14

15 **Abstract:** Aqueous reactions may turn precursors into light-absorbing and toxic  
16 products, leading to air quality deterioration and adverse health effects. In this study,  
17 we investigated comprehensively eugenol photooxidation (a representative biomass  
18 burning emitted, highly substituted phenolic compound) in bulk aqueous phase with  
19 direct photolysis, hydroxyl radical (OH) and an organic triplet excited state ( $^3\text{C}^*$ ).  
20 Results show that the degradation rates of eugenol followed the order of  
21  $^3\text{C}^* > \text{OH} > \text{direct photolysis}$ . During  $^3\text{C}^*$ -initiated oxidation, different reactive oxygen  
22 species (ROS) including  $^3\text{C}^*$ , OH,  $^1\text{O}_2$  and  $\text{O}_2^{\cdot-}$  can participate in oxidation of eugenol,  
23 quenching experiments verified  $^3\text{C}^*$  was the most important one; while during OH-  
24 initiated oxidation,  $\text{O}_2^{\cdot-}$  was a more important ROS than OH to oxidize eugenol. The  
25 rate constants under saturated  $\text{O}_2$ , air and  $\text{N}_2$  followed the order of  $k_{\text{O}_2} > k_{\text{Air}} > k_{\text{N}_2}$  for

26 both direct photolysis and OH-initiated oxidation, but changed to  $k_{\text{Air}} > k_{\text{N}_2} > k_{\text{O}_2}$  for  
27  $^3\text{C}^*$ -mediated oxidation. pH and dissolved oxygen (DO) levels both decreased during  
28 oxidation, indicating formation of acids and the participation of DO in oxidation. UV-  
29 vis light absorption spectra of the reaction products showed clear absorbance  
30 enhancement in the 300-400 nm range for all three sets of experiments and new  
31 fluorescence at excitation/emission=250/(400-500) nm appeared, suggesting the  
32 formation of new chromophores and fluorophores (brown carbon species); and these  
33 species were likely attributed to humic-like substances (HULIS) as shown by the  
34 increases of HULIS concentrations during oxidation. Large mass yields of products  
35 (140%-197%) after 23 hours of illumination were obtained, and high oxidation degrees  
36 of these products were also observed; correspondingly, a series of oxygenated  
37 compounds were identified, and detailed reaction mechanism with functionalization as  
38 a dominant pathway was proposed. At last, dithiothreitol (DTT) assay was applied to  
39 assess oxidation potential of the reaction products, and the end products of all three sets  
40 of experiments showed higher DDT consumption rates than that of eugenol, indicating  
41 more toxic species were produced upon aqueous oxidation. Overall, our results by using  
42 eugenol as a model compound, underscore the potential importance of aqueous  
43 processing of biomass burning emissions in secondary organic aerosol (SOA)  
44 formation.

45

## 46 **1 Introduction**

47 Photochemical reactions in atmospheric aqueous phases (cloud/fog droplets and  
48 aerosol water) can affect lifetimes of many organic species, and are an important source  
49 and pathway of secondary organic aerosol (SOA) formation (Vione et al., 2006; Zhao

50 et al., 2012). Compared to the gasSOA formed via gas-phase photochemical oxidation,  
51 aqueous-phase SOA (aqSOA) is often more oxidized and less volatile, therefore might  
52 play an important role in haze formation, air quality and global climate change (Ervens  
53 et al., 2011; Lim et al., 2010). However, due to complexity of the aqueous reactions and  
54 influencing factors (such as precursors, oxidants, and light intensities), detailed reaction  
55 mechanism, optical property, oxidative potential (OP) and the interplay among them  
56 remain poorly understood.

57 Many laboratory studies have focused on aqueous-phase oxidations of low  
58 molecular weight (LMW) volatile organic compounds (VOCs), such as isoprene,  
59 terpenes ( $\alpha$ -,  $\beta$ -pinene), as well as their gas-phase oxidation products (such as glyoxal,  
60 methylglyoxal, *cis*-pinonic acid and methyl vinyl ketone) (Faust et al., 2017; Herrmann,  
61 2003; Herrmann et al., 2015; Huang et al., 2011; Lee et al., 2012; Zhang et al., 2010).  
62 Recently, aqueous oxidation of semi-/intermediate volatility VOCs (S/IVOCs), such as  
63 the phenolic compounds emitted from combustion or pyrolysis of lignin in biomass,  
64 were also extensively investigated (Barzaghi and Herrmann, 2002; Bonin et al., 2007;  
65 Chen et al., 2020; Gilardoni et al., 2016; He et al., 2019; Jiang et al., 2021; Li et al.,  
66 2014; Li et al., 2021; Ma et al., 2021; Mabato et al., 2022; Smith et al., 2014; Sun et al.,  
67 2010; Tang et al., 2020; Yang et al., 2021; Yu et al., 2016). Generally, chemical  
68 structures of precursors have profound influences on the reaction mechanisms and  
69 products, while effect of oxidants also cannot be neglected. It is evident that liquid water  
70 can contain various types of oxidants, such as singlet oxygen ( $^1\text{O}_2$ ), nitrate radical ( $\text{NO}_3$ ),  
71 hydroxyl radical (OH), and organic triplet excited states ( $^3\text{C}^*$ ), and all can play crucial  
72 roles in photooxidation reactions (Kaur and Anastasio, 2018; Scharko et al., 2014).  
73 Among them, OH is a ubiquitous oxidant with concentrations of  $10^{-13}$ - $10^{-12}$  mol·L<sup>-1</sup>  
74 (Arakaki et al., 2013; Gligorovski et al., 2015; Herrmann et al., 2003). Hence, aqueous

75 OH-induced photooxidation has been extensively studied (Chen et al., 2020; Sun et al.,  
76 2010; Yu et al., 2016). Compared to OH oxidation,  $^3\text{C}^*$ -initiated aqueous oxidation  
77 (photosensitized reactions) has also attracted attentions in recent years (Ma et al., 2021;  
78 Wang et al., 2021). Several classes of organic compounds in ambient air, including non-  
79 phenolic aromatic carbonyls, quinones, aromatic ketones and nitrogen-containing  
80 heterocyclic compounds, can form  $^3\text{C}^*$  after absorbing light (Alegría et al., 1999; Kaur  
81 et al., 2019; Nau and Scaiano, 1996; Rossignol et al., 2014; Chen et al., 2018). These  
82 compounds are termed photosensitizers.  $^3\text{C}^*$  is capable of reacting with  $\text{O}_2$  to produce  
83 singlet oxygen ( $^1\text{O}_2$ ) and superoxide radicals ( $\text{O}_2^{\cdot-}$ ). Various reactive oxygen species  
84 (ROS) can be generated and affect greatly the  $^3\text{C}^*$ -initiated aqueous-phase reactions.  
85 Despite some studies demonstrating importance of ROS in photochemical process (Ma  
86 et al., 2021; Wang et al., 2020; Wang et al., 2021), our current understanding on  $^3\text{C}^*$ -  
87 initiated oxidation is still limited.

88 Excitation-emission matrix (EEM) fluorescence spectroscopy, as a low-cost, rapid,  
89 non-destructive and high-sensitivity technique, can offer detailed information on  
90 chromophores hence has been widely employed for studies of aquatic dissolved organic  
91 matter (Aryal et al., 2015). Nevertheless, it has not been extensively used in  
92 atmospheric aerosol research (Mladenov et al., 2011). Prior studies have investigated  
93 the relationship between the fluorescence components and chemical structures of  
94 atmospheric aerosols by using high-resolution aerosol mass spectrometry (AMS) and  
95 EEM fluorescence spectroscopy (Chen et al., 2016a; Chen et al., 2016b). An earlier  
96 report from Chang and Thompson (2010) found fluorescence spectra of aqueous-phase  
97 reaction products of phenolic compounds, which had some similarities with those of  
98 humic-like substances (HULIS), and Tang et al. (2020) reported that aqueous  
99 photooxidation of vanillic acid could be a potential source of HULIS. Chang and

100 Thompson (2010) also showed that light-absorbing and fluorescent substances  
101 generally had large conjugated moieties (i.e., quinones, HULIS, polycyclic aromatic  
102 hydrocarbons (PAHs)), which can damage human body (Dou et al., 2015; McWhinney  
103 et al., 2013). HULIS are considered as an important contributor to induce oxidative  
104 stress since they can serve as electron carriers to catalyze ROS formation (Dou et al.,  
105 2015; Ma et al., 2019; Huo et al., 2021; Xu et al., 2020), causing adverse health effects.  
106 Dithiothreitol (DTT) assay (Alam et al., 2013; Verma et al., 2015), as a non-cellular  
107 method, was widely employed to determine oxidation activity and OP of atmospheric  
108 PM (Chen et al., 2019; Cho et al., 2005) for the evaluation of its health effects. Some  
109 other works (Fang et al., 2016; McWhinney et al., 2013; Verma et al., 2015; Zhang et  
110 al., 2022) focused on the link between chemical components and OP in PM, and  
111 confirmed that several kinds of compounds, such as quinones, HULIS and transition  
112 metals usually had strong DTT activities. However, DTT method is rarely used to  
113 evaluate the OP of aqueous-phase oxidation products previously (Ou et al., 2021).

114 In the present work, we chose eugenol (allyl guaiacol) as a model compound to  
115 conduct aqueous oxidation experiment. As a representative methoxyphenol emitted  
116 from biomass burning (BB) (Hawthorne et al., 1989; Simpson et al., 2005), it was  
117 widely detected in atmospheric particles. For instance, concentration and emission  
118 factor of this compound from beech wood burning were  $0.032 \mu\text{g}/\text{m}^3$  and  $1.534 \mu\text{g}/\text{g}$ ,  
119 which were twice those of guaiacol ( $0.016 \mu\text{g}/\text{m}^3$  and  $0.762 \mu\text{g}/\text{g}$ ) (Bari et al., 2009).  
120 Eugenol is a semivolatile aromatic compound with a moderate water-solubility ( $2.46$   
121  $\text{g}/\text{L}$  at  $298 \text{ K}$ ). Chemical characteristics of aqueous reaction products under direct  
122 photolysis (without oxidant) and oxidations by OH radicals and  $^3\text{C}^*$  triplet states, were  
123 comprehensively elucidated by a suite of analytical techniques including high-  
124 performance liquid chromatography (HPLC), ultraviolet and visible (UV-Vis)

125 spectrophotometry, gas chromatography mass spectrometry (GC-MS), and soot particle  
126 aerosol mass spectrometry (SP-AMS). Moreover, light absorption, fluorescent and  
127 oxidative properties of the aqueous oxidation products were also investigated.

## 128 **2 Materials and methods**

### 129 **2.1 Chemicals and reagents**

130 Eugenol (99%), tert-butanol (TBA, 99%), 3,4-dimethoxybenzaldehyde (DMB,  
131 99%), para-benzoquinone (*p*-BQ, 99%), dithiothreitol (99%) and 5,5'-dithiobis-2-  
132 nitrobenzoic acid (DTNB, 99%), 2-nitro-5-thiobenzoic (99%), 5,5-dimethyl-1-  
133 pyrroline N-oxide (DMPO), 2,2,6,6-tetramethylpiperidine (TEMP) were all purchased  
134 from Sigma-Aldrich. Superoxide dismutase (SOD) was purchased from Bovine  
135 Erythrocytes BioChemika. Dichloromethane (HPLC-MS grade, 99%), methanol  
136 (HPLC-MS grade, 99%), acetonitrile (HPLC-MS grade, 98%), hydrogen peroxide  
137 (H<sub>2</sub>O<sub>2</sub>, 35 wt %), and 2,4,6-trimethylphenol (TMP, 99%) were all obtained from Acros  
138 Chemicals. Sodium azide (NaN<sub>3</sub>, 98%) was purchased from J&K Scientific Ltd.  
139 (Beijing, China). All solutions were prepared using ultrapure water (Millipore) on the  
140 days of experiments.

