52 Abstract

53

54 This study examines the role played by aerosols which act as cloud condensation nuclei
55 (CCN) in the development of clouds and precipitation in two metropolitan areas in East
56 Asia that have experienced substantial increases in aerosol concentrations over the last
57 decades. These two areas are the Seoul and Beijing areas and the examination has been
58 done by performing simulations using the Advanced Research Weather Research and
59 Forecasting model as a cloud-system resolving model. CCN are advected from the
60 continent to the Seoul area and this increases aerosol concentrations in the Seoul area.
61 These increased CCN concentrations induce the enhancement of condensation that in turn
62 induces the enhancement of deposition and precipitation amount in a system of less deep
63 convective clouds as compared to those in the Beijing area. In a system of deeper clouds
64 in the Beijing area, increasing CCN concentrations also enhance condensation but reduce
65 deposition. This leads to CCN-induced negligible changes in precipitation amount. Also,
66 in the system, there is a competition for convective energy among clouds with different
67 condensation and updrafts. This competition results in different responses to increasing
68 CCN concentrations among different types of precipitation, which are light, medium and
69 heavy precipitation in the Beijing area. CCN-induced changes in freezing play a negligible
70 role in CCN-precipitation interactions as compared to the role played by CCN-induced
71 changes in condensation and deposition in both of the areas.

1. Introduction

83

84

85 With increasing aerosol loading or concentrations, cloud-particle sizes can be changed. In
86 general, with increasing droplet sizes, the efficiency of collision and collection among
87 droplets increases. Increasing aerosol loading is known to make the droplet size smaller
88 and thus make the efficiency of collision and collection among droplets lower. This leads
89 to less droplets or cloud liquid forming raindrops and there is more cloud liquid present in
90 the air to be evaporated or frozen. Studies have shown that increases in cloud-liquid mass
91 due to increasing aerosol loading can enhance the freezing of cloud liquid and parcel
92 buoyancy, which lead to the invigoration of convection (Rosenfeld et al., 2008; Fan et al.,
93 2009). Via the invigoration of convection, precipitation can be enhanced. The dependence
94 of aerosol-induced invigoration of convection and precipitation enhancement on aerosol-
95 induced increases in condensational heating in the warm sector of a cloud system has been
96 shown (e.g., van den Heever et al., 2006; Fan et al., 2009; Lee et al., 2018). Increasing
97 cloud-liquid mass induces increasing evaporation, which intensifies gust fronts. This in
98 turn strengthens convective clouds and increases the amount of precipitation (Khain et al.,
99 2005; Tao et al., 2007; Storer et al., 2010; Tao et al., 2012; Lee et al., 2017; Lee et al.,
100 2018). It is notable that aerosol-induced precipitation enhancement is strongly sensitive to
101 cloud types that can be defined by cloud characteristics such as cloud depth (e.g., Tao et
102 al., 2007; Lee et al., 2008; Fan et al., 2009).

112

113

Since East Asia was industrialized, there have been substantial increases in aerosol
concentrations over the last decades in East Asia (e.g., Lee et al., 2013; Lu et al., 2011; Oh
et al., 2015; Dong et al., 2019). These increases are far greater than those in other regions
such as North America and Europe (e.g., Lu et al., 2011; Dong et al., 2019). While those
increasing aerosols affect clouds, precipitation and hydrologic circulations in the
continental East Asia, the increase in the advected aerosols from the continent to the
Korean Peninsula affect clouds, precipitation and hydrologic circulations in the Korean
Peninsula (Kar et al., 2009). This study aims to examine effects of the increasing aerosols,
which particularly act as cloud condensation nuclei (CCN), and their advection on clouds
and precipitation in East Asia. This study focuses on aerosols which act as CCN, but not
ice-nucleating particles (INPs), to examine those effects, based on the fact that CCN

114 account for most of aerosol mass that affects clouds and precipitation, and CCN, but not
115 INPs, are associated with above-described aerosol-induced invigoration of convection and
116 intensification of gust fronts. Note that these aerosol-induced invigoration and
117 intensification are two well-established major theories of aerosol-cloud interactions. As a
118 first step to the examination, this study focuses on two metropolitan areas in East Asia
119 which are the Beijing and Seoul areas. The population of each of the Beijing and Seoul
120 areas is ~ 20 millions. Associated with this, these areas have lots of aerosol sources (e.g.,
121 traffic) and have made a substantial contribution to the increases in aerosol concentrations
122 in East Asia. Hence, we believe that these two cities can represent overall situations related
123 to increasing aerosol concentrations in East Asia.

124 As mentioned above, aerosol-cloud interactions (and their impacts on precipitation) are
125 strongly dependent on cloud types and thus to gain a more general understanding of those
126 interactions, we select cases from the Beijing and Seoul areas with different cloud types.
127 A selected case from the Beijing area involves deep convective clouds that reach the
128 tropopause, while a selected case from the Seoul area involves comparatively shallow (or
129 less deep) convective clouds. Via comparisons between these two cases, we aim to identify
130 mechanisms that control varying aerosol-cloud interactions with cloud types.

131 To examine impacts of aerosols, which act as CCN, on clouds and precipitation in the
132 cases, numerical simulations are performed, as a way of fulfilling above-described aim.
133 These simulations use a cloud-system resolving model (CSRМ) that has reasonably high
134 resolutions to resolve cloud-scale processes that are related to cloud microphysics and
135 dynamics. Hence, these simulations are able to find process-level mechanisms in
136 association with cloud-scale processes.

137

138 **2. Case description**

139

140 In the Seoul area, South Korea, there is an observed mesoscale convective system (MCS)
141 for a period from 03:00 LST (local solar time) to 18:00 LST December 24th 2017. During
142 this period, there is a recorded moderate amount of precipitation and its maximum
143 precipitation rate reaches ~ 13 mm hr⁻¹. Here, precipitation in the Seoul area is measured
144 by rain gauges in automatic weather stations (AWSs) (King, 2009). The measurement is

145 performed hourly with a spatial resolution that ranges from ~1 km to ~10 km. The Seoul
146 area is marked by an inner rectangle in Figure 1a and Figure 2a and dots in the rectangle
147 in Figure 2a mark the selected locations of rain gauges. At 21:00 LST December 23rd 2017,
148 synoptic-scale features develop in favor of the formation and development of the selected
149 MCS and associated moderate rainfall. A low-pressure trough was over northeast China
150 and the Yellow Sea (Figure 1a). Along the flank of the low-pressure system, there was the
151 southwesterly low-level jets to transport warm and moist air. This warm and moist air is
152 originated from the Yellow Sea and transported to the Korean Peninsula (Figure 1a). The
153 southwesterly low-level jet plays an important role in the formation and development of
154 rainfall events in the Korean Peninsula by fetching warm and moist air (Hwang and Lee
155 1993; Lee et al. 1998; Seo et al. 2013; Oh et al. 2018).

156 There was another observed MCS case in the Beijing area, China for a period from
157 14:00 LST on July 27th to 00:00 LST July 28th 2015. There is a substantial recorded amount
158 of precipitation for this period and its maximum precipitation rate reaches ~ 45 mm hr⁻¹.
159 Here, similar to the situation in the Seoul area, precipitation in the Beijing area is measured
160 by rain gauges in AWSs hourly with a spatial resolution that ranges from ~1 km to ~10 km.
161 The Beijing area is marked by an inner rectangle in Figure 1b and Figure 2b and dots in
162 the rectangle in Figure 2b mark the selected locations of rain gauges. At 09:00 LST July
163 27th 2015, synoptic-scale features develop in favor of the formation and development of
164 the selected MCS. The southerly low-level jet forms and develops heavy rainfall events in
165 the Beijing area by transporting warm and moist air to the area (Figure 1b). Note that
166 synoptic features in Figures 1a and 1b are based on reanalysis data that are produced by
167 the Met Office Unified Model (Brown et al., 2012) every 6 hours with a $0.11^\circ \times 0.11^\circ$
168 resolution.

169

170 **3. CSRM and simulations**

171

172 **3.1 CSRM**

173

174 The Advanced Research Weather Research and Forecasting (ARW) model (version 3.3.1)
175 is used as a CSRM. The ARW model is a compressible model with a nonhydrostatic status.

176 A 5th-order monotonic advection scheme is used to advect microphysical variables (Wang
177 et al., 2009). The Rapid Radiation Transfer Model (RRTMG; Mlawer et al., 1997; Fouquart
178 and Bonnel, 1980) is adopted to parameterize shortwave and longwave radiation in
179 simulations. A microphysics scheme that is used in this study calculates the effective sizes
180 of hydrometeors that are fed into the RRTMG, and the RRTMG simulates how these
181 effective sizes affect radiation.

182 The CSRM adopts a bin scheme as a way of parameterizing microphysics. The
183 Hebrew University Cloud Model (HUCM) detailed in Khain et al. (2011) is the bin scheme.
184 A set of kinetic equations is solved by the bin scheme to represent size distribution
185 functions for each class of hydrometeors and aerosols acting as CCN. The hydrometeor
186 classes are water drops, ice crystals (plate, columnar and branch types), snow aggregates,
187 graupel and hail. Drops whose radius is smaller (larger) than 40 μm are categorized to be
188 droplets (raindrops). There are 33 bins for each size distribution in a way that the mass of
189 a particle m_j in the j bin is to be $m_j = 2m_{j-1}$.

190 A cloud-droplet nucleation parameterization based on Köhler theory represents cloud-
191 droplet nucleation. Arbitrary aerosol mixing states and aerosol size distributions can be fed
192 to this parameterization. To represent heterogeneous ice-crystal nucleation,
193 parameterizations by Lohmann and Diehl (2006) and Möhler et al. (2006) are used. In these
194 parameterizations, contact, immersion, condensation-freezing, and deposition nucleation
195 paths are all considered by taking into account the size distribution of INPs, temperature
196 and supersaturation. Homogeneous droplet freezing is
197 considered following the theory developed by Koop et al. (2000).

