10 **Abstract.** Atmospheric aerosols influence the climate via cloud droplet nucleation and can facilitate the long-range transport  
of harmful pollutants. The lifetime of such aerosols can therefore determine their environmental impact. Fatty acids are found  
in organic aerosol emissions with oleic acid, an unsaturated fatty acid, being a large contributor to cooking emissions. As a  
surfactant, oleic acid can self-organise into nanostructured lamellar bilayers with its sodium salt, and this self-organisation can  
influence reaction kinetics. We developed a kinetic multi-layer model-based description of decay data we obtained from  
15 laboratory experiments of the ozonolysis of coated films of this self-organised system, demonstrating a decreased diffusivity  
for both oleic acid and ozone due to lamellar bilayer formation. Diffusivity was further inhibited by a viscous oligomer product  
forming in the surface layers of the film. Our results indicate that nanostructure formation can increase the reactive half-life of  
oleic acid by an order of days at typical indoor and outdoor atmospheric ozone concentrations. We are now able to place  
nanostructure formation in an atmospherically meaningful and quantifiable context. These results have implications for the  
20 transport of harmful pollutants and the climate.

## 1 Introduction

30 Atmospheric aerosols represent a large uncertainty when considering their impact on human-made climate change (Boucher et al., 2013) and can be associated with poor air quality in urban areas (Chan and Yao, 2008; Kulmala et al., 2021; Li et al., 2018; Molina, 2021). The organic fraction of atmospheric aerosols includes a diverse range of molecules with differing functionalities, varying with season and environment (Jimenez et al., 2009; Wang et al., 2020b).

35 Cooking emissions are key contributors to urban aerosols (Ots et al., 2016; Vicente et al., 2021). Fatty acids are a well-established set of marker compounds used to track cooking emissions due to their relatively high abundance (Wang et al., 2020a; Zhao et al., 2015). In particular oleic acid, an unsaturated fatty acid, has been used to follow the ageing of cooking aerosols (Wang et al., 2020a). The lifetime of oleic acid in the atmosphere is longer compared with laboratory predictions (days compared to hours) (e.g. Pfrang et al., 2011; Robinson et al., 2006; Rudich et al., 2007). This is a long-standing discrepancy and suggests that some physical process is inhibiting the ageing of such aerosols. For these reasons, oleic acid  
40 has been the compound of choice for laboratory studies into aerosol heterogeneous oxidation (Gallimore et al., 2017; King et al., 2020; Milsom et al., 2021b, 2021a; Pfrang et al., 2017; Woden et al., 2021; Zahardis and Petrucci, 2007).

The phase state and viscosity of atmospheric aerosols can impact on heterogeneous processes such as reactive gas and water uptake (Reid et al., 2018; Shiraiwa et al., 2011). Field measurements have shown that semi-solid phase formation takes place in the atmosphere (Virtanen et al., 2010) and that phase state can vary between night and day as well as with organic mass  
45 fraction (Slade et al., 2019). The long-range transport of harmful polycyclic aromatic hydrocarbons (PAHs) has been linked with particle phase and the formation of a viscous organic layer, protecting the aerosol's potentially harmful contents (Mu et al., 2018; Shrivastava et al., 2017). Viscous phase formation is therefore a plausible explanation for the persistence of organic aerosol components in the atmosphere.

As a surfactant, oleic acid can self-organise into a range of nanostructures, known as lyotropic liquid crystals (LLCs), with its  
50 sodium salt and water (Mele et al., 2018; Seddon et al., 1990). The viscosity and the diffusion of small molecules through these phases can vary significantly (Mezzenga et al., 2005; Zabara and Mezzenga, 2014). Some nanostructures, such as the lamellar phase, have highly anisotropic diffusivities resulting in substantially higher diffusivity parallel to the lamellar bilayer compared to the perpendicular direction (Lindblom and Orädd, 1994). This nanostructure formation has been studied in levitated droplets and in coated quartz capillaries (Pfrang et al., 2017; Seddon et al., 2016), where the self-organisation of this  
55 proxy system decreased the reactivity of oleic acid by approximately an order of magnitude (Milsom et al., 2021b).

In the present work, we develop a self-organised phase resolved model description of oleic acid ozonolysis and apply this both to kinetic data of the lamellar phase presented recently by Milsom *et al.* (Milsom et al., 2021b) and also to new liquid phase oleic acid ozonolysis data measured by Raman microscopy. We determine the effect on particle diffusivity of both nanostructure formation and the formation of a later stage reaction product, which congregates in the surface region of the  
60 film. We then predict the impact on the atmospheric lifetime of such films, linking this to the discrepancy between measured and predicted atmospheric lifetimes for oleic acid (Robinson et al., 2006; Rudich et al., 2007).

## 2 Methodology

In this study, oleic acid refers to both oleic acid and sodium oleate as they are both constituents of the lamellar phase bilayer. Pure oleic acid is referred to as liquid oleic acid. Oleic acid and sodium oleate represent the conjugate acid and conjugate base  
65 form of the same common organic aerosol component, and are expected to be present together in intermediate pH ranges (oleic acid  $pK_a$  is *ca.* 5.0).