### 141 **2.2 Photochemical oxidation experiments**

142 Aqueous-phase photochemical reactions were carried out in a Rayonet  
143 photoreactor (model RPR-200) equipped with 16 light tubes (2 RPR-3000, 7 RPR-3500  
144 and 7 RPR-4190 tubes), which was frequently used to mimic sunlight for  
145 photochemical experiments and was described in details by several groups (George et  
146 al., 2015; Hong et al., 2015; Huang et al., 2018; Jiang et al., 2021; Zhao et al., 2014).

147 Pyrex tubes containing sample solutions were placed in the center and received  
148 radiation from surrounded lamps of all sides. To ensure mixing of the solution, a fan  
149 and a magnetic stir bar were placed at the bottom of the reaction tube. The solution  
150 temperature was controlled at  $25 \pm 2^\circ\text{C}$ . The same photoreactor system and a normalized  
151 distribution of photon fluxes inside the reactor have been reported elsewhere (George  
152 et al., 2015), and the wavelength of light was in the range of 280~500 nm. We only  
153 measured light intensity at the surface of the solution with a radiometer (Photoelectric  
154 instrument factory of Everfine Corporation, Hangzhou, China), which was determined  
155 to be  $\sim 2400 \mu\text{W}/\text{cm}^2$  in the range of 290-320 nm (UVB), lower than the sunlight  
156 intensity ( $6257.1 \mu\text{W}/\text{cm}^2$ ).

157 In this work,  $300 \mu\text{M H}_2\text{O}_2$  and  $15 \mu\text{M DMB}$  were added into solutions as sources  
158 of OH and  $^3\text{C}^*$ , respectively. The initial concentration of eugenol was  $300 \mu\text{M}$ . For  $^3\text{C}^*$ -  
159 mediated experiments, solutions were adjusted to pH=3 by sulfuric acid in order to  
160 perform experiments under optimal conditions (Ma et al., 2021; Smith et al., 2014)  
161 since DMB triplet state is protonated to a more reactive form in acidic solution. We  
162 conducted three sets of oxidation experiments: (A)  $300 \mu\text{M eugenol} + 300 \mu\text{M H}_2\text{O}_2$ ,  
163 (B)  $300 \mu\text{M eugenol} + 15 \mu\text{M DMB}$ , and (C)  $300 \mu\text{M eugenol}$  without oxidants. In each  
164 series of experiments, a dark control experiment was performed synchronously with a  
165 Pyrex tube wrapped by aluminum foil. Results showed loss of eugenol under dark  
166 conditions were negligible (data not shown). In addition, to evaluate the roles of ROS  
167 in eugenol degradation during  $^3\text{C}^*$ -initiated oxidation, quenching experiments by using  
168 specific scavengers to capture different ROS were performed, namely TBA for OH,  
169  $\text{NaN}_3$  for  $^1\text{O}_2$ , SOD for  $\text{O}_2^{\cdot-}$ , and TMP for  $^3\text{C}^*$ , respectively (Pan et al., 2020; Chen et  
170 al., 2020). For OH-initiated oxidation, quenching experiments using *p*-BQ for  $\text{O}_2^{\cdot-}$  (Ma  
171 et al., 2019; Raja et al., 2005), and TBA for OH were conducted. For most experiments,

172 solutions were saturated by air and each experiment presented was repeated three times  
173 unless otherwise stated. Average results with one standard deviation were provided. In  
174 order to further evaluate the role of oxygen in photooxidation, experiments were also  
175 conducted by using different saturated gases (air, N<sub>2</sub> and O<sub>2</sub>).

## 176 **2.3 Analytical methods**

### 177 **2.3.1 Determination of eugenol concentrations**

178 Before and during the photochemical experiment, 2 mL of reacted solution was  
179 sampled periodically and subjected to HPLC (LC-10AT, Shimadzu, Japan) analysis to  
180 quantify eugenol concentration. The HPLC was equipped with an InertSustain AQ-C18  
181 reverse phase column (4.6×250 mm, 5.0 μm, Shimadzu) and a UV-vis detector. The  
182 mobile phase was a mixture of acetonitrile/H<sub>2</sub>O (v/v: 60/40) at a flow rate of 0.6  
183 mL/min, and the detection wavelength was 280 nm. The first-order kinetic rate constant  
184 of eugenol degradation can be obtained from the slope of plot of  $-\ln(c_t/c_0)$  versus  
185 reaction time as presented in Eq.(1).

$$186 \qquad \qquad \qquad \ln(c_t/c_0)=-kt \qquad \qquad \qquad (1)$$

187 Where  $c_0$  and  $c_t$  are eugenol concentrations (in μM) at the initial and reaction time  
188  $t$ , while  $k$  represents the pseudo first-order rate constant (in s<sup>-1</sup>).

### 189 **2.3.2 UV-vis and fluorescent spectra**

190 The UV-vis light absorbance spectra of reacted solutions (placed in a 1 cm path  
191 length quartz cuvette) were measured by using an UV-vis spectrophotometer (Specord  
192 210 plus, Analytik Jena., Germany). The instrument has a dual-beam optical system  
193 with tungsten and deuterium lamps as light sources. A reference absorption spectrum

194 of ultrapure water was carried out in the same cuvette prior to sample analysis for  
195 baseline correction.

196 Immediately after the UV-Vis measurement, the cuvette was transferred to a three-  
197 dimensional EEM fluorescence spectrometer (FluoroMax Plus, HORIBA Scientific).  
198 The ranges of wavelength varied from 200 to 450 nm for excitation wavelengths (Ex)  
199 and from 290 to 650 nm for emission wavelength (Em). Intervals of the excitation and  
200 emission wavelengths were 5 nm and 2 nm, respectively. The reported absorbance and  
201 EEM spectra here are averages of the results from experiments in triplicate.

### 202 **2.3.3 Determination of HULIS concentrations**

203 Solid phase extraction (SPE) cartridges (CNW Poly-Sery HLB, 60 mg/cartridge)  
204 were used to isolate HULIS from the reaction products. The SPE cartridge was first  
205 rinsed with 1 mL ultrapure water and 3 mL methanol prior to extraction. The solution  
206 was acidified to pH ~2 using HCl and loaded on an SPE cartridge, which was rinsed  
207 with 1 mL ultrapure water again. Next, 3 mL methanol/ammonia (98:2, v/v) mixture  
208 was added into the SPE cartridge to elute HULIS, and the solution was blown to full  
209 dryness with high purity N<sub>2</sub>, followed by dilution with ultrapure water to 25 mL for  
210 quantification of HULIS using the HPLC coupled with an evaporative light scattering  
211 detector (ELSD3000). Recovery efficiency of the HULIS standard, Suwanne River  
212 Fulvic Acid (SRFA), was 75-80% with the standard deviation of reproducibility less  
213 than 5%. More details have been described elsewhere (Tao et al., 2021).

### 214 **2.3.4 Oxidative potential (OP) based on DTT assay**

215 The OP of reaction products was determined by the DTT method (Cho et al., 2005;  
216 Lin and Yu, 2019) with slight improvements. Briefly, 1.2 mL sample solution was

217 transferred into a 10 mL glass tube, then 6 mL phosphate buffer (0.1 M, pH 7.4) and  
218 300  $\mu$ L of 2.5 mM DTT were added and mixed thoroughly. The DTT mixed solution  
219 was placed in a 37°C water bath for incubation. Over the course of reactions that lasted  
220 for 150 minutes, 1 mL aliquot of DTT mixture was taken every 30 minutes, and 100  $\mu$ L  
221 of 5 mM DTNB (prepared in 0.1 mM phosphate buffer) was added and loaded in a  
222 centrifuge tube. Next, reactions between DTNB and DTT produced bright yellow TNB,  
223 which was quantified by the UV-Vis spectrometer within 30 minutes. Finally, we  
224 measured the light absorbance ( $A_t$ ) at 412 nm to indirectly quantify the remaining DTT.  
225 Another 1.2 mL ultrapure water instead of sample solution was treated in the same way  
226 and the absorbance was denoted as A as the blank value.  $A_0$  represents the initial light  
227 absorbance value. Thus, DTT concentration consumed by the sample solution ( $M_{DTT}$ ,  
228  $\mu$ M) and that by the blank solution ( $M_{DTT0}$ ,  $\mu$ M) can be calculated according to Eq.(2)  
229 and Eq.(3), respectively.

$$230 \quad M_{DTT} = \frac{A_0 - A_t}{A_0} \times C_{DTT0} \quad (2)$$

$$231 \quad M_{DTT0} = \frac{A_0 - A}{A_0} \times C_{DTT0} \quad (3)$$

232 Here,  $C_{DTT0}$  was the initial DTT concentration in sample solution (100  $\mu$ M in this  
233 work). DTT consumption rates ( $R_{DTT}$  and  $R_{DTT0}$ ) were then obtained from the slopes of  
234 plots of  $M_{DTT}$  and  $M_{DTT0}$  versus incubation times. Experiments of blanks and samples  
235 were typically run in a triplicate. The reproducibility of the whole analysis showed that  
236 the relative standard deviation of DTT consumption rate was 3-4%.

### 237 **2.3.5 Product analysis by GC-MS**

238 Reacted solution (about 30 mL) was extracted with 10 mL dichloromethane twice.  
239 The extract was concentrated into 1 mL by blowing  $N_2$  gently, subsequently transferred  
240 to a 2 mL vial, and analyzed by a GC-MS (7890A GC/5975C MS, Agilent) with a DB-

241 5ms capillary column (30 m×0.25 mm×0.5 μm). The operational conditions were set as  
242 follows: injector was at 200°C; ion source was at 230 °C; column oven temperature was  
243 programmed to be held at 35°C for 4 minutes, then ramped to 250 °C at a rate of  
244 20°C/minute and held for 10 minutes. The recovery efficiency, method detection limits  
245 and quality assurance/quality control have been described in our previous work (Ye et  
246 al., 2020).

### 247 **2.3.6 SP-AMS analysis and mass yields of reaction products**

248 An Aerodyne SP-AMS (Onasch et al., 2012) was applied to analyze the low-  
249 volatility organic products, similar to our previous work (Chen et al., 2020; Ge et al.,  
250 2017). SP-AMS data were acquired in V mode and analyzed by Squirrel v.1.56D and  
251 Pika v1.15D software. The organic fragments were classified into six groups: CH, CHO,  
252 CHN, CHO<sub>2</sub>, CHON and HO. Elemental ratios (oxygen-to-carbon, O/C; hydrogen-  
253 to-carbon, H/C), were calculated according to the method proposed by Canagaratna et  
254 al. (2015).

