5. Frequencies of (a) dust events and (b) dust events including dust storms and cases of blowing and floating dust at the (a) Kashi (KS), (b) Akesu (AKS), (c) Kuerle (KEL), (d) Hetian (HT), (e) Minfeng (MF), and (f) Ruoqiang (RQ)  
595 stations in the spring and summer of 2016–2017; the blue dashed line represents the boundary between spring and summer. Seasonal distribution of the dust-top

height in km over the Tarim Basin in (c) spring and (d) summer, inferred from CALIPSO.

600 Figure 6. Profiles of the temperature difference (radiosonde observations minus ERA-5 data) in the spring and summer of 2016–2017 at the (a) Kashi (KS), (b) Akesu (AKS), (c) Kuerle (KEL), (d) Hetian (HT), (e) Minfeng (MF) and (f) Ruoqiang (RQ) radiosonde stations.

Figure 7. (a) Relationship between radiosonde temperature observations and MERRA-2 data at 500–300 hPa altitude in the spring and summer of 2016–2017. (b) Mean square errors (MSE) between the radiosonde observations and MERRA-2 data at each layer between 500 and 300 hPa. Distributions of the temperature difference between MERRA-2 and ERA-5 data (OMR) averaged over 500–300 hPa in the (c) spring and (d) summer of 2016–2017. Black dots indicate the site locations.

605

610 Figure 8. Conceptual scheme of the northward extension of the Tibetan heat source, which is partially attributed to the heating effect of suspended dust aerosols over the Tarim Basin. Solid and dashed lines represent the dust-influenced and dust-free temperature profiles, respectively. Yellow arrows denote solar radiation, including the components reflected and absorbed by clouds, dust aerosols, and the surface. Red arrows at the surface denote sensible heat. White solid arrows denote turbulent and convective mixing in the planetary boundary layer. White dashed lines indicate the altitude.

615

620

Table 1. Fitting equations for each station based on eq. (1).

Station	Season	Fitting equation
KS	Spring	$T_F = 0.117H - 77.564; R^2 = 0.983$
	Summer	$T_F = 0.109H - 64.468; R^2 = 0.994$
AKS	Spring	$T_F = 0.115H - 77.786; R^2 = 0.981$
	Summer	$T_F = 0.109H - 65.186; R^2 = 0.992$
KEL	Spring	$T_F = 0.113H - 77.682; R^2 = 0.981$
	Summer	$T_F = 0.110H - 65.349; R^2 = 0.992$
HT	Spring	$T_F = 0.117H - 76.374; R^2 = 0.981$
	Summer	$T_F = 0.106H - 60.881; R^2 = 0.988$
MF	Spring	$T_F = 0.117H - 76.382; R^2 = 0.981$
	Summer	$T_F = 0.106H - 60.502; R^2 = 0.986$
RQ	Spring	$T_F = 0.115H - 76.971; R^2 = 0.981$
	Summer	$T_F = 0.108H - 62.300; R^2 = 0.989$

625

630

Table 2. Contribution of suspended dust to the anomalous warm atmospheric layer at 500–300 hPa altitude over the TB.

Station	KS		AKS		KEL	
	Spring	Summer	Spring	Summer	Spring	Summer
Contribution (%)	17.51	29.00	11.83	7.87	10.30	3.16

  