For the present study we made liquid oleic acid capillary coatings, exposed them to ozone and followed the kinetics by Raman  
70 microscopy. The coatings were prepared by the following method (compare Milsom et al., 2021b): oleic acid (90 % purity, Sigma-Aldrich) was dissolved as a 10 wt % solution in methanol. A 70  $\mu$ L aliquot of this mixture was passed up and down a quartz capillary tube (Capillary Tube Supplies Ltd., UK,  $1.5 \pm 0.25$  mm diameter, wall thickness 0.010 mm) embedded in a metal holder until the methanol had evaporated from the solution, aided by passing room-temperature condensed air through the capillary.

The Raman microscopy and ozonolysis experiment is based on the setup detailed in Milsom et al. (Milsom et al., 2021b). A  
75 long-working-distance objective lens (0.42 numerical aperture) was used to focus a 532-nm laser on the capillary. The minimum spot diameter was  $\sim 1.5$   $\mu$ m and the laser power emitted was between 20 and 50 mW. Oxygen (BOC, 99.5%) was passed through a pen-ray ozoniser (Ultraviolet Products Ltd, Cambridge, UK) to produce ozone. The ozone concentration was calibrated offline by UV spectroscopy using the absorption cross-section for ozone at 254 nm ( $(1.14 \pm 0.07) \times 10^{-17}$  cm<sup>2</sup>) (Mauersberger et al., 1986). A concentration of  $77 \pm 5$  ppm was used for comparison with the lamellar phase kinetics presented by Milsom et al..

80 The experimental data for lamellar phase oleic acid modelled here are from a recent study where small-angle X-ray scattering (SAXS) was used to follow the kinetic decay of the amount of lamellar phase (nanostructured) fatty acid in films of oleic acid-sodium oleate (Milsom et al., 2021b). The selected decays were from the same experiment carried out simultaneously in the same capillary under the same conditions ( $77 \pm 5$  ppm ozone, dry oxygen-ozone flow). The ozone concentration used was much higher than that found in the atmosphere due to the major time limitations associated with synchrotron beam-time  
85 experiments.

The experimental data were modelled following the approach of the kinetic multi-layer model of aerosol surface and bulk  
chemistry (KM-SUB; Shiraiwa et al., 2010) based on the Pöschl-Rudich-Ammann (PRA) framework (Pöschl et al., 2007). An oleic acid ozonolysis reaction scheme was chosen where oligomer formation, viscosity and diffusivity were explicitly treated (compare Hosny et al., 2016). Our model uses a flat film geometry. The model description and the reaction scheme used are  
90 presented in the Supplement (sect. S1).

The model was written in the *Python* programming language. A series of ordinary differential equations (ODEs) describes the change in concentration for each model component in each model bulk and surface layer over time. These ODEs were integrated using the *SciPy solve\_ivp* solver with a backward differentiation formula (BDF) for stiff ODE solving (Virtanen et al., 2020).

95 Parameters associated with reaction rate constants, Henry's law coefficient and the gas uptake coefficient for ozone into the organic phase were set to values used in previous oleic acid ozonolysis literature (all model parameters are summarised in the Supplement, sect. S2).

The diffusion of model components throughout the film was allowed to vary with composition. It is known that self-organised phase formation affects viscosity and diffusivity (Mezzenga et al., 2005; Zabara and Mezzenga, 2014). Therefore determining the effect of particle diffusivity on reactivity is a key focus of this study. A Vignes-type diffusion regime was employed to account for the effect of composition on molecular diffusivity (Alpert et al., 2019; Vignes, 1966; Zhou et al., 2019). The diffusion of model components was dependent on the fraction of lamellar oleic acid as well as dimer and trimer oligomers formed by oleic acid ozonolysis (Lee et al., 2012; Zahardis et al., 2006).

The Vignes-type diffusion parameterisation is outlined in Eq. 1 & 2.

105

$$D_{Y,i} = (D_{Y,lam})^{1-f_{di,i}-f_{tri,i}} \times (D_{Y,di})^{f_{di,i}} \times (D_{Y,tri})^{f_{tri,i}} \quad (1)$$

$$D_{X,i} = (D_{X,lam})^{1-f_{di,i}-f_{tri,i}} \times (D_{X,di})^{f_{di,i}} \times (D_{X,tri})^{f_{tri,i}} \quad (2)$$

$Y$  in equation 1 refers to oleic acid and 9-carbon products, the diffusion of which in each model layer ( $i$ ) was treated the same.  $X$  corresponds to the reactive gas, in this case ozone. The fraction of dimer ( $f_{di,i}$ ) and trimer ( $f_{tri,i}$ ) in model layer  $i$  was used to represent layer composition. The diffusion coefficients of components in the lamellar ( $D_{Y,lam}$  &  $D_{X,lam}$ ), dimer ( $D_{Y,di}$  &  $D_{X,di}$ ) and trimer ( $D_{Y,tri}$  &  $D_{X,tri}$ ) media were allowed to vary during the model fitting.

The diffusion of the dimer and trimer products was treated using power law relationship via a scaling factor ( $f_{diff}$ ) in line with an oleic acid ozonolysis modelling study that focussed on viscosity data measurements (Hosny et al., 2016). We adapted this parameterisation to define oligomer diffusivity rather than viscosity.

115

$$D_{tri} = D_{di} \left( \frac{M_{di}}{M_{tri}} \right)^{f_{diff}} \quad (3)$$

$D_{tri}$  and  $D_{di}$  are the diffusion coefficients of the trimer and dimer, respectively.  $D_{di}$  was allowed to vary during the model fitting procedure.  $M_{di}$  and  $M_{tri}$  are the respective molecular masses of the dimer and trimer products.