255 Since the AMS analysis requires nebulization of sample solution into particles  
256 before determination, and quantification of organics was influenced by the atomization  
257 efficiency and carrier gas flow, we thus cannot use SP-AMS measured concentration to  
258 quantify the mass of products directly. In this case, according to Li et al. (2014), we  
259 added an internal standard (SO<sub>4</sub><sup>2-</sup>) prior to AMS analysis, and the mass ratio of particle-  
260 phase organics to SO<sub>4</sub><sup>2-</sup> ( $\Delta\text{Org}/\text{SO}_4^{2-}$ ) can be used to calculate the mass concentration  
261 of products. Furthermore, the mass yield of aqueous-oxidation products ( $Y_{\text{products}}$ , %),  
262 which is the mass of products generated per unit mass of precursor consumed, can be  
263 calculated according to Eq. (4).

$$264 \quad Y_{\text{products}}(\%) = \frac{(\Delta\text{Org}/\text{SO}_4^{2-})[\text{SO}_4^{2-}]_0}{c_0 M_{\eta}} \times 100\% \quad (4)$$

265 Where  $[\text{SO}_4^{2-}]_0$  is the  $\text{SO}_4^{2-}$  concentration (here 7.27 mg/L),  $C_0$  is the initial eugenol  
266 concentration (in mmol/L),  $M$  is MW of the precursor (164 g/mol for eugenol), and  $\eta$   
267 is the degraded fraction of eugenol.

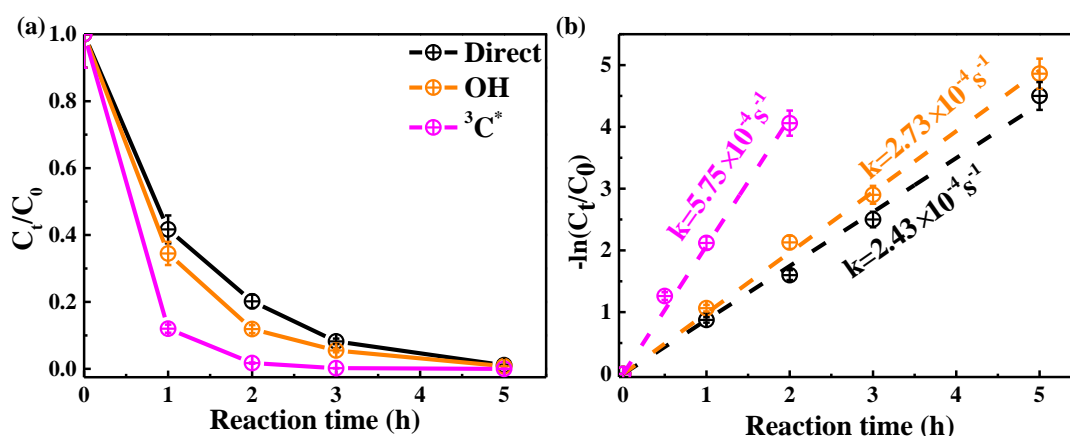

## 268 **3 Results and discussion**

### 269 **3.1 Kinetics of aqueous photooxidation**

270 Figure 1 shows unreacted eugenol concentrations ( $c_t$ ) and the negative logarithm  
271 of  $c_t/c_0$  ( $-\ln(c_t/c_0)$ ) as a function of reaction time, respectively. The pseudo first-order  
272 rate constants ( $k$ ) obtained by Eq.(1) were also presented. As described in Fig. 1a,  
273 eugenol concentration decreased to be <20% of the initial concentration in 3 hours,  
274 suggesting photooxidation was fast under all three reaction conditions. In the presence  
275 of  $^3\text{C}^*$ , eugenol was degraded nearly 100% after 3 hours. Previous study (Chen et al.,  
276 2020) on  $^3\text{C}^*$ -initiated 4-ethylguaiacol oxidation reports a time of 21 hours for a  
277 complete degradation. Apart from difference of precursors, different light irradiation  
278 spectra and stronger energy of light in this work than the previous work might be  
279 responsible for the fast loss of eugenol. The bond dissociation energies (BDEs) are 340  
280 kJ/mol for OH, 374 kJ/mol for C-H in  $-\text{CH}_3$  group, 345 kJ/mol for C=C bond, and 403  
281 kJ/mol for C-H in  $-\text{OCH}_3$  group, respectively (Herrmann et al., 2003; He et al., 2019).  
282 Due to influences of steric hindrance and intramolecular hydrogen bonding, the H-  
283 abstraction from OH group might not be favorable and the most probable H-abstraction  
284 might take place in C=C of the allyl group. As a result, breakage of C=C into C-C at  
285 the allyl group can lead to the formation of 2-methoxy-4-propyl-phenol (Section 3.6.1).  
286 When photon energy is higher than the BDE, chemical bonds can break, leading to  
287 decomposition of compounds and possibly further mineralization. The energy of photon

288 of 300 nm is 412 kJ/mol and can break all major bonds in eugenol, while the energy of  
289 350 nm is 353 kJ/mol, being able to break some of the bonds in eugenol as well. Overall,  
290 eugenol can be easily decomposed after absorbing the photons.

291 As shown in Fig. 1b, the first-order rate constants were  $2.43 \times 10^{-4} \text{ s}^{-1}$ ,  $2.73 \times 10^{-4} \text{ s}^{-1}$   
292 <sup>1</sup>, and  $5.75 \times 10^{-4} \text{ s}^{-1}$  for direct photolysis and photooxidations by OH and <sup>3</sup>C\*,  
293 respectively. <sup>3</sup>C\*-initiated photooxidation was quicker than that attacked by OH, likely  
294 due to combined contributions from reactions with <sup>1</sup>O<sub>2</sub>, O<sub>2</sub><sup>-</sup> and OH (Section 3.2).  
295 Similar results were found for aqueous phase reactions of three phenols against OH and  
296 <sup>3</sup>C\* by Yu et al. (2016) (Note the initial concentrations of H<sub>2</sub>O<sub>2</sub> and DMB were 100 μM  
297 and 5 μM, respectively, with the same ratio as 300 μM H<sub>2</sub>O<sub>2</sub> to 15 μM DMB in this  
298 work)

299  
300 **Figure 1.** Aqueous-phase eugenol decay kinetic curves (a) and first-order rate constants (b) obtained  
301 based on Equation 1 under direct photolysis, OH-initiated oxidation and <sup>3</sup>C\*-initiated oxidation.  
302 Error bar represents one standard deviation from the measurements in triplicate.

### 303 3.2 Relative importance of ROS in photooxidation

#### 304 3.2.1 Quenching experiments in <sup>3</sup>C\*-initiated photooxidation

305 Relative importance of different ROS in photooxidation can be investigated by

306 addition of scavengers/quenchers, and then be evaluated based on the different  
307 degradation efficiencies of eugenol in absence and presence of the corresponding ROS  
308 quenchers. For each quencher, we conducted several gradient experiments with varying  
309 molar ratios of eugenol to quencher. The ratios were 0.075:1, 0.15:1, 0.3:1, 0.75:1, 1.5:1  
310 for quenchers of NaN<sub>3</sub>, TMP and TBA, and 1.2:1, 1.6:1, 2.5:1, 5:1, 10:1 for SOD, which  
311 were all within the typical ranges of ROS quenching experiments reported previously  
312 (Zhou et al., 2018). Excess concentrations of quenchers have been added repeatedly to  
313 ensure the complete reactions between ROS and scavengers. Figure 2 displays the  
314 impacts of quenchers on eugenol degradation. All rate constants (k) with quenchers  
315 were lower than those of the quencher-free solutions. The optimum molar ratio of  
316 eugenol to quencher was selected such that the eugenol degradation did not change with  
317 the increase of added quencher (Wang et al., 2021). For example, along with the  
318 decrease of molar ratios of eugenol to NaN<sub>3</sub> from 1.5:1 to 0.075:1, the variation of  
319 eugenol degradation was stabilized at the ratio of 0.15:1, indicating that <sup>1</sup>O<sub>2</sub> has been  
320 completely quenched at this ratio, therefore a molar ratio of 0.15:1 for NaN<sub>3</sub> was  
321 optimal, since excess scavenger may generate other products that interfere the existing  
322 reactions. Finally, the optimal molar ratios of eugenol to quenchers of TBA, NaN<sub>3</sub>, TMP  
323 and SOD, were determined to be 1.5, 0.15, 0.075 and 2.5, respectively. Table 1 and Fig.  
324 S1 compared the rate constants determined under the ratios above and they were in an  
325 order of TMP<NaN<sub>3</sub><SOD<TBA, suggesting relative importance of generated ROS to  
326 eugenol degradation was in the order of <sup>3</sup>C\* > <sup>1</sup>O<sub>2</sub> > O<sub>2</sub><sup>-</sup> > OH. This result suggests that  
327 <sup>3</sup>C\* plays a major role among all ROS in the photooxidation. Previously, Laurentiis et  
328 al. (2013) reported that 4-carboxybenzophenone (70 μM) could act as <sup>3</sup>C\* and the  
329 photosensitized degradation was more effective than oxidants such as OH, O<sub>3</sub>;  
330 Misovich et al. (2021) investigated the aqueous DMB-photosensitized reaction (5 μM,

331 same as in this study) also demonstrated that  $^3\text{C}^*$  was the greatest contributor to phenol  
332 or guaiacyl acetone degradation, followed by  $^1\text{O}_2$ , while both OH and  $^1\text{O}_2$  contributions  
333 were relatively minor.

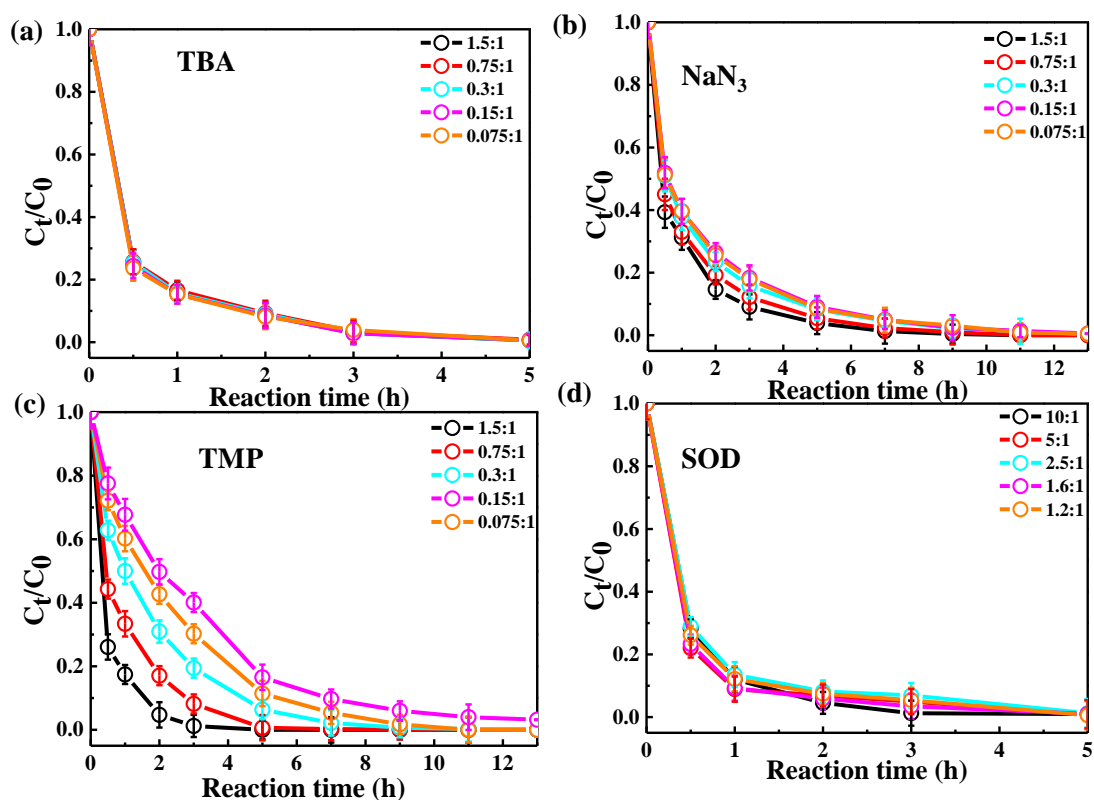

334 To further assess the relative importance of different ROS, we propose to use the  
335 following Eq.(5) for a rough estimation:

$$336 \quad \text{Red}_{\text{ROS}} (\text{in } \%) = (k - k_{\text{quencher}}) / k * 100\% \quad (5)$$

337 Here  $k$  (in  $\text{s}^{-1}$ ) is the original rate constant of  $^3\text{C}^*$ -initiated oxidation (or OH-initiated  
338 oxidation in Section 3.2.2) and  $k_{\text{quencher}}$  (in  $\text{s}^{-1}$ ) is the rate constant after the target ROS  
339 has been completely scavenged by its quencher.  $k$  and  $k_{\text{quencher}}$  in fact refer to those  
340 reported in Fig. S1b.  $\text{Red}_{\text{ROS}}$  then refers to the percentages of reduction due to addition  
341 of quencher for a ROS.