198

199 **3.2 Control runs**

200

201 For a three-dimensional CSRM simulation of the observed case of convective clouds in the
202 Seoul (Beijing) area, i.e., the control-s (control-b) run, a domain just over the Seoul
203 (Beijing) area, which is shown in Figure 1a (1b) and Figure 2a (2b), is used. This domain
204 adopts a 300-m resolution. The control-s run is for a period from 03:00 LST to 18:00 LST
205 December 24th 2017, while the control-b run is for a period from 14:00 LST on July 27th
206 to 00:00 LST July 28th 2015. The length of the domain is 170 (140) km in the east-west

207 (north-south) direction for the control-s run, and 280 (240) km for the control-b run. There
208 are 100 vertical layers and these layers employ a sigma coordinate that follows the terrain.
209 The top pressure of the model is 50 hPa for both of the control-s and control-b runs. On
210 average, the vertical resolution is ~ 200 m.

211 Reanalysis data, which are produced by the Met Office Unified Model, represent the
212 synoptic-scale features, provide initial and boundary conditions of variables such as wind,
213 potential temperature, and specific humidity for the simulations. The simulations adopt an
214 open lateral boundary condition. The Noah land surface model (LSM; Chen and Dudhia,
215 2001) calculates surface heat fluxes.

216 The current version of the ARW model is not able to consider the spatiotemporal
217 variation of aerosol properties. In order to take into account the spatiotemporal variation of
218 aerosol properties, which is typical in metropolitan areas, such as composition and number
219 concentration, an aerosol preprocessor, which is able to consider the variability of aerosol
220 properties, is developed and used in the simulations. This aerosol preprocessor interpolates
221 or extrapolates background aerosol properties in observation data such as aerosol mass
222 (e.g., $PM_{2.5}$ and PM_{10}) into grid points and time steps in the model. In this study, the inverse
223 distance weighting method is used for the extrapolation and interpolation of observation
224 data including aerosol mass into grid points and time steps in the model. PM stands for
225 particulate matter. The mass of aerosols with diameter smaller than 2.5 (10.0) μm per unit
226 volume of the air is $PM_{2.5}$ (PM_{10}).

227 $PM_{2.5}$ or PM_{10} , which are measured by surface observation sites in the domains, is used
228 to consider the variability of aerosol properties. The distance between the observation sites
229 ranges from ~ 1 km to ~ 10 km and the time interval between observations of aerosol mass
230 is ~ 10 minutes; the selected locations of these sites are marked by dots in the inner
231 rectangles in Figure 2. Hence, the variability is represented by fine spatiotemporal
232 resolutions of the sites. The ground sites that are equipped with the aerosol robotic network
233 (AERONET; Holben et al., 2001) are in the domains. Distances between these sites are
234 ~ 10 km. In this study, $PM_{2.5}/PM_{10}$ data are used to represent the spatiotemporal variability
235 of aerosols over the domains and the simulation periods. To represent aerosol composition
236 and size distributions, data from the AERONET sites are employed.

237 The AERONET data are averaged over the AERONET sites at 02:00 LST December
238 24th 2017 (13:00 LST July 27th 2015), which is 1 hour before the observed MCS forms, for
239 the Seoul (Beijing) case. Based on the average data, it is assumed that aerosol particles are
240 internally mixed with 70 (80) % ammonium sulfate and 30 (20) % organic compound for
241 the Seoul (Beijing) case. This mixture is assumed to represent aerosol chemical
242 composition in the whole domain and during the entire simulation period. Since ammonium
243 sulfate and organic compound are representative components of CCN, it is assumed that
244 the mass of aerosols that act as CCN is represented by $PM_{2.5}$ and PM_{10} for the Seoul and
245 Beijing areas, respectively. Aerosols reflect, scatter and absorb shortwave and longwave
246 radiation before they are activated. This type of aerosol-radiation interactions is not taken
247 into account in this study. This is mainly based on the fact that in the mixture, there is
248 insignificant amount of radiation absorbers; black carbon is a representative radiation
249 absorber. The AERONET observation indicates that the size distribution of background
250 aerosols acting as CCN follows the tri-modal log-normal distribution for the Seoul (Beijing)
251 case as exemplified in Figure 3a (3b). It is assumed that for the whole domain and
252 simulation period, the size distribution of background aerosols acting as CCN follows the
253 shape of distribution with specific size distribution parameters (i.e., modal radius and
254 standard deviation of each of Aitken, accumulation and coarse modes, and the partition of
255 aerosol number among those modes) as shown in Figure 3a (3b) for the Seoul (Beijing)
256 case. Modal radius of the shape of distribution is 0.015 (0.012), 0.110 (0.085), and 1.413
257 (1.523) μm , while standard deviation of the shape of distribution is 1.28 (1.10), 1.54 (1.63),
258 and 1.75 (1.73) for Aitken, accumulation and coarse modes, respectively, in the Seoul
259 (Beijing) case. The partition of aerosol number, which is normalized by the total aerosol
260 number of the size distribution, is 0.555 (0.612), 0.444 (0.387), and 0.001 (0.001) for
261 Aitken, accumulation and coarse modes, respectively, in the Seoul (Beijing) case. The
262 distribution parameters of the assumed shape of the size distribution of background
263 aerosols in Figure 3a (3b) are those that are averaged over the AERONET sites at a time
264 point, which is 1 hour before the observed MCS form, for the Seoul (Beijing) case. By
265 using $PM_{2.5}$ or PM_{10} , which is interpolated and extrapolated to grid points immediately
266 above the surface and time steps, and based on the assumption of aerosol composition and
267 size distribution above, the background number concentrations of aerosols acting as CCN

268 are obtained for the simulation for each of the cases. There is no variation with height in
269 background concentrations of aerosols acting as CCN from immediately above the surface
270 to the top of the planetary boundary layer (PBL). However, it is assumed that they decrease
271 exponentially with height from the PBL top upward. With this exponential decrease, when
272 the altitude reaches the tropopause, background concentrations of aerosols acting as CCN
273 reduce by a factor of ~ 10 as compared to those at the PBL top. The size distribution and
274 composition of aerosols acting as CCN do not vary with height. Once background aerosol
275 properties (i.e., aerosol number concentrations, size distribution and composition) are put
276 into each grid point and time step, those properties at each grid point and time step do not
277 change during the course of the simulations.

278 For the control-s and control-b runs, aerosol properties of INPs are not different from
279 those of CCN except for the fact that the concentration of background aerosols acting as
280 CCN is 100 times higher than the concentration of background aerosols acting as INPs at
281 each time step and grid point, following a general difference between CCN and INPs in
282 terms of their concentrations (Pruppacher and Klett, 1978).

283 Once clouds form and background aerosols start to be in clouds, those aerosols are
284 not background aerosols anymore and the size distribution and concentrations of those
285 aerosols begin to evolve through aerosol sinks and sources that include advection and
286 aerosol activation (Fan et al., 2009). For example, once aerosols are activated, they are
287 removed from the corresponding bins of the aerosol spectra. In clouds, after aerosol
288 activation, aerosol mass starts to be inside hydrometeors and via collision-collection, it
289 transfers to different types and sizes of hydrometeors. In the end, aerosol mass disappears
290 in the atmosphere when hydrometeors with aerosol mass touches the surface. In non-cloudy
291 areas, aerosol size and spatial distributions are designed to be identical to the size and
292 spatial distributions of background aerosols, respectively. In other words, for this study,
293 we use “the aerosol recovery method”. In this method, at any grid points, immediately after
294 clouds disappear entirely, aerosol size distributions and number concentrations recover to
295 background properties that background aerosols at those points have before those points
296 are included in clouds. In this way, we can keep concentrations of background aerosols
297 outside clouds in the simulations at observed counterparts. This enables spatiotemporal
298 distributions of background aerosols in the simulations to mimic those distributions that

299 are observed and particularly associated with observed aerosol advection in reality. In the
300 aerosol recovery method, there is no time interval between the cloud disappearance and the
301 aerosol recovery. Here, when the sum of mass of all types of hydrometeors (i.e., water
302 drops, ice crystals, snow aggregates, graupel and hail) is not zero at a grid point, that grid
303 point is considered to be in clouds. When this sum becomes zero, clouds are considered to
304 disappear. Many studies using CSRM have employed this aerosol recovery method. They
305 have proven that with the recovery method, reasonable simulations of overall cloud and
306 precipitation properties are accomplished (e.g., Morrison and Grabowski, 2011; Lebo and
307 Morrison, 2014; Lee et al., 2016; Lee et al., 2018).

308

309

3.3 Additional runs

310

311 We repeat the control-s run by getting rid of aerosol-advection induced increases in
312 concentrations of aerosols acting as CCN as a way of investigating how the aerosol
313 advection affects the cloud system in the Seoul area. This repeated run is named the low-
314 aerosol-s run. An aerosol layer, which is advected from East Asia or from the west of the
315 Seoul area to it, increases aerosol concentrations in the Seoul area. There are stations in
316 islands in the Yellow Sea that monitor the aerosol advection (Eun et al., 2016; Ha et al.,
317 2019). To monitor and identify the aerosol advection, $PM_{2.5}$ which is measured by a station
318 in Baekryongdo island in Yellow Sea are compared to those which are measured in stations
319 in and around the Seoul area. In Figure 2a, a dot outside the inner rectangle marks the
320 island. The time evolution of $PM_{2.5}$ measured by the station on the island and the average
321 $PM_{2.5}$ over stations in the Seoul area, between 07:00 LST on December 22nd and 21:00 LST
322 on December 24th in 2017 when there is the strong advection of aerosols from East Asia to
323 the Seoul area, is shown in Figure 4. At 09:00 LST on December 22nd, the advection of
324 aerosols from East Asia enables aerosol mass to start going up and attain its peak around
325 05:00 LST on December 23rd on the island. Following this, aerosol mass starts to increase
326 in the Seoul area around 01:00 LST on December 23rd, and the mass attains its peak at
327 15:00 LST on December 23rd in the Seoul area. This is because aerosols, which are
328 advected from East Asia, move through the island to reach the Seoul area.