The model output was fitted to experimental data using a differential evolution (DE) global optimisation algorithm (Storn and Price, 1997). An initial population of candidate parameter sets was created by Latin Hypercube sampling of the parameter space (McKay et al., 1979). This was carried out in parallel, similar to the procedure described by Berkemeier *et al.*, who used Monte Carlo sampling to initialise their candidate parameter sets (Berkemeier et al., 2017). The DE algorithm is a popular one for finding the global minimum of a loss function used to evaluate model fitness, which in this case was the mean-squared error of the model fit. This fitting procedure was implemented using the DE method in the *optimise* module of the *SciPy* package (Virtanen et al., 2020). 20 cpu cores were used for parallelisation of the differential evolution algorithm. The model

125

was optimised to all the datasets simultaneously. The loss function from each experimental fit was weighted according to the number of data points fitted to. Separate model optimisations to each individual dataset were carried out in order to find a range of optimised parameter values.

The sensitivity of the model to the varied parameters was investigated using an Elementary Effects algorithm via the method of Morris implementation of the *SALib Python* package (Campolongo et al., 2007; Herman and Usher, 2017; Morris, 1991). The total loss rate of oleic acid at 40 min reaction time was used as the output variable. Normalised sensitivity coefficients for each varied parameter were then obtained by measuring changes in the total loss rate of oleic acid with changes in each model parameter.

### 3 Results and discussion

#### 3.1 Diffusion behaviour

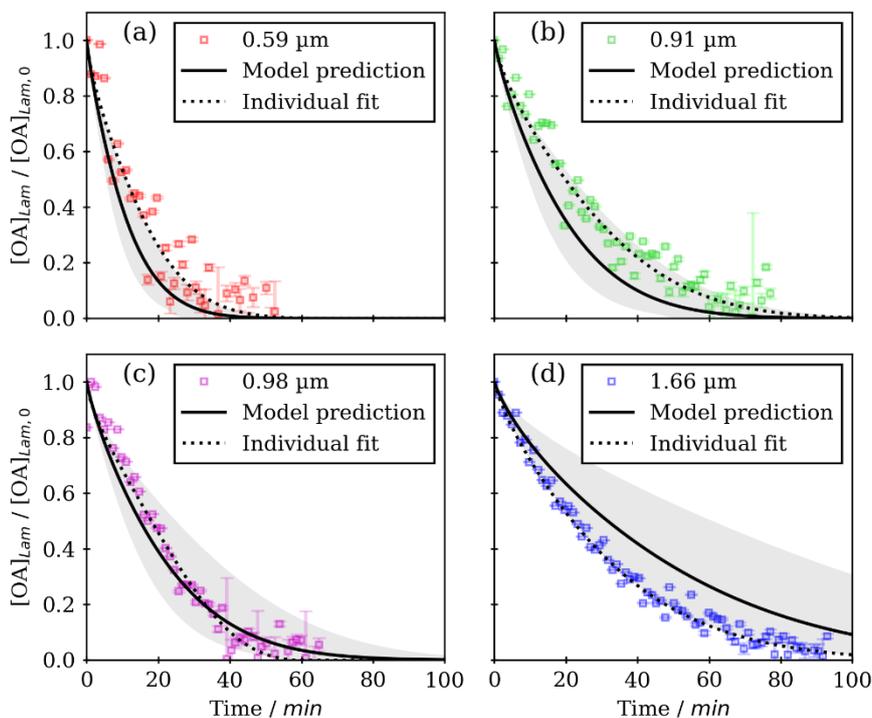

Figure 1. Kinetic decay plots of normalised lamellar phase oleic acid concentration ( $[OA]_{Lam}/[OA]_{Lam,0}$ ) as a function of time (experimental data from Milsom et al., 2021b); model predictions are based on the optimised model parameters determined by fitting all the data simultaneously. Individual fits to each dataset are also presented. Film thicknesses are displayed in each legend. The grey shaded regions represent the range of model outputs using parameter sets optimised from each individual fit.

Parameter	Description	Value* / cm <sup>2</sup> s <sup>-1</sup>	Range** / cm <sup>2</sup> s <sup>-1</sup>
D <sub>dimer</sub>	Bulk diffusion coefficient of the dimer	$1.03 \times 10^{-12}$	$1.03 \times 10^{-12} - 9.49 \times 10^{-10}$
D <sub>X,lam</sub>	Bulk diffusion coefficient of ozone in the lamellar phase	$3.35 \times 10^{-12}$	$1.13 \times 10^{-12} - 8.78 \times 10^{-8}$
D <sub>Y,lam</sub>	Bulk diffusion coefficient of oleic acid in the lamellar phase	$2.81 \times 10^{-12}$	$7.32 \times 10^{-13} - 2.81 \times 10^{-12}$
D <sub>X,di</sub>	Bulk diffusion coefficient of O <sub>3</sub> in the dimer	$4.66 \times 10^{-9}$	$2.14 \times 10^{-9} - 7.34 \times 10^{-9}$
D <sub>Y,di</sub>	Bulk diffusion coefficient of oleic acid in the dimer	$8.85 \times 10^{-11}$	$5.03 \times 10^{-11} - 9.93 \times 10^{-11}$
D <sub>X,tri</sub>	Bulk diffusion coefficient of O <sub>3</sub> in the trimer	$1.49 \times 10^{-12}$	$1.49 \times 10^{-12} - 9.76 \times 10^{-9}$
D <sub>Y,tri</sub>	Bulk diffusion coefficient of oleic acid in the trimer	$8.16 \times 10^{-11}$	$1.24 \times 10^{-11} - 9.88 \times 10^{-11}$