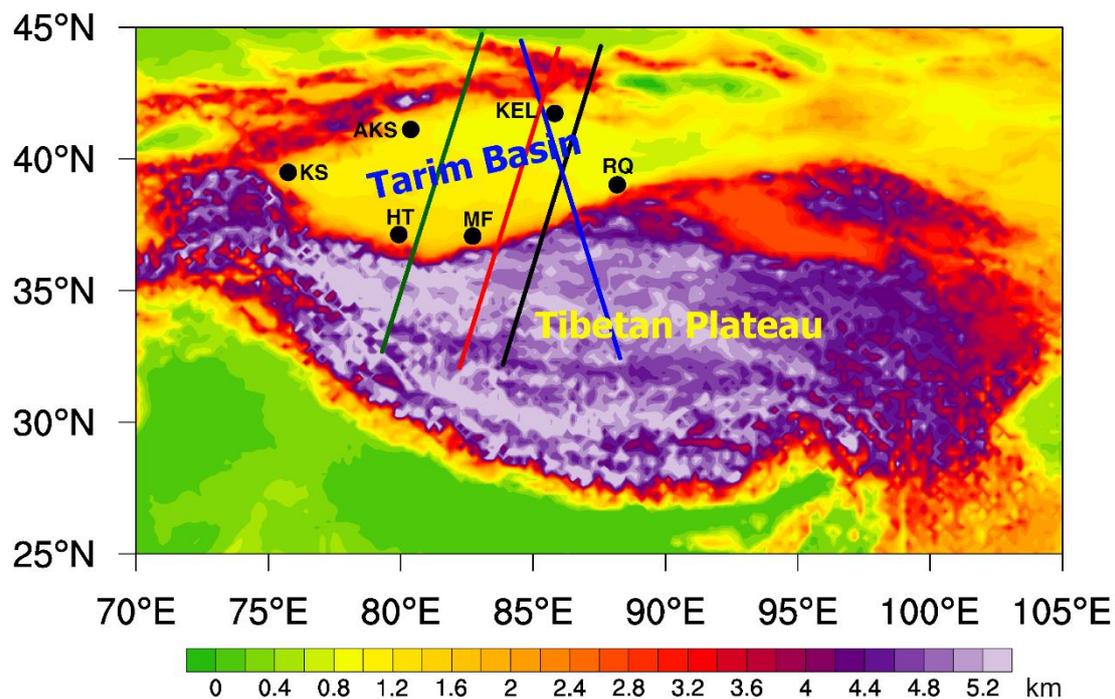

Station	HT		MF		RQ	
	Spring	Summer	Spring	Summer	Spring	Summer
Contribution (%)	14.65	4.06	15.13	6.94	13.21	10.46

 cases of blowing and floating dust at the (a) Kashi (KS), (b) Akesu (AKS), (c) Kuerle  
 (KEL), (d) Hetian (HT), (e) Minfeng (MF), and (f) Ruoqiang (RQ) stations in the spring  
 and summer of 2016–2017; the blue dashed line represents the boundary between spring  
 and summer. Seasonal distribution of the dust-top height in km over the Tarim Basin in  
 705 (c) spring and (d) summer, inferred from CALIPSO.