342 According to Eq.(5),  $\text{Red}_{^3\text{C}^*}$  was calculated to be 85.7%. Similarly, the values of  
343  $^1\text{O}_2$ ,  $\text{O}_2^{\cdot-}$  and OH were 80.5%, 61.4% and 53.9%, respectively. Note  $\text{Red}_{\text{ROS}}$  only  
344 reflects the relative important of ROS and it does not corresponds to the exact  
345 contribution of that ROS in eugenol degradation without quenchers. The reason is that  
346 although the addition of a ROS scavenger can eliminate oxidation by this ROS, but it  
347 also significantly interrupts the original chain reactions as compared to those in the  
348 absence of the scavenger, and reactions with other ROS might be enhanced. In this  
349 regard, the sum of the four  $\text{Red}_{\text{ROS}}$  values may exceed 100%. Therefore, one should be  
350 cautious to use  $\text{Red}_{\text{ROS}}$  as a precise quantification of the ROS contribution in aqueous  
351 oxidation. Determination of ROS concentrations during oxidation should be instead be  
352 an effective way to elucidate the role of ROS. Here, we tried to detect in-situ generated  
353 OH,  $\text{O}_2^{\cdot-}$  and  $^1\text{O}_2$  during photochemical reactions using a micro electron spin resonance  
354 (ESR) spectrometer (Bruker Magnettech, Berlin, Germany) with DMPO as the spin trap  
355 to form stable DMPO-OH or DMPO- $\text{O}_2^{\cdot-}$ , with TEMP to capture  $^1\text{O}_2$  to produce TEMP-

356  $^1\text{O}_2$  spin-adduct (TEMPO). The radicals can be identified and quantified by the peak  
 357 patterns in ESR spectra, such as the quarter line with a height ratio of 1:2:2:1 for  
 358 DMPO-OH, 1:1:1:1 for DMPO- $\text{O}_2^{\cdot-}$  and 1:1:1 for TEMP- $^1\text{O}_2$  (Guo et al., 2021).  
 359 Unfortunately, OH radical cannot be detected since its concentration might be lower  
 360 than the detection limit of the instrument (Fig. S2, ESR spectra of OH). In contrast, we  
 361 were able to detect high concentrations of  $^3\text{C}^*$  and found the intensity of TEMP- $^1\text{O}_2$   
 362 signal reached its maximum at 30 minutes, then decreased slowly (Fig. S2, ESR spectra  
 363 of  $^1\text{O}_2$ ). Combining the great quenching effect of TMP with high  $^1\text{O}_2$  concentration from  
 364 ESR method, we can conclude that  $^3\text{C}^*$  and  $^1\text{O}_2$  play relatively important roles in  
 365 eugenol photooxidation.

366

367 **Figure 2.** Ratio of unreacted eugenol concentration to its initial concentration ( $C_t/C_0$ ) at different  
 368 molar ratios of eugenol to quencher, as a function of reaction time: (a) TBA, (b)  $\text{NaN}_3$ , (c) TMP and  
 369 (d) SOD.

370

### 371 3.2.2 Quenching experiments in OH-initiated photooxidation

372 To examine the contributions of ROS to eugenol degradation for OH-initiated  
373 oxidation, TBA and *p*-BQ as trapping agents were added. Similar to  $^3\text{C}^*$ -initiated  
374 oxidation, several gradient experiments with varying molar ratios of eugenol to  
375 quenchers were conducted. The ratios were set as 6.5:1, 3.2:1, 1.6:1, 1.1:1 and 0.8:1 for  
376 *p*-BQ and 3.0:1, 1.5:1, 0.75:1, 0.3:1 and 0.15:1 for TBA. According to Fig. S3, molar  
377 ratio only had a slight influence on eugenol degradation, although degradation can be  
378 inhibited effectively by quenchers. Thus, we determined the appropriate molar ratios of  
379 0.8 and 0.75 for *p*-BQ and TBA, respectively, as excess scavengers might influence the  
380 chemical reactions.

381 Variations of the rate constants for the aforementioned quenching experiments were  
382 determined, in comparison with those conducted without quenchers, and results are  
383 listed in Table 1 and presented in Fig. S4. For TBA quenching tests, the rate constant  
384 decreased by 18.7% (from  $2.73 \times 10^{-4} \text{ s}^{-1}$  to  $2.22 \times 10^{-4} \text{ s}^{-1}$ ), showing that OH radical  
385 played a certain role in eugenol photooxidation. Since  $\text{H}_2\text{O}_2$  was mainly photolyzed at  
386 wavelength  $< 300 \text{ nm}$  to generate OH radical, irradiation above  $300 \text{ nm}$  did not affect  
387 the reaction significantly. The *p*-BQ could quench  $\text{O}_2^{\cdot-}$ , further suppressing the  
388 generation of other ROS (e.g.,  $\cdot\text{HO}_2$ ), therefore the rate constant decreased the most  
389 (from  $2.73 \times 10^{-4} \text{ s}^{-1}$  to  $1.20 \times 10^{-4} \text{ s}^{-1}$ ), suggesting  $\text{O}_2^{\cdot-}$  was important for eugenol  
390 photooxidation. This hypothesis could be further confirmed by the decline of rate  
391 constant under  $\text{N}_2$ -saturated solution (Section 3.2.3). However, it was difficult to detect  
392 both OH and  $\text{O}_2^{\cdot-}$  directly due to their relatively short lifetimes and low concentrations  
393 via ESR in this work.

394

395 **Table 1.** The first-order rate constants of eugenol in the presence of various scavengers. The initial  
 396 conditions were as follows: 300  $\mu\text{M}$  eugenol; molar ratios of eugenol to quenchers TBA,  $\text{NaN}_3$ ,  
 397 TMP and SOD, of 1.5, 0.15, 0.075 and 2.5, respectively; molar ratios of eugenol to quenchers *p*-BQ  
 398 and TBA of 0.8 and 0.75, respectively.

$^3\text{C}^*$ -initiated quenching experiments			
Quenchers	ROS	Reaction rate constant $k$ ( $\text{s}^{-1}$ )	Pearson's $R^2$
no quencher	-	$5.75 \times 10^{-4}$	0.996
TBA	OH	$2.65 \times 10^{-4}$	0.999
SOD	$\text{O}_2^{\cdot-}$	$2.22 \times 10^{-4}$	0.995
$\text{NaN}_3$	$^1\text{O}_2$	$1.12 \times 10^{-4}$	0.999
TMP	$^3\text{C}^*$	$0.82 \times 10^{-4}$	0.999
OH-initiated quenching experiments			
Quenchers	ROS	Reaction rate constant $k$ ( $\text{s}^{-1}$ )	$R^2$
No quencher	-	$2.73 \times 10^{-4}$	0.995
TBA	OH	$2.22 \times 10^{-4}$	0.998
<i>p</i> -BQ	$\text{O}_2^{\cdot-}$	$1.20 \times 10^{-4}$	0.995

399

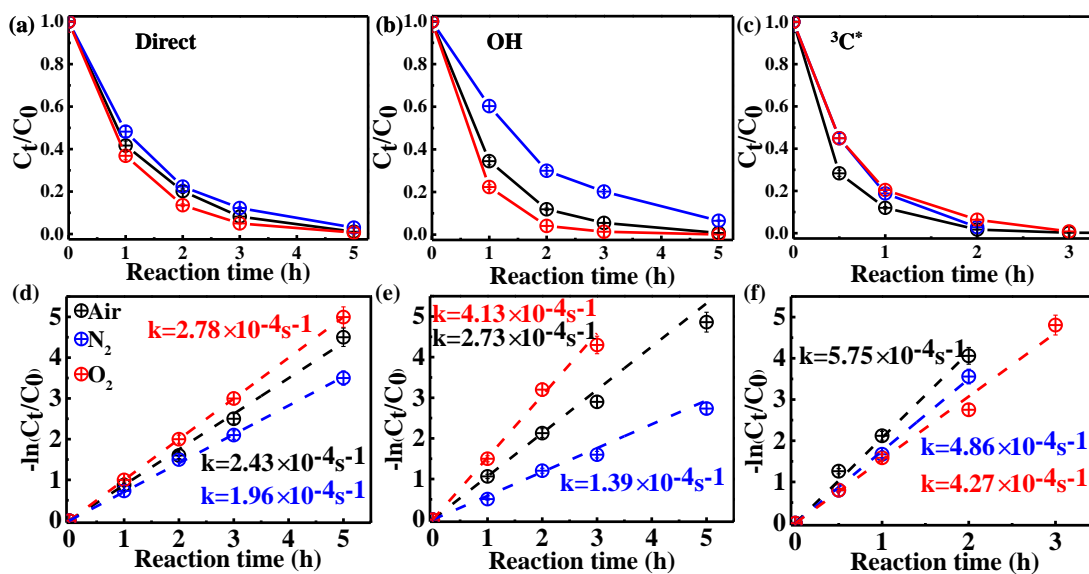

### 400 3.2.3 Influences of different saturated gases

401 In order to assess the role of  $\text{O}_2$  in eugenol degradation, a series of experiments  
 402 were performed under both  $\text{O}_2$ -saturated and  $\text{N}_2$ -saturated conditions in addition to air.  
 403  $\text{N}_2$  gas was purged into reaction solution for  $\sim 30$  minutes before experiment to achieve  
 404 the  $\text{O}_2$ -free condition. Figure 3 compared the changes of eugenol concentrations and  
 405 rate constants under the three gas conditions for direct photolysis, OH-initiated and  $^3\text{C}^*$ -  
 406 initiated oxidations, respectively. The rate constants followed the order of  $k_{\text{O}_2} > k_{\text{Air}} >$   
 407  $k_{\text{N}_2}$  under both direct photolysis and OH oxidation, providing evidence in support of  $\text{O}_2$   
 408 being significant for eugenol degradation. This might be explained by the fact that  $\text{O}_2$   
 409 can act as an electron acceptor to generate  $\text{O}_2^{\cdot-}$  and  $\cdot\text{HO}_2$ , and subsequently form  $\text{H}_2\text{O}_2$   
 410 and OH. For direct photolysis, rate constant under  $\text{O}_2$ -saturated condition increased  
 411 14.4% while it decreased 19.3% under  $\text{N}_2$  saturation from that under saturated air. For

412 OH-initiated oxidation, the difference of rate constants under three saturated gases  
 413 became more distinct.

414 On the contrary, rate constants followed the order of  $k_{\text{Air}} > k_{\text{N}_2} > k_{\text{O}_2}$  in  $^3\text{C}^*$ -  
 415 initiated oxidation. There are two possible explanations. On one hand, under  $\text{N}_2$ -  
 416 saturated condition without oxygen, DMB would involve in reactions (R1-R4), leading  
 417 to a more effective generation of  $^3\text{DMB}^*$  therefore a higher degradation efficiency than  
 418 under  $\text{O}_2$ -saturated condition. On the other hand, for air/ $\text{O}_2$ -saturated solutions,  
 419 irradiation of DMB and eugenol would involve also reactions (R5-R8) in addition to  
 420 (R1-R4), and as a result, the amount of  $^3\text{DMB}^*$  decreased, due to formation of other  
 421 ROS ( $^1\text{O}_2$ ,  $\text{O}_2^{\bullet-}$ , OH, etc) with relatively weak oxidative capacities. In summary,  
 422 quenching of  $^3\text{DMB}^*$  by ground state molecular oxygen could account for the low  
 423 degradation efficiency in  $\text{O}_2$ -saturated condition.