145 **Table 1. Optimised diffusion parameters allowed to vary during model optimisation. The full set of model parameters is available in the Supplement (sect. S2). \*From simultaneous fitting to all experimental datasets in Fig. 1. \*\*From individual fits to each experimental dataset in Fig. 1.**

The optimised model parameters from simultaneous fitting of all datasets returned good fits for the experimental data measured at 0.59 and 0.98 μm film thickness (Fig. 1). The 0.91 μm and 1.66 μm films returned poorer fits than the other films. A summary of the optimised diffusion parameters is presented in Table 1 and those from the individual fits are presented in Table 150 S2 in the Supplement.

Ozone diffusion in the lamellar phase ( $D_{X,lam} = 3.35 \times 10^{-12}$  cm<sup>2</sup> s<sup>-1</sup>) is consistent with the diffusion of a reactive gas through a highly viscous matrix (Shiraiwa et al., 2011a). The spacing between lamellar alkyl chains in this system is 4.41 Å (Milsom et al., 2021b), which is close to the molecular diameter of ozone of 4 Å used (Pfrang et al., 2010; Shiraiwa et al., 2010). It has been suggested that the shorter spacing between fatty acid tails on a particle surface could provide steric hindrance to diffusing 155 ozone molecules, limiting access to the doublebond (Hearn et al., 2005; Vieceli et al., 2004). The anhydrous lamellar phase, being viscous and ordered, is likely to present extra steric hindrance compared to surface monolayers because this effect would prevail throughout the film.

Ozone diffusion in the dimer is ~ 3-fold higher than in the lamellar phase. This is consistent with a steric hindrance argument. The assumed unordered nature of the dimer product suggests that ozone can diffuse past these molecules more easily compared 160 with diffusion through the restricted bilayers formed by the lamellar phase oleic acid. By contrast, diffusion through the trimer product is slower than in the dimer and lamellar phase. The trimer product in this model represents all the higher-order oligomers that can be formed during oleic acid ozonolysis, contributing to an increase in particle viscosity (Hosny et al., 2016). The diffusivity of oleic acid is low in the lamellar phase ( $D_{Y,lam} = 2.81 \times 10^{-12}$  cm<sup>2</sup> s<sup>-1</sup>) compared to ~  $1.53 \times 10^{-9}$  cm<sup>2</sup> s<sup>-1</sup> for pure liquid oleic acid ( $D_{Y,liq}$ ) based on its viscosity at 293.15 K (Sagdeev et al., 2019). Experimentally determined lateral 165 diffusion coefficients in hydrated lamellar bilayers are at least four orders of magnitude higher than our model optimisation

170 returned ( $\sim 10^{-8} - 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ ) (Lindblom and Orädd, 1994; Lindblom and Wennerström, 1977). Note that these experimental determinations were on hydrated lamellar phases, which are expected to be less viscous than the anhydrous lamellar phase studied here due to water acting as a plasticiser. The model does not account for directionally dependent diffusion through the lamellar phase because no bilayer orientation was observed: 2-D SAXS patterns obtained for these samples did not exhibit any alignment of the lamellar phase (see Fig. S2, the Supplement).

The diffusivity of oleic acid in the trimer product is within an order of magnitude of the lamellar phase oleic acid diffusivity. After an increase in diffusivity going from the lamellar to the dimer phase ( $D_{Y,di} = 8.85 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$ ), oleic acid diffusivity decreases in the trimer ( $D_{Y,tri} = 8.16 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$ ).

175 Differences between the model and data arise for a number of reasons: (i) there is an uncertainty associated with the film thickness measurement, in particular the 0.91 and 0.98  $\mu\text{m}$  films are similar when considering their quoted thickness uncertainties representing one standard deviation (0.03  $\mu\text{m}$ ) (Milsom et al., 2021b). (ii) If the film structure changes over time exposed to ozone, which has been observed under a microscope (Hung and Tang, 2010), the surface area available for ozone uptake may also change. This change in surface structure is not considered in the model since it would require an experimental determination of the surface roughness. (iii) The film may have been slightly thicker on one side of the capillary compared to the other: this technique required the X-ray beam to pass through both sides of a coated quartz capillary. Given that film thickness affects reaction kinetics, a difference in film thickness between both sides could impact the experimental result. (iv) The film thickness could have varied over the part of the film illuminated by the X-ray beam: the beam was  $\sim 320 \mu\text{m} \times 400 \mu\text{m}$  in size and therefore the film thickness is an average of the illuminated area. These arguments could account for the range of fitted model parameters when each dataset was fitted separately (see Table 1).