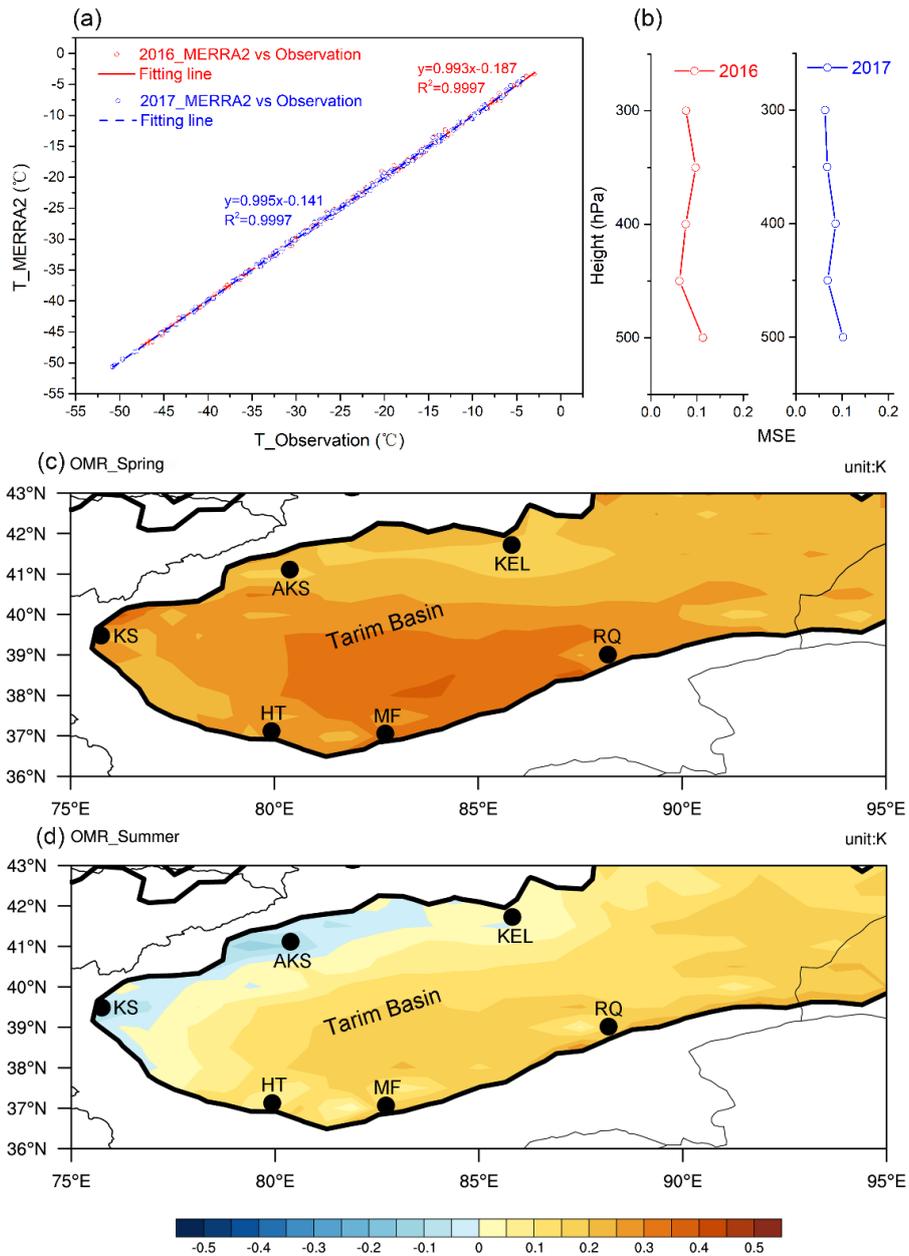

710

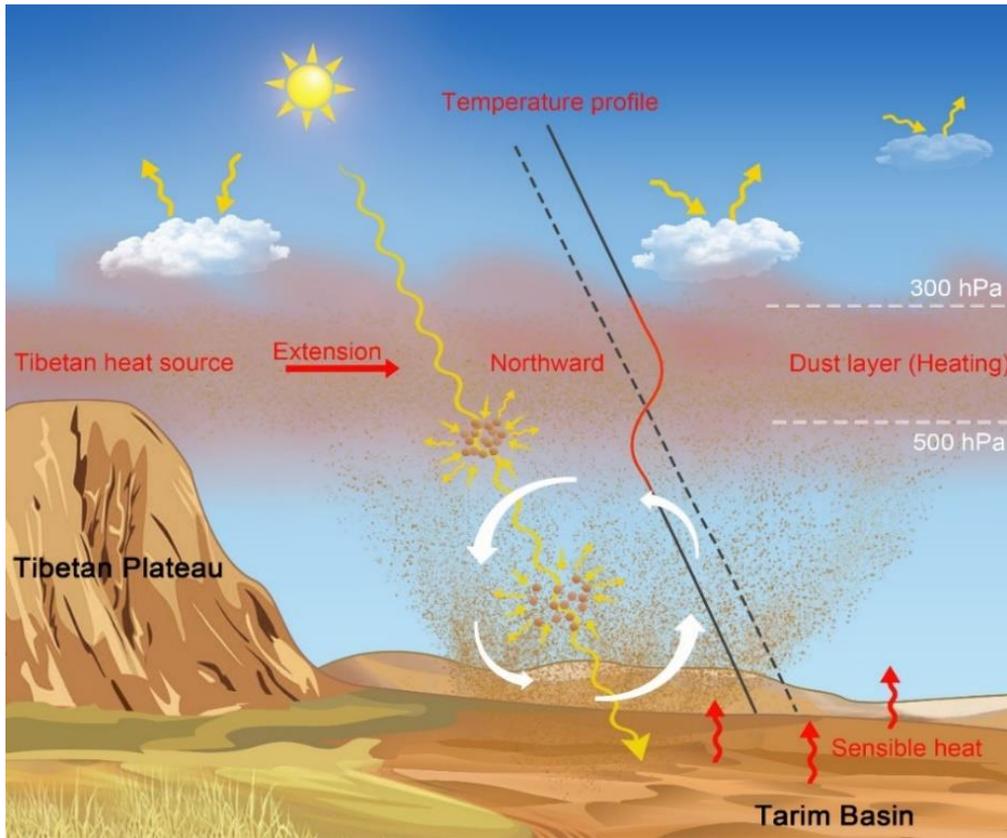

715 **Figure 6.** Profiles of the temperature difference (radiosonde observations minus ERA-5  
 data) in the spring and summer of 2016–2017 at the (a) Kashi (KS), (b) Akesu (AKS), (c)  
 Kuerle (KEL), (d) Hetian (HT), (e) Minfeng (MF) and (f) Ruoqiang (RQ) radiosonde  
 stations.

725

**Figure 7.** (a) Relationship between radiosonde temperature observations and MERRA-2 data at 500–300 hPa altitude in the spring and summer of 2016–2017. (b) Mean square errors (MSE) between the radiosonde observations and MERRA-2 data at each layer between 500 and 300 hPa. Distributions of the temperature difference between MERRA-2 and ERA-5 data (OMR) averaged over 500–300 hPa in the (c) spring and (d) summer of 2016–2017. Black dots indicate the site locations.

735 **Figure 8.** Conceptual scheme of the northward extension of the Tibetan heat source,  
 which is partially attributed to the heating effect of suspended dust aerosols over the Tarim  
 Basin. Solid and dashed lines represent the dust-influenced and dust-free temperature  
 profiles, respectively. Yellow arrows denote solar radiation, including the components  
 reflected and absorbed by clouds, dust aerosols, and the surface. Red arrows at the surface  
 740 denote sensible heat. White solid arrows denote turbulent and convective mixing in the  
 planetary boundary layer. White dashed lines indicate the altitude.