432

433 **Figure 3.** Ratio of unreacted eugenol concentration to its initial concentration ( $C_t/C_0$ ) as a function  
 434 of reaction time at different saturated gases under (a) direct photolysis (b) OH-initiated oxidation  
 435 and (c)  $^3C^*$ -initiated oxidation. Rate constants of (a-c) are presented in (d-f) correspondingly.

### 436 3.2.4 Variations of pH and dissolved oxygen

437 The initial pH values of reaction solutions for direct photolysis and OH-initiated  
 438 oxidation were unadjusted, while that for the  $^3C^*$ -oxidation was adjusted to 3. The  
 439 variation of solution pH is presented in Fig. 4a. The pH values decreased quickly at the  
 440 beginning of illumination (from 7.4 to  $\sim 5.0$  in the first 1 hour) then tended to be flat for  
 441 both direct photolysis and OH-initiated oxidation. However, little change of pH (less  
 442 than 0.1 unit) was observed for the  $^3C^*$ -initiated photooxidation throughout the  
 443 oxidation, which can be likely ascribed to its low initial pH of 3. Since the solution pH  
 444 was acidic (pH=3), we cannot rule out formation of acidic products (such as organic  
 445 acids) during  $^3C^*$ -initiated oxidation as during direct photolysis and OH-initiated  
 446 oxidation.

447 As discussed in Section 3.2.3, oxygen can take part in photochemical reaction to  
 448 form ROS, which may in turn destroy the structure of precursor. Here we measured the

449 oxygen consumption during oxidation through determination of dissolved oxygen (DO)  
 450 contents by a dissolved oxygen meter (Seven2Go Pro S9, Zurich, Switzerland). DO was  
 451 consumed mainly at the first 1 hour and remained stable afterwards (Figs. 4b-c and Fig.  
 452 S5). The amounts of consumed DO followed the order of  ${}^3\text{C}^* > \text{OH} > \text{direct photolysis}$ .  
 453 The maximum consumed DO was found in  ${}^3\text{C}^*$ -initiated oxidation, which might be  
 454 explained by the consumption of  $\text{O}_2$  that reacts with  ${}^3\text{C}^*$  form  ${}^1\text{O}_2$  (R5). Obviously, a  
 455 steady-state DO level was reached when the consumption rate was equal to the diffusion  
 456 of  $\text{O}_2$  into the solution (Pan et al., 2020). Overall, these results re-emphasize that  $\text{O}_2$   
 457 can influence eugenol degradation and chemical transformation via induction of radical  
 458 chain reactions.

459 **Figure 4.** (a) pH values and (b) dissolved oxygen (DO) contents against reaction time under direct  
 460 photolysis, OH-initiated oxidation,  ${}^3\text{C}^*$ -initiated oxidation, and (c) DO contents during  ${}^3\text{C}^*$ -initiated  
 461 oxidation under air or  $\text{O}_2$ -saturated conditions.  
 462

463

### 464 3.3 Optical properties of reaction products

#### 465 3.3.1 Light-absorbing properties

466 The UV-vis light absorption spectra of the solutions at different reaction times are  
 467 presented in Fig. 5. The light absorption by eugenol itself mainly occurs in the range of  
 468 260-300 nm ( $n \rightarrow \pi^*$  electronic transition, 270-350 nm), which overlaps with the major  
 469 photon fluxes (280 and 500 nm) of our lamp for photooxidation. Therefore, we can  
 470 clearly observe that the characteristic absorption peak at 280 nm of precursor decreased

471 with the propagation of direct photolysis (Fig. 5a), similar to that in OH-initiated  
472 photooxidation (Fig. 5b). However, the reaction was quick in the presence of  $^3\text{C}^*$ , and  
473 the characteristic absorption peak at 280 nm after 3 hours of illumination almost  
474 disappeared, suggesting nearly a complete loss of eugenol, consistent with the results  
475 in Section 3.1 that more than 99% eugenol was degraded in 3 hours. Additionally, there  
476 was an obvious absorption enhancement at longer wavelengths (300-400 nm) during  
477 the photooxidation, whereas eugenol itself did not absorb light in this range, indicating  
478 some light-absorbing products (e.g., brown carbon (BrC) species) were generated.  
479 Aqueous photooxidation of some phenolic compounds (e.g., vanillic acid) also  
480 presented long-wavelength (300-400nm) light absorbance, with intensity increasing  
481 with illumination time (Tang et al, 2020; Zhao et al., 2015). In addition, there were  
482 some differences for light absorbance at wavelength of 300-400 nm in the three reaction  
483 conditions. For direct photolysis and OH-initiated oxidation, light absorbance increased  
484 during the first 15 hours, then remained at a plateau until 23 hours. However, for  $^3\text{C}^*$ -  
485 initiated oxidation, light absorbance increased during the first 7 hours, then decreased  
486 slowly afterwards. The different shapes of UV-vis spectra between OH and  $^3\text{C}^*$   
487 photooxidations indicate formations of different products.

488         Compared to the light spectrum of eugenol, there were also increases of light  
489 absorbance at  $\sim 260$  nm ( $\pi \rightarrow \pi^*$  electronic transitions) upon aqueous oxidation in all  
490 three reaction conditions (Fig. 5), demonstrating the generation of new substances  
491 likely with both aromatic C=C and carbonyl (C=O) functional groups (Tang et al., 2020).  
492 The enhancement at 300-400 nm may point to products with high MWs and conjugated  
493 structures. Unfortunately, we were unable to quantify the relative contributions of  
494 individual products to the overall light absorbance between 300 to 400 nm due to lack  
495 of a full speciation of the products and their light absorption spectra.

496

497 **Figure 5.** UV-vis light absorption spectra of reacted solutions at different reaction times under (a)  
 498 direct photolysis, (b) OH-initiated oxidation, and (c)  $^3\text{C}^*$ -initiated oxidation.

### 499 3.3.2 Fluorescence properties

500 The fluorescence properties of solutions before (0 hour) and during photooxidation  
 501 (3 and 7 hours) were investigated via the EEM technique, as shown in Fig. 6. For  
 502 comparison, we also presented EEM profiles of pure eugenol (non-irradiated), pure  
 503 DMB, and the end solutions (23 hours) of direct photolysis and OH-initiated oxidation  
 504 in Fig. S6. The peaks at Excitation/Emission (Ex/Em)=275/313 nm can be attributed to  
 505 fluorescence of the phenolic structure of parent substance (eugenol here), as suggested  
 506 by Laurentiis et al. (2013). As shown in both Fig. 6 and Fig. S6, the fluorescence  
 507 intensity decreased after oxidation due to eugenol decay, and the reduction was very  
 508 fast for  $^3\text{C}^*$ -initiated oxidation. This finding matches with the fast degradation and large  
 509 rate constant for  $^3\text{C}^*$ -initiated oxidation. The EEM plots for direct photolysis and OH-  
 510 initiated oxidation had similar contour patterns as shown in Figs. 6a and b, although  
 511 EEM profiles changed significantly with irradiation time. We also observed distinct  
 512 fluorescent peaks at Ex/Em=235/(400-500) nm, indicating that illumination can cause  
 513 a red shift in fluorescence emission wavelength. As suggested by Chang et al. (2010),  
 514 fluorophores at Ex/Em=240/400 nm are linked with aromatic structures and condensed  
 515 saturated bonds including polycyclic aromatic hydrocarbons. Another work (Li et al.,  
 516 2021) showed that red shift in the fluorescence spectra was usually related to an

517 increase in the size of ring system and an increase in the degree of conjugation. Previous  
518 studies (Chen et al., 2016a; Chen et al., 2019) have reported that fluorescent compounds  
519 with emission wavelength at 400-500 nm were likely linked with HULIS. Additionally,  
520 HULIS have two typical fluorescent peaks in EEM profile at  $Ex/Em=(200-300)/(400-$   
521  $500)$  nm and  $Ex/Em=350/(400-500)$  nm with the former one having a higher intensity  
522 (Graber and Rudich, 2006; Laurentiis et al., 2013; Vione et al., 2019). There was also  
523 evidence that direct photolysis of tyrosine and 4-phenoxyphenol generated HULIS with  
524 new fluorescence signals at  $Ex/Em=(200-250)/(400-450)$  nm and  $300/(400-450)$  nm  
525 (Bianco et al., 2014). In this regard, we inferred that new peak at  $Ex/Em=235/(400-500)$   
526 nm here was likely attributed to HULIS. For the  $^3C^*$ -initiated oxidation, extra  
527 fluorescent peaks at  $Ex/Em=(220-300)/(400-500)$  nm appeared in the first 1 hour (data  
528 not shown), but their intensities weakened and gradually disappeared upon prolonged  
529 reactions (3 hours). Nevertheless, EEM results should be interpreted with caution  
530 because many substances might contribute to absorption and emission at a certain  
531 wavelength, and it is hard to distinguish and isolate fluorescent and nonfluorescent  
532 constituents simply via the EEM technique.

533 Another interesting finding was that a small fluorescence peak appeared at  
534  $Ex/Em=(300-350)/(300-350)$  nm in some of the EEM profiles. Specifically, it appeared  
535 earlier for  $^3C^*$ -oxidation (at 3 hours) than the other two systems, yet its intensity seemed  
536 to be a bit stronger in the end solutions of direct photolysis and OH-oxidation (Fig. S6).  
537 Moreover, as suggested by Leenheer and Croue (2003), fluorescence peak position of  
538 the maximum  $Ex/Em$  for HULIS with lower MWs would shift towards lower  
539 wavelengths, thus, we inferred fluorescence peak at  $Ex/Em=(300-350)/(300-350)$  nm  
540 might be in part attributed to the organic acids with a few carbon atoms (probably  $C_1-$   
541  $C_6$ ). Nevertheless, large uncertainties still exist in using EEM fluorescence technique

542 to identify molecular compositions of the products due to lack of standard EEM profiles  
543 for specific compounds from aqueous phase oxidation and clearly more studies are  
544 needed in future.