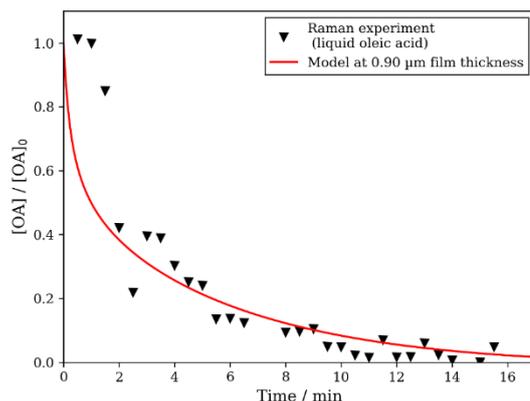

185 We can rule out any variation in sample environment because all of these datasets were taken from different positions along the same capillary during the same ozonolysis experiment. Thus, we are confident that the film structure and morphology must have some impact on reactivity on this thickness scale.

190 In order to contrast liquid and nanostructured oleic acid kinetic decays, ozonolysis of liquid oleic coated inside a quartz capillary was carried out and followed by Raman microscopy – a technique previously used to follow oleic acid reaction kinetics (King et al., 2004; Pfrang et al., 2017). We then applied the optimised model to these experimental data, replacing the diffusivity of ozone and oleic acid in the lamellar phase ( $D_{X,lam}$  and  $D_{Y,lam}$ , respectively) with values for diffusion through liquid phase oleic acid ( $D_{X,liq}$  and  $D_{Y,liq}$ , respectively). For the diffusion of ozone in liquid oleic acid we used the value from previous modelling studies on oleic acid ozonolysis (Pfrang et al., 2010; Shiraiwa et al., 2010).

195

200

**Figure 2. Kinetic decay plot of the ozonolysis of liquid oleic acid measured by Raman microscopy. Model fit for a 0.90  $\mu\text{m}$  film thickness with liquid oleic acid diffusion parameters ( $D_{Y,\text{liq}} = 1.53 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ,  $D_{X,\text{liq}} = 1.00 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ , replacing  $D_{Y,\text{lam}}$  and  $D_{X,\text{lam}}$ ). Experimental  $[\text{O}_3] = 77 \pm 5 \text{ ppm}$ .**

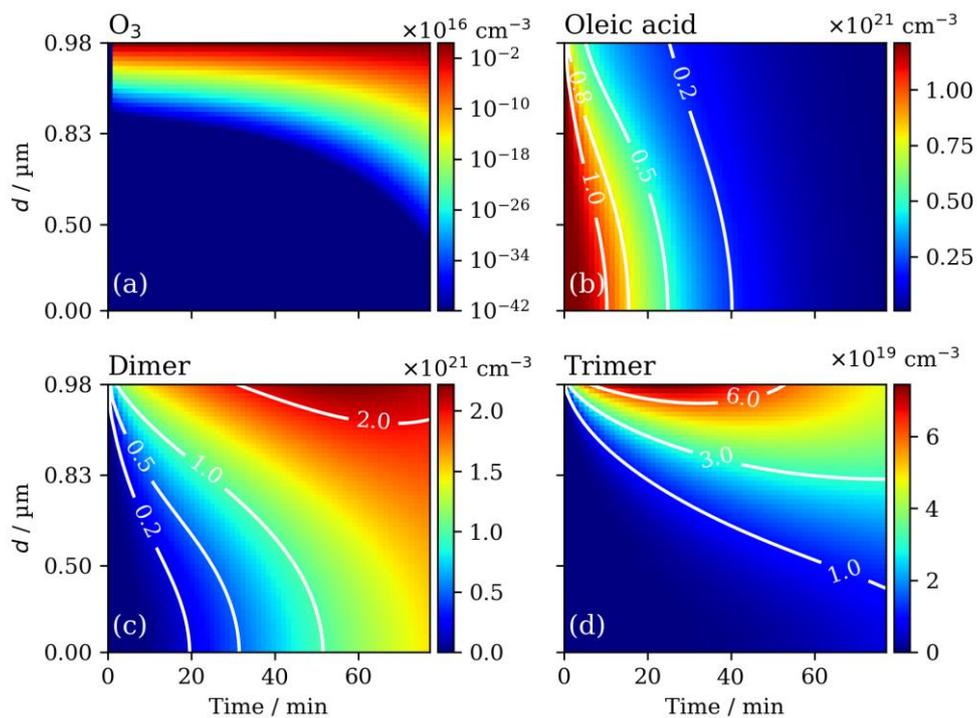

Encouragingly, the optimised model returned a good fit to ozonolysis decay data obtained by Raman spectroscopy on a film  
205 coated with pure oleic acid in the liquid state (Fig. 2). This film was prepared in the same way as the semi-solid films, therefore  
it is not unreasonable to assume a similar film thickness. We varied the modelled film thickness and found that a value of 0.90  
 $\mu\text{m}$  fitted best to these data. The concentration evolution of the model components from this fit is presented in the Supplement  
(Fig. S1).

### 3.2 Spatial and temporal evolution of composition and diffusion

225 **Figure 3.** Spatially and temporally resolved concentration evolution of ozone ((a) – Log-scale concentration), oleic acid (b), dimer (c) and trimer (d) model components during ozonolysis for a  $0.98 \mu\text{m}$  film -  $d$ : the distance from the film-substrate interface. Contours illustrate the change in concentration gradient over time for the non-reactive gas species.  $[\text{O}_3] = 77 \text{ ppm}$ .

**Figure 4.** The evolution of ozone diffusivity throughout a  $0.98 \mu\text{m}$  film during ozonolysis.  $[\text{O}_3] = 77 \text{ ppm}$ .  $d$ : the distance from the film-substrate interface.