329 In the low-aerosol-s run, as a way of getting rid of aerosol-advection induced increases
330 in concentrations of aerosols acting as CCN, it is assumed that $PM_{2.5}$, which is assumed to
331 represent the mass of aerosols acting as CCN, and the associated background concentration
332 of aerosols acting as CCN after 01:00 LST on December 23rd do not evolve with the aerosol
333 advection in the Seoul area. Hence, the background concentration of aerosols acting as
334 CCN is assumed to have that at 01:00 LST on December 23rd at each time step and grid
335 point at the beginning of the simulation period. However, to isolate CCN effects on clouds,
336 background aerosol concentration acting as INPs at each time step and grid point in the
337 low-aerosol-s run is not different from that in the control-s run during the simulation period.
338 In the observed PM data for the Seoul area, there is reduction in PM by a factor of ~ 10 on
339 average over a period between $\sim 07:00$ and $\sim 14:00$ LST on December 24th, since
340 precipitation scavenges aerosols (Figure 4). To emulate this scavenging and reflect it in
341 background aerosols acting as CCN for the low-aerosol-s run, $PM_{2.5}$ and corresponding
342 background concentrations of aerosols acting as CCN at each grid point is gradually
343 reduced for the period between 07:00 and 14:00 LST on December 24th. This reduction is
344 done in a way that background concentrations of aerosols acting as CCN at each grid point
345 at 14:00 LST on December 24th is 10 times lower than that at 07:00 LST on December 24th
346 in the low-aerosol-s run. Then, $PM_{2.5}$ and corresponding background concentrations of
347 aerosols acting as CCN at each grid point at 14:00 LST on December 24th maintains until
348 the end of the simulation period. This results in the evolution of the average $PM_{2.5}$ over the
349 Seoul area in the low-aerosol-s run as shown in Figure 4. Here, the concentration of
350 background aerosols acting as CCN, which is averaged over the whole domain and
351 simulation period, in the control-s run is 3.1 times higher than that in the low-aerosol-s run.
352 Via comparisons between the runs, how the increasing concentration of background
353 aerosols acting as CCN due to the aerosol advection has an impact on clouds can be
354 examined. The concentration of background aerosols acting as CCN is different among
355 grid points and time steps in the control-s run. Hence, the ratio of the concentration of
356 background aerosols acting as CCN between the runs is different among grid points and
357 time steps.

358 For the Beijing case, to examine how aerosols acting as CCN affect clouds and
359 precipitation, we repeat the control-b run with simply reduced concentrations of

360 background aerosols acting as CCN at each time step and grid point by a factor of 3.1. This
361 repeated run is named the low-aerosol-b run. The 3.1-fold increase in aerosol
362 concentrations from the low-aerosol-b run to the control-b is based on the 3.1-fold increase
363 in the average concentration of background aerosols acting as CCN from the low-aerosol-
364 s run to the control-s run. However, as in the control-s and low-aerosol-s runs, to isolate
365 CCN effects on clouds, background aerosol concentration acting as INPs at each time step
366 and grid point in the low-aerosol-b run is identical to that in the control-b run during the
367 simulation period. Hence, on average, a pair of the control-s and low-aerosol-s runs has the
368 same perturbation of aerosols acting as CCN as in a pair of the control-b and low-aerosol-
369 b runs. Here, we define aerosol perturbation as a relative increase in aerosol concentration
370 when compared to that before the increase occurs. The brief summary of all simulations in
371 this study is given in Table 1.

372

373 **4. Results**

374

375 **4.1 Cumulative precipitation**

376

377 We compare the observed precipitation to the simulated counterpart in the control-s run for
378 the Seoul case and in the control-b run for the Beijing case. For this comparison, the
379 observed and simulated precipitation rates at the surface are averaged over the domain for
380 each of the Seoul and Beijing cases (Figures 5a and 5b). Here, the simulated precipitation
381 rates are smoothed over 1 hour. The comparison shows that the evolution of the simulated
382 precipitation rate does not deviate from the observed counterpart significantly (Figures 5a
383 and 5b).

384 In the Seoul case, overall, the precipitation rate is higher in the control-s run than in
385 the low-aerosol-s run. As a result of this, the domain-averaged cumulative precipitation
386 amount at the last time step is 14.1 mm and 12.0 mm in the control-s run and the low-
387 aerosol-s run, respectively. The control-s run shows ~20 % higher cumulative precipitation
388 amount. In the Beijing case, the evolution of the mean precipitation rate in the control-b
389 run is not significantly different from that in the low-aerosol-b run. Due to this, the control-
390 b run shows only ~2 % higher cumulative precipitation amount, despite the fact that the

391 concentrations of background aerosols acting as CCN are ~ 3 times higher in the control-b
392 run than in the low-aerosol-b run. Note that in the Seoul case, the time- and domain-
393 averaged concentration of background aerosols acting as CCN is also ~ 3 times higher in
394 the control-s run than in the low-aerosol-s run. Despite this, the difference in the cumulative
395 precipitation amount between the runs with different concentrations of background
396 aerosols acting as CCN is greater in the Seoul case than in the Beijing case.

397

398 **4.2 Precipitation, and associated latent-heat and dynamic processes**

399

400 Figures 6a and 6b show the cumulative frequency distributions of precipitation rates at the
401 last time step in the simulations for the Seoul and Beijing cases, respectively. In each of
402 those figures, the observed frequency distribution is shown and compared to the simulated
403 distribution. The observed distribution is obtained by interpolating and extrapolating the
404 observed precipitation rates to grid points and time steps in each of the control-s and
405 control-b runs. The observed maximum precipitation rates are 13.0 and 44.5 mm hr⁻¹ for
406 the Seoul and Beijing cases, respectively, and these maximum rates are similar to those in
407 the control-s and control-b runs, respectively. Overall, the observed and simulated
408 frequency distributions are in good agreement for each of the cases. This enables us to
409 assume that results in the control-s (control-b) run are benchmark results to which results
410 in the low-aerosol-s (low-aerosol-b) run can be compared to identify how aerosols acting
411 as CCN have an impact on clouds and precipitation for the Seoul (Beijing) case. Here, it is
412 notable that for the Beijing case, while differences in the cumulative precipitation amount
413 between the control-b and low-aerosol-b runs are not significant, features in the frequency
414 distribution of precipitation rates between those runs are substantially different (Figure 6b).

415

416 **1) Seoul case**

417

418 **a. Precipitation Frequency distributions**

419

420 Regarding precipitation whose rates are higher than ~ 2 mm hr⁻¹, the cumulative
421 precipitation frequency at the last time step is higher in the control-s run as compared to

422 that in the low-aerosol-s run (Figure 6a). In particular, for the precipitation rate of 11.4 mm
423 h^{-1} , there is an increase in the cumulative frequency by a factor of as much as ~ 10 in the
424 control-s run. When it comes to precipitation rates above 11.5 mm hr^{-1} , precipitation is
425 present in the control-s run and precipitation is absent in the low-aerosol-s run. Regarding
426 precipitation whose rates are lower than $\sim 2 \text{ mm hr}^{-1}$, differences in the cumulative
427 frequency between the runs are insignificant. Hence, we see that there are significant
428 increases in the frequency of relatively heavy precipitation whose rates are above $\sim 2 \text{ mm}$
429 hr^{-1} in the control-s run when compared to that in the low-aerosol-s run. At the last time
430 step, this results in a larger amount of cumulative precipitation in the control-s run than in
431 the low-aerosol-s run.

432 The time evolution of the cumulative precipitation frequency is shown in Figure 7. At
433 06:00 LST December 24th 2017, which corresponds to the initial stage of the precipitation
434 development, the maximum precipitation rate reaches $\sim 3 \text{ mm hr}^{-1}$ and there is the greater
435 frequency over most of precipitation rates in the control-s run than in the low-aerosol-s run
436 (Figure 7a). With the time progress from 06:00 LST to 10:00 LST, the maximum
437 precipitation rate increases to reach 12 mm hr^{-1} and the cumulative frequency is higher over
438 precipitation whose rates are higher than $\sim 3 \text{ mm hr}^{-1}$ in the control-s run, while for
439 precipitation whose rates are lower than $\sim 3 \text{ mm hr}^{-1}$, differences in the cumulative
440 frequency between the runs are negligible (Figures 7a and 7b). When time reaches 12:00
441 LST, which is around time when the peak in the evolution of the area-averaged
442 precipitation rates occurs and thus the system is at its mature stage, the maximum
443 precipitation rate increases up to $\sim 13 \text{ mm hr}^{-1}$ (Figures 5a and 7c). The basic patterns of
444 differences in the cumulative precipitation frequency between the runs with the maximum
445 precipitation rate around 13 mm hr^{-1} , which are established at 12:00 LST, maintain until
446 the end of the simulation period (Figures 6a and 7c).