545  
546 **Figure 6.** EEM fluorescence spectra of the initial solution (0 hour) and those at different reaction  
547 time (3 and 7 hours) under (a) direct photolysis, (b) OH-initiated oxidation, and (c)  $^3\text{C}^*$ -initiated  
548 oxidation.

### 549 3.4 Characteristics of HULIS

550 The EEM spectra revealed new prominent fluorescent peak at Ex/Em=250/(400-  
551 500) nm, which was likely owing to HULIS. HULIS can be divided into fulvic acid  
552 (water soluble at all pHs), humic acid (base soluble, acid insoluble) and humin  
553 (insoluble at all pHs). In principle, extracted HULIS in this work with polymer-based

554 HLB SPE packing include LMW organic acids, fulvic acids and other humic substances.

555 Figure 7 presents the measured HULIS concentrations against the reaction time.

556 The results show clearly that aqueous-phase eugenol oxidation is a source of HULIS,

557 and the amount increased gradually in the first 7 hours, then remained at a similar level

558 (about 30 mg/L) for the OH-initiated oxidation. For direct photolysis, HULIS

559 concentration increased until 11 hours and then became steady at a level around 40

560 mg/L. For the  $^3\text{C}^*$ -oxidation, HULIS concentration increased to a maximum at 7 hours,

561 then declined slightly afterwards. A plausible reason of such variabilities is that

562 generated HULIS was capable of further taking part in photochemical reactions since

563 it can act as photosensitizer. Moreover, Yu et al. (2016) characterized the products from

564 aqueous oxidations of phenols by  $^3\text{C}^*$  triplet states and OH radicals, and found both

565 could produce oligomers and hydroxylated species but the  $^3\text{C}^*$ -oxidation could produce

566 more of these compounds when 50% of the precursor was reacted. Considering the

567 large increases of HULIS in the first 7 hours and the much faster increase of  $^3\text{C}^*$ -

568 oxidation in the first 3 hours shown in Fig. 7, we postulate that HULIS species might

569 be some of the high MW oligomers, which can in turn contributed to fluorescence at

570 emission of  $\sim 400$  nm (Barsotti et al., 2016).

571

572 **Figure 7.** HULIS concentrations as a function of reaction time under direct photolysis, OH-

573 initiated oxidation and  $^3\text{C}^*$ -initiated oxidation.

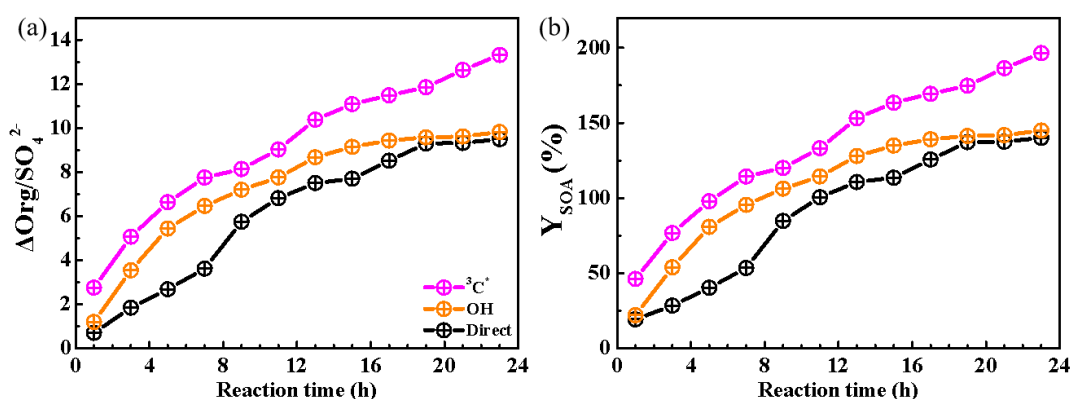

## 574 3.5 Mass yield and oxidation degree of reaction products

### 575 3.5.1 Mass yields

576 HULIS is only a subset of the products from aqueous oxidation, and here we used  
577 AMS to further quantify the total reaction products. Figure 8a shows SP-AMS  
578 measured organic mass profiles (normalized by sulfate mass,  $\Delta\text{Org}/\text{SO}_4^{2-}$ ) against the  
579 reaction time. As the reaction propagated,  $\Delta\text{Org}/\text{SO}_4^{2-}$  increased continuously in  $^3\text{C}^*$ -  
580 initiated system. Nevertheless it arose stepwise and reached a maximum at 19 hours,  
581 then remained at a plateau for the direct photolysis and OH-mediated oxidation. Figure  
582 8b illustrates the calculated mass yields at different reaction times. The mass yields  
583 were in the ranges of 46.2%-196.5%, 22.1%-144.9%, 19.3%-140.1% for  $^3\text{C}^*$ -oxidation,  
584 OH-oxidation and direct photolysis, respectively. For the same oxidation time, mass  
585 yield from  $^3\text{C}^*$ -oxidation was generally higher than those from OH-oxidation and direct  
586 photolysis. There are two plausible reasons for high mass yield of  $^3\text{C}^*$ -initiated  
587 oxidation. First, oxidation by  $^3\text{C}^*$  was more efficient to form oligomers and  
588 functionalized/oxygenated products (Richards-Henderson et al., 2014; Yu et al., 2016).  
589 Higher oxidative degree of products from  $^3\text{C}^*$ -initiated photooxidation (see Sec.3.5.2)  
590 supports this hypothesis. Secondly, more light-absorbing products formed during initial  
591 stage of  $^3\text{C}^*$ -oxidation (Fig. 5c) may accelerate oxidation by acting as photosensitizers  
592 (Tsui et al., 2018).

593 The product mass yields obtained in this work (~20%-197%) overall agree with  
594 those reported previously for phenolic compounds. For examples, Huang et al. (2018)  
595 reported mass yields of 30-120% for syringaldehyde and acetosyringone; Smith et al.  
596 (2014) found that mass yields of aqSOA from three phenols with  $^3\text{C}^*$  were nearly 100%,  
597 and Ma et al. (2021) reported a yield ranging from 59 to 99% for six highly substituted

598 phenols with  $^3\text{C}^*$ ; Mass yields of SOA from three benzene-diols were near 100% with  
 599 both OH and  $^3\text{C}^*$  oxidants (Smith et al., 2015); Direct photolysis of phenolic carbonyls,  
 600 and oxidation of syringol by  $^3\text{C}^*$ , had SOA mass yields ranging from 80 to 140% (Smith  
 601 et al., 2016). Our previous study on eugenol OH oxidation illuminated by a 500 W Xe  
 602 lamp reported a mass yield of  $\sim 180\%$  (Ye et al., 2020), slightly higher than the value  
 603 determined here owing to different light wavelengths/intensities.

604  
 605 **Figure 8.** Variations of the organic mass normalized by sulfate (a) ( $\Delta\text{Org}/\text{SO}_4^{2-}$ ) and (b) mass yields  
 606 of reaction products with reaction time under direct photolysis, OH-initiated oxidation and  $^3\text{C}^*$ -  
 607 initiated oxidation.

608

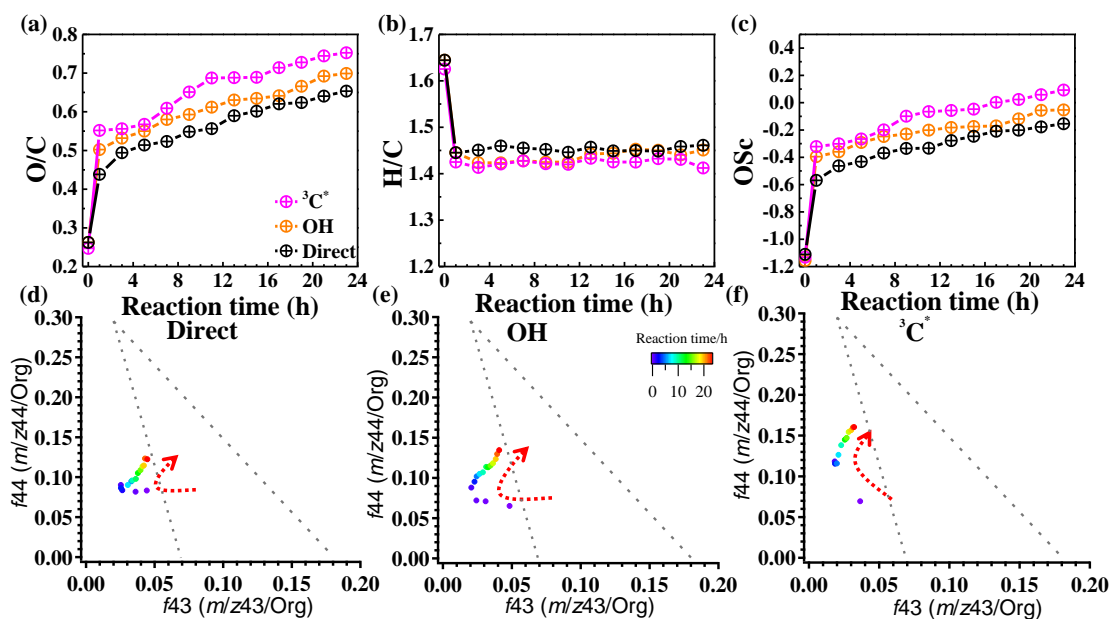

### 609 3.5.2 Oxidation degree

610 In order to further probe oxidation levels of the reaction products, O/C derived  
 611 from SP-AMS mass spectrum of the organics was used to represent the oxidation degree  
 612 of products. In addition, carbon oxidation state (OSc, defined as  $2 \cdot \text{O}/\text{C} - \text{H}/\text{C}$ ) (Kroll  
 613 et al., 2011) was also calculated. Figures 9a-c depict variations of the elemental ratios  
 614 (O/C and H/C) and OSc during oxidations. Dramatic increases of O/C and OSc during  
 615 the initial stage of oxidation (within 1 hour) were observed, with O/C changing from  
 616 0.26 to 0.65, from 0.26 to 0.70, from 0.25 to 0.75, as well as OSc from -1.11 to -0.15,  
 617 from -1.16 to -0.05, from -1.13 to 0.09 for direct photolysis, OH-oxidation and  $^3\text{C}^*$ -

618 oxidation, respectively. The O/C was lower than those of other phenolic aqSOA (Yu et  
619 al., 2014) due to different substituted groups in aromatic ring of the precursors. Both  
620 O/C and OSc gradually increased, while H/C changed little after 1 hour. The  
621 enhancements of OSc in the end were 1.22, 1.11 and 0.86 for  $^3\text{C}^*$ -initiated oxidation,  
622 OH-initiated oxidation and direct photolysis, respectively.

623 Furthermore, the  $f_{44}$  vs.  $f_{43}$  diagram (“triangle plot”) can be used to demonstrate  
624 the evolution of SOA during oxidation (Ng et al., 2010). The  $f_{44}$  and  $f_{43}$  are defined as  
625 the ratios of signal intensities of  $m/z$  44 (mainly  $\text{CO}_2^+$ ) and 43 (mainly  $\text{C}_2\text{H}_3\text{O}^+$ ) to the  
626 total organics. The results that the  $f_{44}$  increased continuously (moved upwards) during  
627 both OH and  $^3\text{C}^*$  oxidations, indicating persistent formation of highly oxygenated  
628 compounds including organic acids, such as formic acid and oxalic acid (Sun et al.,  
629 2010). Note the  $f_{44}$  enhancement was much more significant for  $^3\text{C}^*$  oxidation (from  
630 0.07 to 0.16) than direct photolysis (from 0.07 to 0.12) and OH oxidation (from 0.07 to  
631 0.13), consistent with the behaviors of its higher O/C and OSc. The  $f_{43}$  value decreased  
632 in the first stage (1-3 hours) and then increased at later stages. The final  $f_{43}$  values were  
633 almost the same as those of the initial solutions and were small. As a result, all data  
634 points located outside the  $f_{44}$  vs.  $f_{43}$  region (bounded by the two dash lines in Figs. 9d-  
635 f) for ambient aerosols established by Ng et al. (2010).