The spatial and temporal evolution of ozone concentration is consistent with a bulk diffusion-limited reaction. The concentration of ozone in the majority of the film bulk does not exceed ~ 1 % of the concentration in the surface layers (Fig. 3(a) – effectively no ozone near the film substrate). The steep ozone concentration gradient developed during the reaction is illustrated by the log-scale in Fig. 3(a).

235 Diffusion of ozone through regions of higher viscosity is expected to be slower and the formation of a crust in the surface layers of the film, consisting of the viscous trimer product, inhibits the diffusion of ozone through the particle (Fig. 3(d) and Fig. 4). The formation of a surface crust has been postulated in the literature (Pfrang et al., 2011; Zhou et al., 2013) and direct experimental evidence of surface product aggregation has recently been presented in a similar proxy (Milsom et al., 2021a). Similarly, an oleic acid concentration gradient also develops during the reaction (Fig. 3(b)). This gradient is not as steep as the one observed for ozone but is still noteworthy. Surface crust formation is the source of increasing diffusive inhibition during the reaction and therefore a key factor inhibiting the oleic acid ozonolysis kinetics for this system.

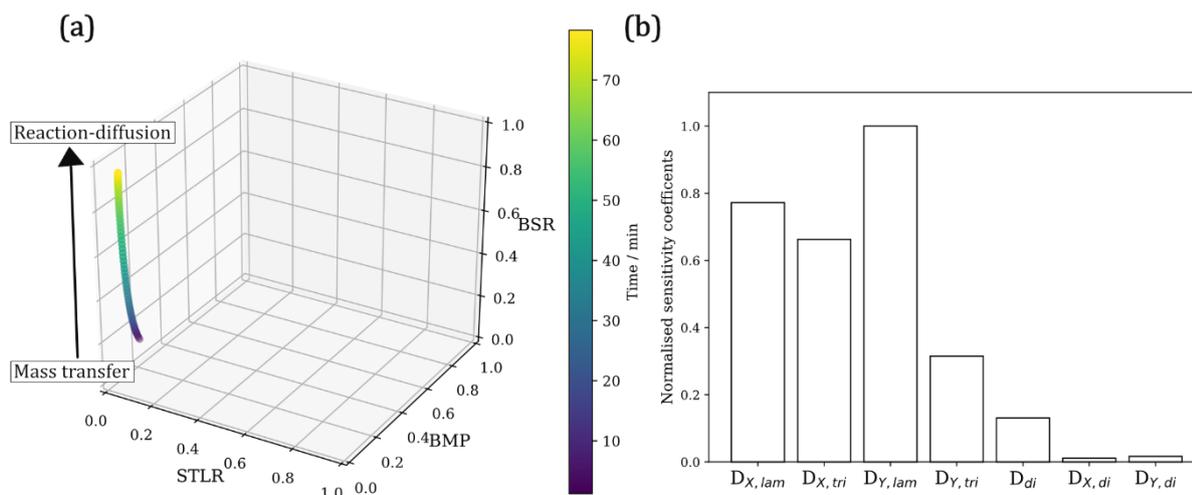

240 The atmospheric implications of this diffusive inhibition, caused by the initial phase state and crust formation, is explored in the *Atmospheric implications* section.

245

250

### 3.3 Kinetic regime analysis

255 **Figure 5. (a)** A “kinetic cube” plot (described by Berkemeier *et al.*) (Berkemeier *et al.*, 2013) of surface-to-total loss ratio (STLR), bulk mixing parameter (BMP) and bulk saturation ratio (BSR) for a model run at 77 ppm ozone and 0.98  $\mu\text{m}$  film thickness. The black arrow illustrates the movement from the mass transfer to the reaction-diffusion kinetic regimes described by Berkemeier *et al.* (b) A summary of the normalised sensitivity coefficients for each varied model parameter.

The model output was most sensitive to ozone and oleic acid diffusivity, highlighting that film phase heavily influences its lifetime (Fig. 5(b)). From this analysis and the concentration profiles (Fig. 3) we can conclude that the reaction is limited both by bulk oleic acid diffusion to the reaction region and by the diffusivity of ozone through the film – illustrated by the concentration gradients observed for both components (Fig. 3(a) & (b)). The model was least sensitive to diffusion coefficients of ozone and oleic acid in the dimer.

260 Further analysis using a method described by Berkemeier *et al.* for multi-layer model outputs demonstrates the evolution of kinetic regime as ozonolysis proceeds (Fig. 5(a)) (Berkemeier *et al.*, 2013). The surface-to-total loss ratio (STLR) observed throughout the reaction is close to zero, suggesting that reactant loss is not a surface-dominated process. The bulk mixing parameter (BMP) starts at  $\sim 0.18$  and decreases with time. This is a measure of how well mixed the particle is in terms of both the reactive gas and condensed phase reactant – a value of one is well-mixed. The film therefore starts poorly mixed and becomes less well-mixed as the reaction progresses. After an initial transient phase, the bulk saturation ratio (BSR) increases steadily over time. This reflects the supply of the reactive gas to the film, which is inhibited by viscous product formation and the viscous lamellar phase.

270 For an appreciable amount of time the reaction regime lies between a mass-transfer and reaction-diffusion regime, illustrating the importance of both bulk diffusion and accommodation parameters at different times during the reaction (Fig. 5(a)). The

transient nature of the kinetic regime demonstrates the added insight obtained through this more explicit description. Limiting cases based on a resistor model do not account for changes in kinetic regime (Worsnop et al., 2002). This kind of analysis demonstrates the power of spatially and temporally resolved kinetic modelling, enabling us to present a more nuanced picture of the kinetic regimes underpinning this reaction.