447

448 **b. Condensation, deposition, updrafts and associated variables**

449

450 Note that the source of precipitation is precipitable hydrometeors which are raindrops,
451 snow, graupel and hail particles. Droplets and ice crystals are the source of those
452 precipitable hydrometeors mostly via collision and coalescence processes. Droplets and ice

453 crystals gain their mass mostly via condensation and deposition. Based on this, to explain
454 the greater cumulative precipitation amount in the control-s run than in the low-aerosol-s
455 run, the evolutions of differences in condensation, deposition and associated updrafts
456 between the runs are analyzed. The vertical profiles of differences in the area-averaged
457 condensation, deposition and freezing rates, updraft mass fluxes and the associated mass
458 density of each class of hydrometeors between the runs at 03:20, 03:40, 06:00 and 12:00
459 LST are shown in Figure 8. In Figure 8, differences in freezing rates are added for a more
460 comprehensive understanding of processes that are related to differences in cumulative
461 precipitation amount between the runs. Freezing includes riming processes between liquid
462 and solid hydrometeors and these riming processes act as a source of precipitable
463 hydrometeors. Cloud fractions are 0.32 (0.30), 0.85 (0.82), 0.93 (0.92) and 1.00 (1.00) in
464 the control-s (low-aerosol-s) run at 03:20, 03:40, 06:00 and 12:00 LST, respectively. We
465 see that cloud fraction does not vary significantly between the runs. Note that in all of
466 figures, which display snow and hail mass density and include Figure 8, snow mass density
467 includes ice-crystal mass density, while hail mass density includes graupel mass density
468 for the sake of the display brevity. In Figure 8, horizontal black lines represent the altitudes
469 of freezing and melting.

470 Condensation rates in the control-s run start to be larger than that in the low-aerosol-
471 s run at 03:20 LST (Figure 8a). Higher aerosol or CCN concentrations induce more
472 nucleation of droplets, higher cloud droplet number concentration (CDNC) and associated
473 greater integrated surface of droplets in the control-s run. CDNC, which is averaged over
474 grid points and time steps with non-zero CDNC, is 1050 and 352 cm^{-3} in the control-s and
475 low-aerosol-s runs, respectively. Hence, more droplet surface is provided for water vapor
476 to condense onto in the control-s run. This leads to more condensation in the control-s run.
477 This establishes stronger feedbacks between updrafts and condensation, leading to greater
478 droplet (or cloud-liquid) mass at 03:20 LST in the control-s run (Figure 8a). Then, these
479 stronger feedbacks, which involve stronger updrafts particularly above 2 km in altitude,
480 subsequently induce greater deposition and snow mass as time progresses from 03:20 LST
481 to 03:40 LST, while more condensation and greater droplet mass maintain in the control-s
482 run with the time progress to 03:40 LST (Figure 8b). These stronger updrafts enable clouds
483 to grow higher in the control-s run. This eventually leads to a situation where the maximum

484 cloud depth is ~ 7 km in the control-s run and this depth is ~ 5 % deeper than that in the low-
485 aerosol-s run for the whole simulation period.

486 Through aerosol-induced stronger feedbacks between condensation, deposition and
487 updrafts in the control-s run, while more condensation and more overall deposition
488 maintain in the control-s run, differences in condensation and deposition between the
489 control-s and low-aerosol-s runs increase as time progresses from 03:40 LST to 06:00 LST
490 (Figures 8b and 8c). Associated with this, the greater mass of raindrops and hail particles
491 appears up, while the greater mass of droplets and snow in the control-s run than in the
492 low-aerosol-s run maintains with the time progress from 03:40 LST to 06:00 LST (Figure
493 8c). At 06:00 LST, there is more freezing starting to occur in the control-s run than in the
494 low-aerosol-s run. However, differences in freezing are \sim one and \sim two orders of
495 magnitude smaller than those in deposition and condensation, respectively. After 06:00
496 LST until time reaches 12:00 LST when the overall differences in the cumulative
497 precipitation frequency between the runs are established, differences in freezing become at
498 an order of magnitude, which is similar to that of differences in deposition, and become
499 around one order of magnitude smaller than those in condensation (Figures 8c and 8d). The
500 greater mass of hydrometeors in the control-s run also continues after 06:00 LST until time
501 reaches 12:00 LST (Figures 8c and 8d). At 12:00 LST, condensation, deposition and
502 freezing rates are still higher in the control-s run. Here, we see that CCN-induced more
503 cumulative precipitation amount and associated differences in the precipitation frequency
504 distribution between the control-s and low-aerosol-s runs are primarily associated with
505 CCN-induced more condensation which induce CCN-induced more deposition and higher
506 mass density of hydrometeors as sources of precipitation but weakly connected to CCN-
507 induced changes in freezing. This is supported by the fact that the time- and domain-
508 averaged differences in freezing rate are \sim one to \sim two order of magnitude smaller than
509 those in condensation and deposition rates.

510

511 **c. Condensation frequency distributions and horizontal distributions of**
512 **condensation and precipitation**

513

514 Based on the importance of condensation for CCN-induced changes in precipitation, the
515 horizontal distribution of the column-averaged condensation rates over the domain and the
516 cumulative frequency distribution of the column-averaged condensation rates at each time
517 step is obtained. To better visualize the role of condensation in precipitation, the horizontal
518 distribution of the column-averaged condensation rates is superimposed on that of
519 precipitation rates (Figure 9). At 03:40 LST, condensation mainly occurs around the
520 northern part of the domain as marked by a yellow rectangle. The synoptic wind condition
521 in the marked area favors the collision between northward and southward wind and the
522 associated convergence around the surface (Figures 9a and 9b). This convergence induces
523 updrafts and condensation in the marked area. In the marked area, more aerosols acting as
524 CCN induce more and more extensive condensation, which leads to the higher domain-
525 averaged condensation rates in the control-s run than in the low-aerosol-s run (Figures 8b,
526 9a and 9b). More droplets are formed on more aerosols acting as CCN and more droplets
527 provide more surface areas where condensation occurs and this enables more and more
528 extensive condensation in the control-s run than in the low-aerosol-s run (Figures 8b, 9a
529 and 9b). At 06:20 LST, a precipitating system is advected into the domain via the western
530 boundary, and as seen in Figures 9c and 9d for 07:20 LST, as time progresses to 07:20 LST,
531 the advected precipitating system is further advected to the east and extended mostly over
532 areas in the northern part of the domain where condensation mainly occurs. This confirms
533 that condensation is the main source of cloud mass and precipitation. In the eastern part of
534 the domain, there are mountains and in particular, higher mountains are on the northeastern
535 part of the domain than in the other parts of the domain. These higher mountains induce
536 forced convection and associated condensation more effectively in the northeastern part
537 than in the other parts. This is in favor of the precipitating system that extends further to
538 the east in the northern part of the domain. Due to more aerosols acting as CCN,
539 condensation, which is induced by forced convection over mountains, is more and more
540 extensive in the control-s run (Figures 9c and 9d).

541 As time progresses to 08:40 LST, the precipitating system moves eastward further in
542 the northern part of the domain and the system in the control-s run extends to the east
543 further as compared to that in the low-aerosol-s run (Figures 9e and 9f). In association with
544 more aerosols acting as CCN and associated more condensation over mountains in the

545 northeastern part, there is more extension of the system in the control-s run than in the low-
546 aerosol-s run. This enables the system in the control-s run to reach the eastern boundary at
547 08:40 LST, which is earlier than in the low-aerosol-s run (Figures 9e and 9f). The system
548 in the low-aerosol-s run reaches the eastern boundary at 09:00 LST. Here, we see that
549 although aerosols acting as CCN do not change overall locations of the precipitation system,
550 they affect how fast the system extends to the east by affecting the amount of condensation
551 which is produced by forced convection. Associated with this, as seen in Figure 10, the
552 control-s run has the much higher cumulative condensation frequency than the low-aerosol-
553 s run over all of condensation rates during the period between 07:20 and 09:00 LST.
554 Contributed by this, the higher precipitation frequency over most of precipitation rates
555 occurs in the control-s run during and after the period (Supplementary Figures 1a and 1b
556 and Figures 7b and 7c).

557 At 10:00 LST, in the southern part of the domain, there is a precipitating area forming
558 as marked by a yellow rectangle (Figures 9g and 9h). The precipitation area in the southern
559 part of the domain extends and merge into the advecting main precipitating system in the
560 northern part of the domain as time progresses to 11:00 LST (Figures 9i and 9j). The merge
561 leads to precipitation that occupies most of the domain at 12:00 LST (Figures 9k and 9l).
562 After 10:00 LST, associated with this merge, the maximum precipitation rate increases to
563 13 mm hr^{-1} at 12:00 LST (Figures 7c). After 13:00 LST, the precipitation enters its
564 dissipating stage and its area reduces and nearly disappears. Even after the merge, CCN-
565 induced more condensation maintains and this in turn contributes to a situation where the
566 control-s run has the greater precipitation frequency over most of precipitation rates than
567 in the low-aerosol-s run until the simulations progress to their last time step (Figures 6a,
568 7c and 8d).

569

570 **2) Beijing case**

571

572 Stronger convection and deeper clouds develop in the Beijing case than in the Seoul case.
573 The maximum cloud depth is ~ 7 and ~ 12 km in the control-s and control-b runs,
574 respectively. In the Seoul case, clouds do not reach the tropopause, while they reach the
575 tropopause in the Beijing case. Deeper clouds in the Beijing case produce the maximum

576 precipitation rate of $\sim 45 \text{ mm hr}^{-1}$ in the control-b run. However, less deep clouds in the
577 Seoul case produce the maximum precipitation rate of $\sim 13 \text{ mm hr}^{-1}$ in the control-s run
578 (Figure 6).