636 In summary, our results shown here demonstrate that aqueous phase eugenol  
637 photochemical oxidation can generate highly oxygenated products and hence increase  
638 the degree of oxygenation of overall SOA.

639

640 **Figure 9.** Variations of the elemental ratios of (a) O/C, (b) H/C and (c) oxidation state (OSc) as a  
 641 function of reaction time;  $f_{44}$  vs.  $f_{43}$  plots of reaction products under (d) direct photolysis, (e) OH-  
 642 initiated oxidation, and (f)  $^3\text{C}^*$ -initiated oxidation.

### 643 3.6 Molecular characterization of reaction products and proposed reaction 644 mechanism

#### 645 3.6.1 Major products identified by GC-MS

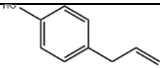

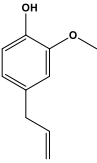

646 SP-AMS was limited to probe bulk composition of low-volatility oxidation  
 647 products, thus the molecular-level characterization of products was performed by using  
 648 GC-MS here. The total ion chromatograph (TIC) of GC-MS on the solutions before  
 649 illumination (0 hour) and at illumination times of 11 and 23 hours for the  $^3\text{C}^*$ -initiated  
 650 photooxidation is shown in Fig. S7. As shown in Fig.S7, eugenol (retention time (RT)  
 651 at 11.50 min) loss was more than 90% at 11 hours, which could be confirmed by the  
 652 experimental data reported in Section 3.1. Comparison of products at 11 hours and 23  
 653 hours showed no significant difference. Similar to aqueous photochemical oxidation  
 654 with OH (Ye et al., 2020), a series of products were identified and listed in Table 2.

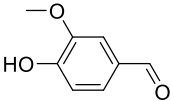

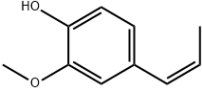

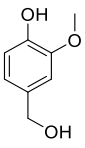

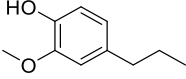

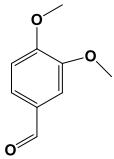

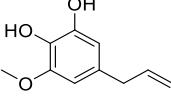

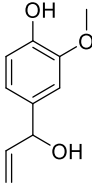

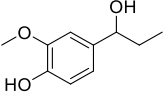

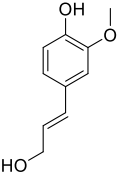

655 Except 5-allyl-3-methoxybenzene-1,2-diol (MW 180, RT=12.59 min), the other eight  
 656 products were detected for both OH and  $^3\text{C}^*$ -initiated photooxidations. Some of them  
 657 (Eugenol, DMB, product 1, 2, 5) were identified by using certified reference materials,  
 658 some of them (product 3, 4, 6, 7, 8, 9) were inferred according to the molecular ion  
 659 peaks and fragments from GC-MS, based on spectra from the NIST database (Stein,  
 660 2014) and on the reactants and reaction conditions.

661 We also found 4-(1-hydroxypropyl)-2-methoxyphenol (product 8) was relatively  
 662 abundant (Fig.S7), suggesting functionalization might dominates as compared to  
 663 oligomerization and fragmentation. Products were mainly from addition/elimination of  
 664 hydroxyl (-OH), methoxyl (-OCH<sub>3</sub>) to benzene ring or allyl group and further oxidized  
 665 to carbonyl or carboxyl compounds. As suggested by Bonin et al. (2007), the OH-  
 666 addition to the aromatic ring of phenol preferentially takes place at the ortho (48%) and  
 667 the para (36%) positions, leading to the formation of OH-adduct product 6 (5-allyl-3-  
 668 methoxybenzene-1,2-diol). Notably, dimers and ring-opening products were not  
 669 observed, but they cannot be excluded since they would be probably out of the detection  
 670 of GC-MS technique (Vione et al., 2014).

671

672 **Table 2.** Major reaction products identified via GC-MS

	<b>RT</b>	<b>Name*</b>	<b>Proposed chemical</b>	<b>Chemical</b>	<b>Nominal</b>
	<b>(min)</b>		<b>structure</b>	<b>formula</b>	<b>MW</b>
					<b>(g/mol)</b>
Product 1	10.68	4-allylphenol		C <sub>9</sub> H <sub>10</sub> O	134
Precursor	11.50	Eugenol		C <sub>10</sub> H <sub>12</sub> O <sub>2</sub>	164

Product 2	11.81	4-hydroxy-3-methoxybenzaldehyde		$C_8H_8O_3$	152
Product 3	12.06	(E)-2-methoxy-4-(prop-1-en-1-yl)phenol		$C_{10}H_{12}O_2$	164
Product 4	12.11	4-(hydroxymethyl)-2-methoxyphenol		$C_8H_{10}O_3$	154
Product 5	12.18	2-methoxy-4-propylphenol		$C_{10}H_{14}O_2$	166
Photosensitizer	12.29	3,4-dimethoxybenzaldehyde (DMB)		$C_9H_{10}O_3$	166
Product 6**	12.59	5-allyl-3-methoxybenzene-1,2-diol		$C_{10}H_{12}O_3$	180
Product 7	12.65	4-(1-hydroxyallyl)-2-methoxyphenol		$C_{10}H_{12}O_3$	180
Product 8	12.79	4-(1-hydroxypropyl)-2-methoxyphenol		$C_{10}H_{14}O_3$	182
Product 9	12.91	(E)-4-(3-hydroxyprop-1-en-1-yl)-2-methoxyphenol		$C_{10}H_{12}O_3$	180

673 \*Precursor (eugenol) and triplet precursor (DMB) are also shown.

674 \*\*This compound was only identified in  $^3\text{C}^*$ -oxidation solution.

### 675 **3.6.2 Reaction mechanism**

676 The reaction pathways of  $^3\text{C}^*$ -initiated photooxidation of eugenol are  
677 demonstrated in Scheme 1 based on the products identified by GC-MS. The  
678 other intermediates and the potential pathways were proposed according to the  
679 identified products and the reaction rationality from the starting reactant. To better  
680 depict the mechanism, DMB was expressed as [RCHO] and eugenol as Ph-R for  
681 simplicity. [RCHO] absorbs light and undergoes excitation to  $^1[\text{RCHO}]^*$ , then  
682 experiences the intersystem crossing (ISC) to form  $^3[\text{RCHO}]^*$ .  $^3[\text{RCHO}]^*$  can  
683 participate in subsequent reactions via three channels. First, it can react with  $\text{O}_2$  to form  
684  $^1\text{O}_2$  via energy transfer. Secondly, it can transform to  $[\text{RCHO}]^{\cdot-}$ , subsequently reacts  
685 with  $\text{O}_2$  to generate  $\text{O}_2^{\cdot-}$  via electron transfer, which can disproportionate to  $\text{H}_2\text{O}_2$ . The  
686 decomposition of  $\text{H}_2\text{O}_2$  can generate OH radical. Thirdly, the  $^3[\text{RCHO}]^*$  can react with  
687 Ph-R to form  $[\text{Ph-R}\cdot]$  via H-abstraction. The cleavage of  $[\text{Ph-R}\cdot]$  to free radical segment  
688 (such as  $\text{CH}_2\text{CH}\cdot$  or  $\text{CH}_3\text{O}\cdot$ ) takes place, then an additional hydrogen transfer could  
689 occur, resulting in a 2H-addition to the new intermediate to form 4-allyl-phenol  
690 (product 1). Similarly, when the  $\text{CH}_2\text{CH}\cdot$  is lost from  $[\text{Ph-R}\cdot]$ , an addition of  $\text{H}_2\text{O}$   
691 would happen on the new compound (product 4) and further oxidized to 4-hydroxy-3-  
692 methoxybenzaldehyde (product 2). Another possibility is the intermediate  $[\text{Ph-R}\cdot]$  can  
693 resonate to several different isoelectronic species, the radical position changes to  
694 aromatic ring or allyl group site, which would couple with  $\text{HO}\cdot$  to form hydroxylated  
695 eugenol monomer (product 6, 7, 9 MW=180). Consequently, the isoelectronic species  
696 at allyl group site could also abstract a hydrogen to form isoeugenol (product 3  
697 MW=164). Also, breakage of  $\text{C}=\text{C}$  into  $\text{C}-\text{C}$  and 2H-addition at allyl group site could

698 form 2-methoxy-4-propyl-phenol (product 5, MW=166). Besides, the C=C breaking  
699 intermediate can couple with HO• to form 4-(1-hydroxypropyl)-2-methoxyphenol  
700 (product 8, MW=182). In conclusion,  $^3\text{C}^*$  can directly oxidize eugenol to form SOA  
701 products or small molecular compounds, or indirectly oxidize eugenol via energy  
702 transfer, electron transfer, hydrogen abstraction, proton-coupled electron transfer or  
703 other radical chain reactions.

704 The organic groups, such as methoxy, allyl groups can be eliminated from  
705 aromatic ring, which then participate in photochemical reaction, resulting in generation  
706 of dimers, small organic acids, CO<sub>2</sub> and H<sub>2</sub>O, etc. Dimers previously reported from  
707 aqueous reaction of 4-methylsyringol with OH were not detected via GC-MS in the  
708 present work but dimer fragment ions (C<sub>20</sub>H<sub>22</sub>O<sub>4</sub><sup>+</sup>) were detected by SP-AMS with trace  
709 amounts. Functionalization due to the additions of hydroxyl, carbonyl functional groups  
710 to the aromatic rings could account for the enhancement of light absorption at  
711 wavelength of 300-400 nm. However, polar high MW organic acids were not detected  
712 likely due to the limitation of GC-MS technique.