275 There is no experimental information available regarding the uptake of reactive gasses to this particular proxy system, therefore parameters such as Henry's law coefficient ( $H^{\text{CP}}$ ) and gas surface accommodation coefficient ( $\alpha_{s,0}$ ) for ozone were set to values used in other literature modelling studies of the oleic acid-ozone system (details of model parameters are presented in the Supplement sect. S2).

### 3.3 Atmospheric implications

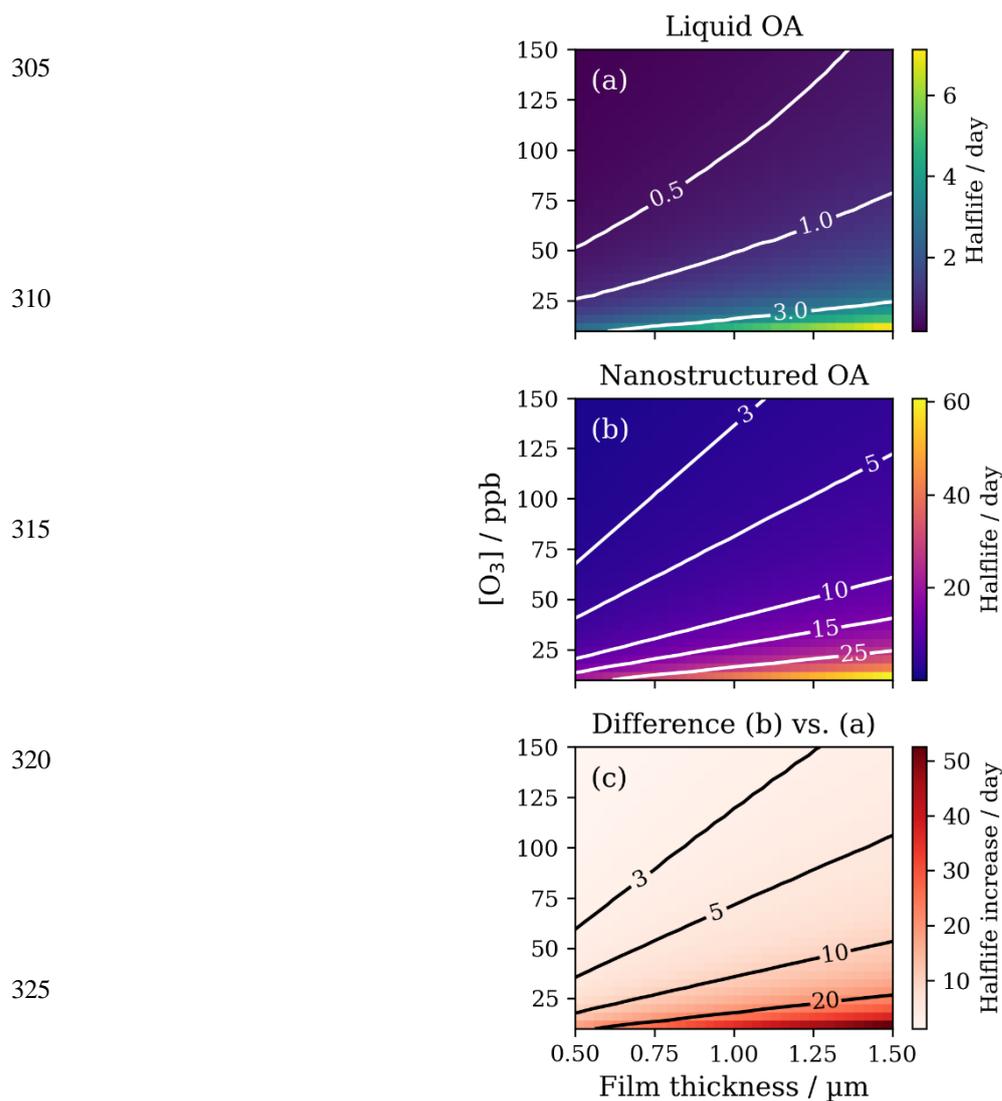

Figure 6. Plots of film half-life as a function of ozone concentration ( $[\text{O}_3]$ ) and film thickness. (a) model runs using parameters for liquid oleic acid ( $D_{Y,\text{liq}} = 1.53 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ,  $D_{X,\text{liq}} = 1.00 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ ); (b) model runs using the optimised parameters for lamellar phase (nanostructured) oleic acid ( $D_{Y,\text{lam}} = 2.81 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ ,  $D_{X,\text{lam}} = 3.35 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ ); (c) resulting increase in half-life due to nanostructure formation. Contours on each plot represent lines of constant half-life.

There is a known discrepancy between laboratory-determined and field-based lifetimes of fatty acids, such as oleic acid (Robinson et al., 2006; Rudich et al., 2007). In order to demonstrate the potential impact self-organisation has on the atmospheric lifetime of such organic coatings, our model was run with a film thickness range of 0.50 – 1.50  $\mu\text{m}$  and an ozone concentration range of 10 – 150 ppb, covering pristine ( $\sim 10$  ppb), typical (20 – 40 ppb) and polluted ( $> 40$  ppb) ozone concentrations in the urban and indoor environment (Fig. 6) (Weschler, 2000).