579

580 **a. Precipitation frequency distributions**

581

582 When it comes to precipitation whose rates are higher than $\sim 12 \text{ mm hr}^{-1}$, the control-b run
583 has the higher cumulative precipitation frequency at the last time step than the low-aerosol-
584 b run (Figure 6b). Particularly, for the precipitation rates of 28.1 and 30.0 mm hr^{-1} , the
585 cumulative frequency increases by a factor of as much as ~ 10 . Moreover, regarding
586 precipitation rates higher than $\sim 33 \text{ mm hr}^{-1}$, precipitation is present in the control-b run,
587 however, precipitation is absent in the low-aerosol-b run. Hence, we see that the frequency
588 of comparatively heavy precipitation whose rates are higher than $\sim 12 \text{ mm hr}^{-1}$ rises
589 significantly in the control-b run as compared to that in the low-aerosol-b run. Below ~ 2
590 mm hr^{-1} , there is also the greater precipitation frequency in the control-b run than in the
591 low-aerosol-b run. Unlike the situation for precipitation rates above $\sim 12 \text{ mm hr}^{-1}$ and below
592 $\sim 2 \text{ mm hr}^{-1}$, for precipitation rates from $\sim 2 \text{ mm hr}^{-1}$ to $\sim 12 \text{ mm hr}^{-1}$, the control-aerosol-b
593 run has the lower precipitation frequency than in the low-aerosol-b run. Here, we see that
594 the higher precipitation frequency above $\sim 12 \text{ mm hr}^{-1}$ and below $\sim 2 \text{ mm hr}^{-1}$ balances out
595 the lower precipitation frequency between ~ 2 and $\sim 12 \text{ mm hr}^{-1}$ in the control-b run. This
596 results in the similar cumulative precipitation amount between the runs.

597 Figure 11 shows the time evolution of the cumulative precipitation frequency. When
598 precipitation starts around 16:00 LST, the higher precipitation frequency occurs over most
599 of precipitation rates in the low-aerosol-run-b run than in the control-b run (Figure 11a).
600 At 16:00 LST, the maximum precipitation rate is lower than 1.0 mm hr^{-1} for both of the
601 runs. As time progresses to 17:00 LST, the maximum precipitation rate increases to ~ 17
602 mm hr^{-1} and the higher (lower) cumulative precipitation frequency over precipitation rates
603 higher than $\sim 12 \text{ mm hr}^{-1}$ (between ~ 2 and $\sim 12 \text{ mm hr}^{-1}$) in the control-b run than in the
604 low-aerosol-b run, which is described above as shown in Figure 6b for the last time step,
605 starts to emerge (Figure 11b). At 17:20 LST, the higher frequency for precipitation rates
606 below 2 mm hr^{-1} in the control-b run, which is also described above as shown in Figure 6b

607 for the last time step, starts to show up, while the higher (lower) frequency for precipitation
 608 rates higher than $\sim 12 \text{ mm hr}^{-1}$ (between ~ 2 and $\sim 12 \text{ mm hr}^{-1}$) in the control-b run, which is
 609 established at 17:00 LST, maintains as time progresses from 17:00 LST to 17:20 LST
 610 (Figure 11c). At 17:20 LST, the maximum precipitation rate increases to 42 (19) mm hr^{-1}
 611 in the control-b (low-aerosol-b) run (Figure 11c). At 19:00 LST, the maximum
 612 precipitation rate increases to ~ 45 (33) mm hr^{-1} for the control-b (low-aerosol-b) run, while
 613 the qualitative nature of differences in the precipitation frequency distributions with the
 614 tipping precipitation rates of ~ 2 and $\sim 12 \text{ mm hr}^{-1}$ between the runs does not vary much
 615 between 17:20 and 19:00 LST (Figures 11c and 11d). The qualitative nature of differences
 616 in the cumulative precipitation frequency between the runs and the maximum precipitation
 617 rates in each of the runs, which are established at 19:00 LST, do not vary significantly until
 618 the end of the simulation period (Figures 6b and 11d).

619

620 **b. Condensation, deposition, updrafts and associated variables**

621

622 As done for the Seoul case, as a way of better understanding differences in the cumulative
 623 precipitation amount and frequency between the control-b and low-aerosol-b runs, the
 624 evolutions of differences in the vertical distributions of the area-averaged condensation
 625 rates, deposition rates, freezing rates, the mass density of each class of hydrometeors and
 626 updrafts mass fluxes are obtained and shown in Figures 12. Cloud fractions are 0.12 (0.11),
 627 0.25 (0.22), 0.36 (0.32), 0.43 (0.40) and 0.48 (0.47) in the control-b (low-aerosol-b) run at
 628 14:20, 15:40, 16:00, 17:20 and 19:00 LST, respectively. Here, we see that cloud fraction
 629 does not vary significantly between the runs. In Figure 12, horizontal black lines represent
 630 the altitudes of freezing and melting. As seen in Figure 5b, precipitation starts around 16:00
 631 LST but differences in condensation rates start at 14:20 LST with higher condensation rates
 632 in the control-b run (Figure 12a). Similar to the situation in the Seoul case, higher
 633 concentrations of aerosols acting as CCN induce more nucleation of droplets, higher
 634 CDNC and associated greater integrated surface of droplets in the control-b run. CDNC,
 635 which is averaged over grid points and time steps with non-zero CDNC, is 992 and 341
 636 cm^{-3} in the control-b and low-aerosol-b runs, respectively. Hence, more droplet surface is
 637 provided for water vapor to condense onto in the control-b run. This leads to more

638 condensation in the control-b run. Due to this, cloud-liquid or droplet mass becomes greater
639 in the control-b run at 14:20 LST (Figure 12a). Increased condensation rates induce
640 increased condensational heating and thus intensified updrafts (Figure 12a). These
641 updrafts enable the maximum cloud depth to be ~ 12 km in the control-b run and this depth
642 is just ~ 1 % deeper than that in the low-aerosol-b run for the whole simulation period. This
643 negligible difference in the maximum cloud depth between the runs is due to the fact that
644 clouds with the maximum depth reach the tropopause in both of runs and thus there is not
645 much wiggle room to make significant differences in cloud depth between the runs.

646 When time reaches 15:40 LST, deposition rates and snow mass start to show
647 differences between the runs, while higher condensation rates and droplet mass maintain
648 in the control-b run with the time progress from 14:20 LST to 15:40 LST. However, unlike
649 the situation in the Seoul case, higher concentrations of aerosols acting as CCN result in
650 lower deposition rates and snow mass in the control-b run (Figure 12b). When time
651 progresses from 15:40 LST to 16:00 LST, differences in freezing start to occur and freezing
652 rates are lower (higher) at altitudes between ~ 6 and ~ 8 km (~ 4 and ~ 6 km), while higher
653 condensation rates and droplet mass, and lower snow mass maintain in the control-b run
654 (Figure 12c). Due to stronger updrafts, which are mainly ascribed to more condensation,
655 deposition rates start to be higher at altitudes between ~ 7 and ~ 9 km and freezing rates are
656 higher at altitudes between ~ 4 and ~ 6 km in the control-b run with the time progress from
657 15:40 LST to 16:00 LST (Figure 12c). Differences in freezing rates are at the same order
658 of magnitude of those in deposition and \sim two orders of magnitude smaller than those in
659 condensation at 16:00 LST (Figure 12c). At 16:00 LST, differences in hail mass between
660 the runs appear up and hail mass is slightly lower in the control-b run (Figure 12c). At
661 17:20 LST, overall, freezing rates are lower at altitudes between ~ 4 and ~ 8 km, while
662 overall, snow and hail mass is still lower, and droplet mass is still higher in the control-b
663 run (Figure 12d). Differences in freezing rates are at the same order of magnitude of those
664 in deposition and \sim one orders of magnitude smaller than those in condensation at 17:20
665 LST (Figure 12d). Due to more condensation and droplet mass, greater raindrop mass
666 appears up in the control-b run at 17:20 LST (Figure 12d). As the time progresses to 19:00
667 LST, deposition rates become lower at the altitudes from ~ 7 km to ~ 12 km and overall
668 freezing rates become higher at altitudes from ~ 4 km to ~ 10 km in the control-b run (Figure

669 12e). Overall, lower snow and hail mass maintains in the control-b run as time progresses
670 from 17:20 LST to 19:00 LST. As time progresses from 17:20 LST to 19:00 LST, overall
671 higher condensation rates, droplet and raindrop mass maintain in the control-b run (Figure
672 12e). Here, while the time- and domain-averaged deposition (condensation and freezing)
673 rates are lower (higher) in the control-b run over the whole simulation period, the average
674 differences in freezing rates are ~one to ~two orders of magnitude smaller than those in
675 deposition and condensation rates between the runs. Hence, more condensation (but not
676 deposition and freezing) is a main cause of stronger updrafts in the control-b run. More
677 condensation and more freezing tend to induce increases in the mass of precipitable
678 hydrometeors in the control-b run. Less deposition tends to induce decreases in the mass
679 of precipitable hydrometeors in the control-b run. This competition between condensation,
680 deposition and freezing leads to negligible differences in the cumulative precipitation
681 amount at the last time step between the control-b and low-aerosol-b runs, although roles
682 of freezing in this competition are negligible as compared to those of condensation and
683 deposition.