713

714 **Scheme 1.** Proposed reaction mechanism of  $^3C^*$ -initiated photooxidation of eugenol. The red text

715 represents the precursor, and the compounds labeled by Product 1-9 are those identified by GC-

716 MS (Table 2).

### 717 3.7 Oxidative potential (OP) of reaction products

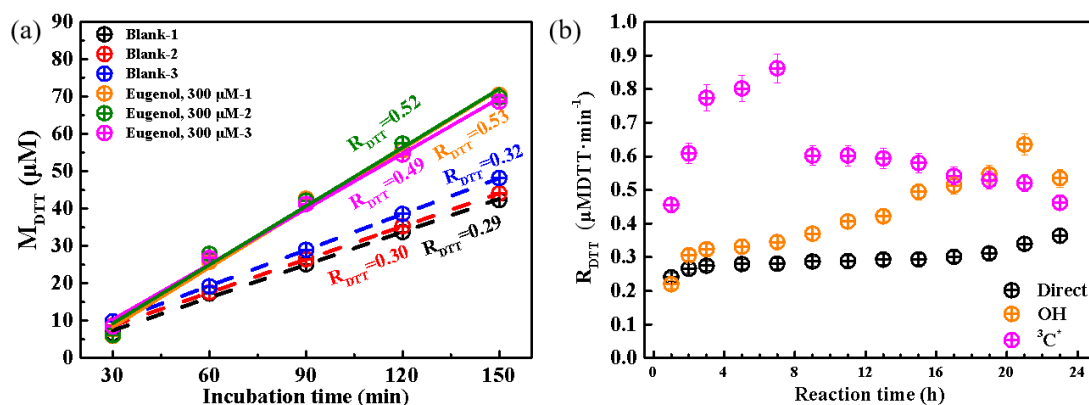

718 The OP of oxidation products can be represented by the consumption rate of DTT

719 concentration, defined as  $R_{DTT}$ . Figure 10a shows the DTT consumed mass ( $M_{DTT}$ ) as

720 a function of incubation times (0, 30, 60, 90, 120 and 150 min) for a triplicate sample

721 (300  $\mu\text{M}$  eugenol) and blank (ultrapure water).  $M_{\text{DTT}}$  values for both blank and eugenol  
722 were proportional to incubation time, indicating that ROS-generating substances in  
723 reaction solution act only as catalyst and itself was not consumed. The slopes represent  
724 DTT consumption rates, which are also illustrated in Fig. 10a. Average  $R_{\text{DTT0}}$  (blank)  
725 was 0.31  $\mu\text{M}/\text{min}$  and  $R_{\text{DTT}}$  for initial 300  $\mu\text{M}$  eugenol (before experiment) was 0.52  
726  $\mu\text{M}/\text{min}$ . Since self-oxidation of DTT might lead to the consumption of DTT in  
727 ultrapure water, final DTT consumption rate of reacted solution after oxidation was then  
728 blank-corrected by subtracting the average  $R_{\text{DTT0}}$ .

729 Figure 10b shows changes of blank-corrected  $R_{\text{DTT}}$  with reaction time for direct  
730 photolysis, OH-initiated oxidation and  $^3\text{C}^*$ -initiated oxidation, respectively. The  $R_{\text{DTT}}$   
731 value of  $^3\text{C}^*$ -oxidation products increased quickly and reached the maximum (0.9) at 7  
732 hours, then decreased slowly and its end value was lower than that from OH-oxidation.  
733 The  $R_{\text{DTT}}$  value of OH-oxidation products on the other hand increased slowly and  
734 reached the maximum at 21 hours. The  $R_{\text{DTT}}$  value of products from direct photolysis  
735 increased continuously but also slowly to  $\sim 0.36$  till the end of oxidation. Nevertheless,  
736 we can see that the final  $R_{\text{DTT}}$  values were all higher than that of eugenol, proving that  
737 aqueous-phase processing can generate products with higher OP, resulting in more  
738 health hazards than the precursor does. The DTT consumption rates are comparable to  
739 those using the same DTT method (Charrier and Anastasio, 2012; Lin and Yu, 2019).  
740 The weak correlation was found between HULIS concentration and  $R_{\text{DTT}}$ , implying that  
741 OP was not only dependent upon HULIS. Moreover, HULIS with diverse molecular  
742 structures also exhibit different ROS-generation potentials (Kramer et al., 2016),  
743 therefore the HULIS as an ensemble may not correlate well with OP.

744

745 **Figure 10.** (a) DTT consumed mass versus incubation times for blank (ultrapure water) and 300  $\mu\text{M}$   
 746 eugenol solutions in a triplicate, and (b) blank-corrected DTT consumption rates versus reaction  
 747 time for direct photolysis, OH-initiated oxidation and  $^3\text{C}^*$ -induced oxidation.

#### 748 4. Atmospheric implications

749 The high mass yields of aqueous-phase photooxidation of eugenol (exceeding 100%  
 750 after 23 hours of illumination) found here are similar or even higher than those  
 751 previously reported yields of a number of phenolic compounds (e.g., Smith et al., 2014,  
 752 2015, 2016; Ma et al., 2021), which re-emphasizes the importance of biomass burning  
 753 (BB) to SOA budget (Gilardoni et al., 2016), particularly in regions or periods with  
 754 significant BB activities. In addition, our study here used 300  $\mu\text{M}$   $\text{H}_2\text{O}_2$  and 15  $\mu\text{M}$   
 755 DMB as sources of OH and  $^3\text{C}^*$ , and  $^3\text{C}^*$ -mediated oxidation appeared to be faster than  
 756 OH-initiated oxidation of eugenol. Of course, whether or not  $^3\text{C}^*$  is more important  
 757 than OH in real atmosphere depends upon their concentrations. OH and  $^3\text{C}^*$  are difficult  
 758 to measure and concentrations vary greatly in real atmospheric samples. Herrmann et  
 759 al. (2010) estimated an average OH level of  $0.35 \times 10^{-14}$  M in urban fog water; Kaur and  
 760 Anastasio (2018) measured  $^3\text{C}^*$  concentration to be  $(0.70-15) \times 10^{-14}$  M, 10-100 times  
 761 higher than the co-existing OH in ambient fog waters; Kaur et al. (2019) determined  
 762 both OH and  $^3\text{C}^*$  concentrations in PM extracts, OH steady-state concentration was

763  $4.4(\pm 2.3) \times 10^{-16}$  M, similar to its level in fog, cloud and rain, while  $^3\text{C}^*$  concentration  
764 was  $1.0(\pm 0.4) \times 10^{-13}$  M, a few hundred times higher than OH and nearly double its  
765 average value in fog. Therefore, together with these measurements, our findings signify  
766 a likely more important role of  $^3\text{C}^*$  than OH in aqueous-phase (especially aerosol water)  
767 reactions. However, the liquid water content of aerosol is typically  $\sim 10000$  times  
768 smaller than that of cloud (for instance,  $\sim 50 \mu\text{g m}^{-3}$  versus  $0.5 \text{g m}^{-3}$ ). Even if the  
769 reaction rates in aerosol water were 10 times higher than those in cloud water, the  
770 overall importance of aqueous reactions initiated by the same oxidant in aerosol phase  
771 would be still  $\sim 1000$  times smaller than it in cloud water. Moreover, quenching  
772 experiments reveal that  $\text{O}_2$  can inhibit eugenol degradation by effectively scavenging  
773  $^3\text{C}^*$  while it can promote degradation by fostering chain reactions in OH-induced  
774 oxidation, which offer insights to the control of reaction pathways by regulating ROS  
775 generations; of course, such operation calls for application of highly sensitive EPR  
776 method.

777 Eugenol has a strong light absorption peak around 280 nm, therefore it can undergo  
778 direct photolysis, and addition of OH or other photosensitizers ( $^3\text{C}^*$ ) can gradually  
779 diminish its light absorption around 280 nm, but increase the absorption in visible light  
780 range ( $>300$  nm). In the meantime, HULIS was generated continuously, and GC-MS  
781 identified a number of high MW organic products, in line with those detected in earlier  
782 aqueous photooxidation of phenolic compounds (Jiang et al., 2021; Misovich et al.,  
783 2021; Tang et al., 2020; Yu et al., 2014). Overall, our work demonstrates that aqueous  
784 oxidation of BB emissions is a source of BrC, and this BrC may act as photosensitizer  
785 to oxidize other species; a portion of this BrC might be HULIS, and some high MW  
786 aromatic compounds are a subset of this HULIS. However, a recent study by Wang et  
787 al. (2021) shows that fossil fuel derived OA (FFOA) can be an effective precursor of

788 aqSOA, but the aqSOA became less light-absorbing than the FFOA. These contrasting  
789 results indicate that contribution of aqueous oxidation to BrC is largely dependent upon  
790 the precursors; molecular structures of major chromophores, changes of the structures  
791 upon oxidation as well as their interplay with light absorptivity should be carefully  
792 investigated to achieve a full understanding of the impacts of aqueous processing on air  
793 quality, radiative forcing and climate change.

794 Investigations on the OPs of reaction products from eugenol photooxidation show  
795 that aqueous processing can produce more toxic products than the precursor. This result  
796 is in agreement with our previous work on resorcinol, hydroquinone and  
797 methoxyhydroquinone (Ou et al., 2021). Although more studies on a broad spectrum of  
798 atmospherically relevant species and multiple indicators of toxicity are clearly needed,  
799 our findings here underscore the potential of aqueous processing on the enhancement  
800 of particle toxicity.

## 801 **5 Conclusions**

802 This study comprehensively investigated the aqueous photooxidation of eugenol  
803 upon direct photolysis and attacks by OH radicals and  $^3\text{C}^*$  triplet states. By using a  
804 suite of techniques, the decay kinetics of eugenol, chemical, optical properties as well  
805 as toxicity of reaction products were studied. The first-order rate constants followed the  
806 order of  $^3\text{C}^* > \text{OH} > \text{direct photolysis}$  (300  $\mu\text{M}$   $\text{H}_2\text{O}_2$  and 15  $\mu\text{M}$  DMB as sources of OH  
807 and  $^3\text{C}^*$ ). Further quenching experiments on different ROS during  $^3\text{C}^*$ -mediated  
808 oxidation showed that  $^3\text{C}^*$  was the major contributor, followed by  $^1\text{O}_2$ ,  $\text{O}_2^-$  and OH;  
809  $\text{O}_2^-$  played a more important role than OH during OH-initiated oxidation. The rate  
810 constants under saturated  $\text{O}_2$ , air and  $\text{N}_2$  followed the order of  $k_{\text{O}_2} > k_{\text{Air}} > k_{\text{N}_2}$  for both  
811 direct photolysis and OH-initiated oxidation, but changed to  $k_{\text{Air}} > k_{\text{N}_2} > k_{\text{O}_2}$  for  $^3\text{C}^*$ -

812 mediated oxidation. O<sub>2</sub> appeared to be a scavenger of <sup>3</sup>C\* therefore suppressing <sup>3</sup>C\*  
813 oxidation while it could promote generation of OH thus accelerate OH-mediated  
814 oxidation. pH and DO levels both decreased during oxidation, indicating formation of  
815 acids and a certain role of DO in oxidation.

816 Eugenol itself can absorb lights significantly around 280 nm, and aqueous  
817 oxidation gradually decrease this absorption of UV light but enhanced the absorbance  
818 in the visible light range (mainly 300-400 nm), indicative of the generation of BrC  
819 species. These species were likely linked with HULIS, as HULIS concentration  
820 increased during the course of oxidation, in particular for the initial stage of <sup>3</sup>C\*-  
821 mediated reactions. The final mass yields of reaction products (after 23 hours of  
822 irradiation) were 140.1%, 144.9% and 196.5% for direct photolysis, OH-oxidation and  
823 <sup>3</sup>C\*-oxidation, respectively. Oxidation degrees of the products increased continuously  
824 with the illumination time, indicating persistent formation of highly oxygenated  
825 compounds, especially during <sup>3</sup>C\*-mediated reactions. Molecular characterization by  
826 GC-MS identified a series of oxygenated compounds, allowing us to propose the  
827 detailed oxidation mechanism. Functionalization appeared to be a dominant pathway to  
828 form the observed species.

829 DTT method was used to assess OP of the reaction products. The end products in  
830 all three sets of experiments showed higher DDT consumption rates than that of the  
831 precursor; products from <sup>3</sup>C\*-oxidation showed particularly fast increase in the first  
832 few hours of reactions. This result demonstrates that species that are more toxic than its  
833 precursors could be produced upon aqueous oxidation, indicative of the potential toxic  
834 effects induced by aqueous processing.