340 Taking a 1  $\mu\text{m}$  film as an example, where the model agrees the best with the experiment (Fig. 1(c)), the half-life increases from  
~ 1 to 10 days when moving from the liquid to the nanostructured (lamellar) state at ~ 30 ppb ozone concentration (Fig. 6(c)).  
Such an increase in the atmospheric lifetime of the organic film has implications for the persistence of organic matter in such  
particles.

345 These predictions are most likely an upper half-life estimate, especially for the thicker films; the model over-predicts the  
experiment at 1.66  $\mu\text{m}$  (Fig. 1(d)). Phase changes can occur with changes in relative humidity (RH) (Pfrang et al., 2017;  
Seddon et al., 2016). This particular system is stable below 55 % RH, above which the anhydrous lamellar phase can break  
down into inverse micelles which are thought to be less viscous. Atmospheric humidity is variable. Therefore, any phase  
transition to a less-viscous phase could enhance ozone uptake and promote a faster reaction, decreasing the half-life. The effect  
of different molecular arrangements are very challenging to determine experimentally (compare Milsom et al., 2021b).

350 An increased organic film lifetime has also direct implications for the lifetime of other particle constituents. Organic particulate  
matter can contain a range of chemical species, many of which are harmful to human health (Chan and Yao, 2008). The long-  
range transport of carcinogenic PAHs has been linked with particle phase state and the formation of a semi-solid organic  
coating on PAH-containing particles, increasing the risk of ill-health (Mu et al., 2018; Shrivastava et al., 2017). Our model  
predictions show that the semi-solidification of this atmospheric aerosol proxy can increase the lifetime of the organic film  
substantially. Moreover, the formation of a surface layer of high-molecular-weight products (represented as the trimer in the  
model) forms an extra diffusional barrier to oxidants such as ozone.

355 This extension of atmospheric lifetime implies a slower rate of particle oxidation. The degree of oxygenation, measured by the  
O:C ratio, is linked to aerosol hygroscopicity (Wu et al., 2016). Therefore it is possible that the inhibition of particle oxidation  
by the formation of this semi-solid phase could have an impact on the cloud condensation nucleus (CCN) ability of the particle.  
The increased lifetime of oleic acid, and therefore the 9-carbon products included in this model, suggests that surface-active  
material can persist for longer times in the atmosphere in a semi-solid organic film. Two of the 9-carbon primary oleic acid  
ozonolysis products, azelaic acid and nonanoic acid, may also be surface active under certain conditions (King et al., 2009;  
Tuckermann, 2007, but also compare King et al., 2020). Such surface-active material has the potential to alter aerosol  
hygroscopicity by decreasing the surface tension of aqueous droplets, affecting the aerosol's ability to act as a CCN  
(Ovadnevaite et al., 2017). The link between clouds and aerosols is clear and any process affecting the ability of an aerosol to  
act as a CCN can have an impact on the climate (Boucher et al., 2013).

365 With cooking aerosols accounting for up to 10 % of reported  $\text{PM}_{2.5}$  emissions in the UK (Ots et al., 2016) and fatty acids being  
major contributors to cooking emissions also in other regions such as China (Wang et al., 2020a), it follows that these effects  
would most likely be observed in the urban environment.

#### 4 Conclusion

The effect of the aerosol phase state continues to be a key topic for the atmospheric aerosol community. In this study, a multi-  
370 layer kinetic model was fitted to experimental data collected during ozonolysis of oleic acid coatings in a self-organised semi-  
solid state.

A key advantage of this particular co-ordinated model-experiment approach is that all fitted experimental data were from  
samples exposed to exactly the same conditions in the same sample environment. Therefore differences between model fits  
and experimental data are most likely originating from variations in film structure and morphology rather than experimental  
375 conditions, thus minimising uncertainties associated with other kinetic techniques.

The increase in atmospheric lifetime of this proxy from hours to days is consistent with field measurements of oleic acid  
demonstrating a much extended atmospheric lifetime in comparison to laboratory measurements.

We are now able to place nanostructure formation in an atmospherically meaningful and quantifiable context, thus establishing  
a clear pathway to determining the impact nanostructure formation could have on the atmospheric lifetime of organic aerosol  
380 emissions.

#### Acknowledgements

AM acknowledges funding by the NERC SCENARIO DTP (NE/L002566/1) and support from the NERC CENTA DTP. This  
work was carried out with the support of the Diamond Light Source (DLS), instrument I22 (proposal SM21663). The authors  
are grateful to the Central Laser Facility for access to key equipment for the Raman work carried out simultaneously with the  
385 DLS beamtime experiments. Nick Terrill (DLS), Andy Smith (DLS) and Tim Snow (DLS) are acknowledged for their support  
during the beamtime. The computations described in this paper were performed using the University of Birmingham's  
BlueBEAR HPC service, which provides a High Performance Computing service to the University's research community.

#### Author contributions

AM wrote the initial draft of the manuscript, wrote the model in Python and carried out the analysis and interpretation. CP  
390 contributed to the interpretation of the results and contributed to the manuscript. AMS contributed to the manuscript and  
discussion. ADW set up and supported the Raman microscopy experiment on I22 at DLS. All authors were involved in the  
Raman microscopy experiment.