684

685 **c. Condensation frequency distributions, horizontal distributions of**
686 **condensation and precipitation, and condensation-precipitation**
687 **correlations**

688

689 Figure 13 shows the horizontal distribution of the column-averaged condensation rates over
690 the domain and Figure 14 shows the cumulative frequency distributions of column-
691 averaged condensation rates at selected times. As in the Seoul case, the horizontal
692 distribution of condensation rates is superimposed on that of precipitation rates and the
693 terrain in Figure 13. At 14:20 LST, condensation starts to occur in places with mountains,
694 which induce forced convection, and condensation is concentrated around the center of the
695 domain as marked by a yellow circle (Figures 13a and 13b). Note that condensation does
696 not occur in the plain area which is the south of the 100-m terrain-height contour line
697 (Figures 13a and 13b). Due to higher concentrations of aerosols acting as CCN, there is
698 more condensation around the center in the control-b run than in the low-aerosol-b run
699 (Figures 13a and 13b). This leads to a situation where the control-b run has the higher area-

700 averaged condensation rates than the low-aerosol-b run (Figure 12a). Then, as time
 701 progresses to 17:20 LST, the condensation area extends to the eastern and western parts of
 702 the domain mostly over mountain areas (Figures 13c and 13d). Hence, the main source of
 703 condensation is considered to be forced convection over mountains. As seen in Figures 13c
 704 and 13d, higher concentrations of aerosols acting as CCN induce the control-b run to have
 705 much more condensation spots and thus much bigger areas with condensation than the low-
 706 aerosol-b run at 17:20 LST. Associated with this, CCN-induced more condensation in the
 707 control-b run maintains with the time progress to 17:20 LST (Figure 12d). At 17:20 LST,
 708 precipitation mainly occurs in a spot which is in the western part of areas with relatively
 709 high condensation rates (Figures 13c and 13d).

710 At 17:20 LST, as seen in the cumulative frequency of condensation rates, the control-
 711 b run has the higher condensation frequency above condensation rate of $\sim 10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$
 712 ¹ and below that of $\sim 3 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ than the low-aerosol-b run (Figure 14a). This pattern
 713 of differences in the condensation frequency distribution with the tipping condensation-
 714 rate points at $\sim 10 \times 10^{-3}$ and $\sim 3 \times 10^{-3} \text{ g m}^{-2} \text{ s}^{-1}$ continues up to 19:00 LST (Figures 14b).
 715 Figure 15 shows the mean precipitation rate over each of the column-averaged
 716 condensation rates for the period up to 17:20 LST in the control-b run. A column-averaged
 717 condensation rate in an air column with a precipitation rate at its surface is obtained and
 718 these condensation and precipitation rates are paired at each column and time step. Then,
 719 collected precipitation rates are classified and grouped based on the corresponding paired
 720 column-averaged condensation rates. The classified precipitation rates corresponding to
 721 each of the column-averaged condensation rates are averaged arithmetically to construct
 722 Figure 15. There are only less than 10 % differences in the mean precipitation rate for each
 723 of the column-averaged condensation rates between the control-b and low-aerosol-b runs
 724 (not shown). Figure 15 shows that generally a higher condensation rate is related to a higher
 725 mean precipitation rate. It is also roughly shown that, according to the mean precipitation
 726 rate for each condensation rate, overall, condensation rates below $\sim 3 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ and
 727 above $\sim 10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ are correlated with precipitation rates below $\sim 2 \text{ mm hr}^{-1}$ and
 728 above $\sim 12 \text{ mm hr}^{-1}$, respectively, while condensation rates between ~ 3 and $\sim 10 \times 10^{-3} \text{ g}$
 729 $\text{m}^{-3} \text{ s}^{-1}$ are correlated with precipitation rates between ~ 2 and $\sim 12 \text{ mm hr}^{-1}$ (Figure 15).
 730 Hence, on average, the higher frequency of condensation with rates above $\sim 10 \times 10^{-3} \text{ g m}^{-3}$

731 s^{-1} and below $\sim 3 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ can be considered to lead to the higher frequency of
732 precipitation whose rates are higher than $\sim 12 \text{ mm hr}^{-1}$ and lower than $\sim 2 \text{ mm hr}^{-1}$ in the
733 control-b run, respectively. It can also be considered that the lower condensation frequency
734 between ~ 3 and $\sim 10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ leads to the lower precipitation frequency between ~ 2
735 and $\sim 12 \text{ mm hr}^{-1}$ in the control-b run. It is found that this correspondence between
736 condensation and precipitation rates is valid whether analyses to construct Figure 15 are
737 repeated only for a time point at 16:30 LST or for a period between 16:30 and 17:00 LST.
738 These time point and period are related to analyses of the moist static energy as described
739 in Section e below.

740 At 17:20 LST, the larger precipitation frequency between ~ 2 and $\sim 12 \text{ mm hr}^{-1}$ in the
741 low-aerosol-b run nearly offsets the larger precipitation frequency in the other ranges of
742 precipitation rates in the control-b run (Figure 11c). This leads to the similar average
743 precipitation rate between the runs at 17:20 LST and contributes to the similar cumulative
744 precipitation at the last time step between the runs (Figure 5b).

745

746 **d. Evaporation and gust fronts**

747

748 As time progresses from 17:00 to 19:00 LST, the precipitation system moves northward
749 (Figure 16). At the core of the precipitation system, due to evaporation and downdrafts,
750 there is the horizontal outflow forming at 17:00 LST (Figures 16a and 16b). The core is
751 represented by the field of precipitation whose rates are higher than 1 mm hr^{-1} in Figure 16.
752 At the core, the northward outflow is magnified by the northward synoptic-scale wind,
753 while at the core, the outflow in the other directions is offset by the northward synoptic-
754 scale wind. Hence, the outflow is mainly northward from 17:00 LST onwards as marked
755 by yellow circles in Figures 16. This enables convergence or a gust front, which is produced
756 by the outflow from the core, to be mainly formed at the north of the core. Note that the
757 intensity of a gust front is proportional to that of outflow from a core of precipitation or
758 convective system (Weisman and Klemp, 1982; Houze, 1993). The strong gust front at the
759 north of the core generates strong updrafts, a significant amount of condensation and
760 precipitation. Then, a subsequent area with clouds and precipitation is formed at the north
761 of the core as time progresses, which means that the precipitation system extends or moves

762 to the north as seen in comparisons between sub-panels with different times in Figure 16.
763 This movement, which is induced by collaborative work between outflow, synoptic wind
764 and gust fronts, is typical in deep convective clouds.

765 As described above, the more droplet nucleation and greater integrated droplet surface
766 induce more condensation before 17:00 LST in the control-b run. This and lower efficiency
767 of collision and collection among droplets enable the control-b run to have a larger amount
768 of cloud liquid or droplets as a source of evaporation. This in turn enables more droplet
769 evaporation, more associated cooling and stronger downdrafts, although less rain
770 evaporation is in the control-b run particularly for the period from 17:00 LST to 19:00 LST
771 (Figure 17). More evaporation of droplets and associated stronger downdrafts with higher
772 concentrations of aerosols acting as CCN have been shown by the numerous previous
773 studies (e.g., Tao et al., 2007; Tao et al., 2012; Khain et al., 2008; Lee et al., 2018).

774 During the period between 17:00 and 19:00 LST, with the development of convergence
775 or the gust front, as mentioned above, the maximum precipitation rate increases from ~ 17
776 (17) to ~ 45 (33) mm hr^{-1} in the control-b (low-aerosol-b) run (Figure 11). This indicates
777 that the gust-front development contributes to the overall intensification of the precipitation
778 system, while it moves northward. If there were only northward synoptic-scale wind with
779 no formation of the gust front, the system would move northward with less intensification.
780 Over the period from 17:00 LST to 19:00 LST, stronger downdrafts and associated stronger
781 outflow generate a stronger gust front and more subsequent condensation in the control-b
782 run. This enhances the small initial difference, which is at 17:00 LST, in the frequency of
783 precipitation with rates above ~ 12 mm hr^{-1} between the runs substantially as time
784 progresses from 17:00 LST to 19:00 LST (Figure 11). Associated with this, with the time
785 progress, the nearly identical maximum precipitation rate between the runs at 17:00 LST
786 turns into the significantly higher maximum precipitation rate in the control-b run than in
787 the low-aerosol-b run (Figure 11). Around 19:00 LST, the system enters its dissipating
788 stage, accompanying reduction in the precipitating area and the area-averaged precipitation
789 rate (Figures 5b, 16m and 16n).

790

791 **e. Moist static energy**

792

793 Condensation, which controls droplet mass and precipitation, is controlled by updrafts and
 794 updrafts are in turn controlled by instability. One of important factors that maintain
 795 instability is the moist static energy. Motivated by this, to better understand differences in
 796 the precipitation frequency distribution in association with those in the condensation
 797 frequency distribution between the control-b and low-aerosol-b runs, we calculate the flux
 798 of the moist static energy and the flux is defined as follows:

799

$$800 \quad \vec{F}_S = S \times \rho \times \vec{V} \quad (1),$$

801

802 where \vec{F}_S represents the flux of the moist static energy, S the moist static energy, ρ the air
 803 density and \vec{V} the horizontal-wind vector. In Eq. (1), we see that the flux is in the vector
 804 form and has two components, which are its magnitude and direction. The fluxes of the
 805 moist static energy in the PBL are obtained over the domain at 16:30 LST, since in general,
 806 the moist static energy in the PBL has much stronger effects on instability and updrafts
 807 than that above the PBL. In particular, we focus on the PBL fluxes of the energy that cross
 808 the boundary over a time step at 16:30 LST between areas with the column-averaged
 809 condensation rate from $3 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ to $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$, which are referred to as “area
 810 A”, and those with the column-averaged condensation rate above $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$, which
 811 are referred to as “area B”. This is because we are interested in the exchange of the moist
 812 static energy between areas A and B and this exchange can be seen by looking at those
 813 fluxes which cross the boundary between those areas.

814 We are interested in the exchange of the energy, since we hypothesized that the
 815 exchange somehow alters instability in each of areas A and B in a way that there are
 816 increases (decreases) in instability, the updraft intensity, condensation and precipitation
 817 with increasing concentrations of aerosols acting as CCN in area B (A), leading to the
 818 higher (lower) frequency of condensation whose rates are higher than $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$
 819 (between 3×10^{-3} and $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$) and precipitation whose rates are higher than 12
 820 mm hr^{-1} (between 2 and 12 mm hr^{-1}) in the control-b run than in the low-aerosol-b run.
 821 When the PBL fluxes, which crosses the boundary over the time step at 16:30 LST, are
 822 summed at 16:30 LST, there is the net flux from area A to area B. This means that there is
 823 the net transportation of the moist static energy from areas with condensation rates between

824 3×10^{-3} and $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ to those with condensation rates greater than $10 \times 10^{-3} \text{ g m}^{-3}$
825 s^{-1} in the PBL at 16:30 LST as shown in Table 2. Table 2 shows the net summed flux of the
826 moist static energy which crosses the boundary between areas A and B in the control-b run
827 as well as the low-aerosol-b run. To calculate the net flux at 16:30 LST in Table 2, the
828 fluxes, which cross the boundary between areas A and B over the time step at 16:30 LST,
829 only at grid points in the PBL are summed. For the calculation, the flux from area A to area
830 B has a positive sign, while the flux from area B to area A has a negative sign. Since the
831 net flux is positive for both of the runs as shown in Table 2, there is the net flux from area
832 A to area B in the PBL. The above-described analysis for the fluxes crossing the boundary
833 between areas A and B is repeated for every time step between 16:30 and 17:00 LST and
834 based on this, the net summed flux over the period between 16:30 and 17:00 LST is
835 obtained. As shown in Table 2, the net flux for the period between 16:30 and 17:00 LST is
836 also positive as in the situation only for 16:30 LST. This means that there is the net
837 transportation of the moist static energy from area A to area B in the PBL during the period
838 between 16:30 and 17:00 LST.

839 At 16:30 LST, condensation with rates above $10 \times 10^{-3} \text{ g m}^{-3} \text{ s}^{-1}$ starts to develop and
840 this forms area B. Area B has stronger updrafts via greater condensational heating than in
841 other areas, including area A, with lower condensation rates. Stronger updrafts in area B
842 induce the convergence of air and associated moist static energy from area A to area B.
843 Since the average condensation rate and updrafts at 16:30 LST over area B are higher and
844 stronger due to increasing concentrations of aerosols acting as CCN, respectively, the air
845 convergence and the associated transportation of the moist static energy in the PBL from
846 area A to area B are stronger and more, respectively, in the control-b run than in the low-
847 aerosol-b run (Table 2). Stated differently, area B steals the moist static energy from area
848 A, and this occurs more effectively in the control-b run. This increases instability and
849 further intensifies updrafts in area B, and decreases instability and weakens updrafts in area
850 A, while these increases and decreases (intensification and weakening) of instability
851 (updrafts) are greater in the control-b run for the period from 16:30 LST to 17:00 LST.
852 This increases condensation, cloud mass and precipitation whose rates are higher than 12
853 mm hr^{-1} in area B, and decreases condensation, cloud mass and precipitation whose rates
854 are from 2 mm hr^{-1} to 12 mm hr^{-1} in area A. These increases and decreases occur more

855 effectively for the control-b run than for the low-aerosol-b run during the period. This in
856 turn leads to the lower precipitation frequency for the precipitation rates from 2 mm hr⁻¹ to
857 12 mm hr⁻¹ and the higher frequency for the precipitation whose rates are higher than 12
858 mm hr⁻¹ at 17:00 LST in the control-b run (Figure 11b). The weakened updrafts and reduced
859 condensation turn a portion of precipitation with rates between 2 and 12 mm hr⁻¹ to
860 precipitation whose rates are below 2 mm hr⁻¹, and this takes place more efficiently in the
861 control-b run during the period between 16:30 and 17:00 LST. This eventually increases
862 the frequency of precipitation rates below 2 mm hr⁻¹ and this increase is greater for the
863 control-b run, leading to the greater precipitation frequency for the precipitation rates
864 below 2 mm hr⁻¹ in the control-b run at 17:20 LST (Figure 11c).

865

866 **5. Discussion**

867

868 **5.1 Comparison of the Seoul and Beijing cases**

869

870 In this section, we compare the Seoul case to the Beijing case. For the comparison,
871 remember that on average, a pair of the control-s and low-aerosol-s runs has the same
872 perturbation of aerosols acting as CCN as in a pair of the control-b and low-aerosol-b runs.
873 Associated with the fact that clouds in the Seoul case are less deep than those in the Beijing
874 case, overall, updrafts in the Seoul case are not as strong as those in the Beijing case. Hence,
875 unlike the situation in the Beijing case, stronger updrafts, which accompany higher
876 condensation rates, and associated convergence in the Seoul case are not strong enough to
877 steal the sufficient amount of the moist static energy from weaker updrafts which
878 accompany lower condensation rates. This makes the redistribution of the moist static
879 energy between areas with relatively higher condensation rates and those with relative
880 lower condensation rates, such as that between areas A and B for the Beijing case,
881 ineffective for the Seoul case. Due to this, the sign of CCN-induced changes in the
882 frequency of precipitation rates does not vary throughout all of the precipitation rates
883 except for the range of low precipitation rates where there are nearly no CCN-induced
884 changes in the frequency in the Seoul case as shown in Figure 6a. As seen in Figure 6a,
885 mainly due to increases in condensation and deposition, precipitation frequency increases

886 for most of precipitation rates, although the precipitation frequency does not show
887 significant changes as concentration of aerosols acting as CCN increases for relatively low
888 precipitation rates in the control-s run as compared to that in the low-aerosol-s run. This
889 means that there are no tipping precipitation rates where the sign of CCN-induced changes
890 in the frequency of precipitation rates changes in the Seoul case, contributing to the higher
891 cumulative precipitation amount in the simulation with higher concentrations of aerosols
892 acting as CCN for the Seoul case, which are different from the situation in the Beijing case.

893 In the Beijing case with deeper clouds as compared to those in the Seoul case, clouds
894 develop gust fronts via strong downdrafts and associated strong outflow. These gust fronts
895 play an important role in developing strong convection and associated high precipitation
896 rates. Unlike the situation in the Seoul case, there are strong clouds and associated updraft
897 entities that are able to steal heat and moisture (or the moist static energy) as sources of
898 instability from areas with relatively less strong clouds and updrafts with medium strength;
899 note that these strong clouds here involve stronger updrafts via greater condensational
900 heating as described in Section e above and this enables these clouds to be thicker and have
901 higher cloud mass than these less strong clouds. This further intensifies strong clouds and
902 weakens less strong clouds with medium strength. Due to this, the cumulative frequency
903 of heavy (medium) precipitation in association with strong clouds (less strong clouds with
904 medium strength) increases (decreases). Some of the weakened clouds eventually produce
905 light precipitation, which increase the cumulative frequency for light precipitation. The
906 intensification of strong clouds and the weakening of less strong clouds with medium
907 strength gets more effective with increasing concentration of aerosols acting as CCN.
908 Hence, in the Beijing case, for medium precipitation in association with less strong clouds,
909 the simulation with higher concentration of aerosols acting as CCN shows the lower
910 cumulative precipitation frequency at the last time step. However, for heavy precipitation,
911 which is associated with strong clouds, and light precipitation, the simulation with higher
912 concentrations of aerosols acting as CCN shows the higher cumulative precipitation
913 frequency at the last time step. These differential responses of precipitation to increasing
914 concentration of aerosols acting as CCN among different types of precipitation occur in the
915 circumstances of the similar cumulative precipitation amount between the simulations with
916 different concentration of aerosols acting as CCN. This similar precipitation amount is due

917 to above-mentioned competition between CCN-induced changes in condensation,
918 deposition and freezing.

919 In both of the Seoul and Beijing cases, CCN-induced changes in condensation plays an
920 important role in making differences in the precipitation amount and/or the precipitation
921 frequency distribution between the simulations with different concentration of aerosols
922 acting as CCN. It is notable that in less deep clouds in the Seoul case, in addition to
923 condensation, deposition plays a role in precipitation to induce CCN-induced increases in
924 the precipitation amount. CCN-induced increases in condensation initiate the differences
925 in cloud mass and precipitation and then CCN-induced increases in deposition follow to
926 further enhance those differences. In deep clouds in the Beijing case, condensation tends
927 to induce increases in cloud mass and precipitation, while deposition tends to induce
928 decreases in cloud mass and precipitation with increasing concentration of aerosols acting
929 as CCN. Hence, as clouds get shallower and thus ice processes become less active, the role
930 of deposition in CCN-induced changes in precipitation amount turns from CCN-induced
931 suppression of precipitation to enhancement of precipitation. Here, we find that contrary
932 to the traditional understanding, the role of variation of freezing, which is induced by the
933 varying concentration of aerosols acting as CCN but not INPs, in precipitation is negligible
934 as compared to that of condensation and deposition in both of the cases.

935

936 **6. Summary and conclusions**

937

938 This study examines impacts of aerosols, which act as CCN, on clouds and precipitation in
939 two metropolitan areas, which are the Seoul and Beijing areas, in East Asia that has
940 experienced substantial increases in aerosol concentrations over the last decades. The
941 examination is performed via simulations, which use a CSRM. These simulations are for
942 deep clouds which reach the tropopause in the Beijing case and for comparatively less deep
943 clouds which do not reach the tropopause yet grow above the level of freezing in the Seoul
944 case.

945 In both of the cases, CCN-induced changes in condensation plays a critical role in
946 CCN-induced variation of precipitation properties (e.g., the precipitation amount and the
947 precipitation frequency distribution). In the Seoul case, CCN-induced increases in

948 condensation and subsequent increases in deposition lead to CCN-induced increases in the
949 precipitation frequency over most of precipitation rates and thus in the precipitation amount.
950 However, in the Beijing case, while there are increases in condensation with increasing
951 CCN concentrations, there are decreases in deposition with increasing CCN concentrations.
952 This competition between increases in condensation and decreases in deposition leads to
953 negligible CCN-induced changes in cumulative precipitation amount in the Beijing case.
954 In both of the cases, CCN-induced changes in freezing are negligible as compared to those
955 in condensation and deposition. In the Beijing case, there is another competition for the
956 moist static energy among clouds with different updrafts and condensation. This
957 competition results in CCN-induced differential changes in the precipitation frequency
958 distributions. With clouds getting deeper from the Seoul case to the Beijing case, clouds
959 and associated updrafts, which are strong enough to steal the moist static energy from other
960 clouds and their updrafts, appear. This makes strong clouds stronger and clouds with
961 medium strength weaker. With higher CCN concentrations, strong clouds steal more
962 energy, and thus strong clouds become stronger and clouds with medium strength weaker
963 with a greater magnitude. As a result of this, there are more frequent heavy precipitation
964 (whose rates are higher than 12 mm hr^{-1}) and light precipitation (whose rates are lower than
965 2 mm hr^{-1}), and less frequent medium precipitation (with rates from 2 mm hr^{-1} to 12 mm
966 hr^{-1}) with increasing CCN concentrations in the Beijing case.

967 In both of the Seoul and Beijing cases, there are mountains and they play an important
968 role in how cloud and precipitation evolve with time and space. In both of the cases, the
969 precipitating system moves or expands over mountains which induce forced convection
970 and generate condensation. This important role of mountains and forced convection in the
971 formation and evolution of the precipitation system has not been examined much in the
972 previous studies of aerosol-cloud interactions, since many of those previous studies (e.g.,
973 Jiang et al., 2006; Khain et al., 2008; Li et al., 2011; Morrison et al., 2011) have dealt with
974 convective clouds that develop over plains and oceans. Hence, findings in this study, which
975 are related to mountain-forced convection and its interactions with aerosols, can be
976 complementary to those previous studies. Stated differently, this study can shed light on
977 our path to the understanding of aerosol-cloud interactions over more general domains not
978 only with no terrain but also with terrain.

979 **Code/Data availability**

980

981 Our private computer system stores the code/data which are private and used in this study.
982 Upon approval from funding sources, the data will be opened to the public. Projects related
983 to this paper have not been finished, thus, the sources prevent the data from being open to
984 the public currently. However, if information on the data is needed, contact the
985 corresponding author Seoung Soo Lee (slee1247@umd.edu).

986

987 **Author contributions**

988 Essential initiative ideas are provided by SSL, KJH and KHS to start this work. Simulation
989 and observation data are analyzed by SSL, JC and GK. JU and YZ review the results and
990 contribute to their improvement. CHJ and JG perform additional simulations, which are
991 required by the review process, and their basic analyses. CHJ also provide ideas to handle
992 the reviewers' comments.

993

1139 **FIGURE CAPTIONS**

1140

1141

1142 Figure 1. Wind (m s^{-1}), equivalent potential temperature (K), and geopotential height (m)
1143 at 850 hPa level over Northeast Asia at (a) 21:00 LST December 23rd 2017 and (b) 09:00
1144 LST July 27th 2015. Wind, equivalent potential temperature, and geopotential height are
1145 represented by arrows, a shaded field, and contours, respectively. An inner rectangle in
1146 the Korean Peninsula in (a) marks the Seoul area and that in the East-Asia continent in (b)
1147 marks the Beijing area.

1148

1149

1150 Figure 2. Inner rectangles in (a) and (b) mark the Seoul area in the Korean Peninsula and
1151 the Beijing area in the East-Asia continent, respectively. A dot outside the inner rectangle
1152 in (a) marks Baekryongdo island. Dots in the inner rectangles in (a) and (b) mark the
1153 selected locations where precipitation and aerosol mass are measured. In (a) and (b), the
1154 light blue represents the ocean and the green the land area.

1155

1156 Figure 3. Surface size distribution of aerosols (a) for the Seoul case and (b) for the Beijing
1157 case. Aerosol number concentration per unit volume of air is represented by N and aerosol
1158 diameter by D .

1159

1160 Figure 4. Time series of $\text{PM}_{2.5}$ observed at the ground station in Baekryongdo island (blue
1161 line) and of the average $\text{PM}_{2.5}$ over ground stations in the Seoul area (red line) between
1162 07:00 LST on December 22nd and 21:00 LST on December 24th in 2017. Note that $\text{PM}_{2.5}$
1163 observed at stations in the Seoul area is applied to the control-s run whose period is marked
1164 by the dashed rectangle. Time series of the average $\text{PM}_{2.5}$ over stations in the Seoul area in
1165 the low-aerosol-s run for the simulation period is also shown (black solid line).

1166

1167 Figure 5. Time series of precipitation rates at the surface, which are averaged over the
1168 domain and smoothed over 1 hour, (a) for the control-s and low-aerosol-s runs in the Seoul
1169 area and (b) for the control-b and low-aerosol-b runs in the Beijing area. In (a) and (b), the

1170 averaged and observed precipitation rates over the observation sites in the Seoul and
1171 Beijing areas, respectively, are also shown.

1172

1173 Figure 6. Observed and simulated cumulative frequency distributions of precipitation rates
1174 at the surface for (a) the Seoul case, which are collected over the Seoul area, and (b) the
1175 Beijing case, which are collected over the Beijing area, at the last time step. Simulated
1176 distributions are in the control-s and low-aerosol-s runs for the Seoul case and in the
1177 control-b and low-aerosol-b runs for the Beijing case. The observed distribution is obtained
1178 by interpolating and extrapolating the observed precipitation rates to grid points and time
1179 steps in the control-s and control-b runs for the Seoul and Beijing cases, respectively.

1180

1181 Figure 7. Cumulative frequency distributions of the precipitation rates at the surface in the
1182 control-s and low-aerosol-s runs for the Seoul case at (a) 06:00, (b) 10:00 and (c) 12:00
1183 LST.

1184

1185 Figure 8. Vertical distributions of differences in the area-averaged condensation,
1186 deposition and freezing rates, and cloud-liquid, raindrop, snow and hail mass density, and
1187 updraft mass fluxes between the control-s and low-aerosol-s runs at (a) 03:20, (b) 03:40,
1188 (c) 06:00 and (d) 12:00 LST. The horizontal black line in each panel represents the altitude
1189 of freezing or melting. Here, for the sake of the display brevity, snow mass density includes
1190 ice-mass density, while hail mass density includes graupel mass density.

1191

1192 Figure 9. Spatial distributions of terrain heights, column-averaged condensation rates,
1193 surface wind vectors and precipitation rates at (a) and (b) 03:40, (c) and (d) 07:20, (e) and
1194 (f) 08:40, (g) and (h) 10:00, (i) and (j) 11:00, and (k) and (l) 12:00. The distributions in the
1195 control-s run are shown in (a), (c), (e), (g), (i) and (k), and the distributions in the low-
1196 aerosol-s run are shown in (b), (d), (f), (h), (j) and (l). Condensation rates are shaded. Dark-
1197 yellow and dark-red contours represent precipitation rates at 0.5 and 3.0 mm hr⁻¹,
1198 respectively, while beige, light brown and brown contours represent terrain heights at 100,
1199 300 and 600 m, respectively. See text for yellow rectangles in (a), (b), (g) and (h)

1200

1201 Figure 10. Cumulative frequency distributions of the column-averaged condensation rates
1202 in the control-s and low-aerosol-s runs for the Seoul case at (a) 07:20 and (b) 09:00 LST.

1203

1204 Figure 11. Cumulative frequency distributions of the precipitation rates at the surface in
1205 the control-b and low-aerosol-b runs for the Beijing case at (a) 16:00, (b) 17:00, (c) 17:20,
1206 and (d) 19:00 LST.

1207

1208 Figure 12. Same as Figure 8 but for differences between the control-b and low-aerosol-b
1209 runs at (a) 14:20, (b) 15:40, (c) 16:00, (d) 17:20 and (e) 19:00 LST.

1210

1211 Figure 13. Spatial distributions of terrain heights, column-averaged condensation rates,
1212 surface wind vectors and precipitation rates at (a) and (b) 14:20, and (c) and (d) 17:20 LST.
1213 (a) and (c) are for the control-b run and (b) and (d) are for the low-aerosol-b run.
1214 Condensation rates are shaded. Dark-yellow and dark-red contours represent precipitation
1215 rates at 1.0 and 2.0 mm hr⁻¹, respectively, while beige, light brown, brown and dark brown
1216 contours represent terrain heights at 100, 500, 1000 and 1500 m, respectively. See text for
1217 yellow circles in (a) and (b).

1218

1219 Figure 14. Cumulative frequency distributions of the column-averaged condensation rates
1220 in the control-b and low-aerosol-b runs for the Beijing case at (a) 17:20 and (b) 19:00 LST.

1221

1222 Figure 15. Mean precipitation rates corresponding to each column-averaged condensation
1223 rate for the period between 14:00 and 17:20 LST in the control-b run. One standard
1224 deviation of precipitation rates is represented by a vertical bar at each condensation rate.

1225

1226 Figure 16. Spatial distributions of precipitation rates (shaded) and wind vectors (arrows)
1227 for the Beijing case at (a) and (b) 17:00, (c) and (d) 17:20, (e) and (f) 17:40, (g) and (h)
1228 18:00, (i) and (j) 18:20, (k) and (l) 18:40, and (m) and (n) 19:00 LST. The distributions in
1229 the control-b run are in (a), (c), (e), (g), (i), (k) and (m). The distributions in the low-
1230 aerosol-b run are in (b), (d), (f), (h), (j), (l) and (n).

1231

1232 Figure 17. Vertical distributions of (a) the area-averaged cloud-liquid and rain evaporation
1233 rates and (b) downdraft mass fluxes in the control-b and low-aerosol-b runs over a period
1234 from 17:00 to 19:00 LST.
