21 **Abstract:**

22 Co-occurrences of high concentrations of PM<sub>2.5</sub> and ozone (O<sub>3</sub>) have been  
23 frequently observed in haze aggravating processes in the North China Plain (NCP) over  
24 the past few years, and higher O<sub>3</sub> concentrations during hazy days were supposed to be  
25 related to nitrous acid (HONO), but the key sources of HONO enhancing O<sub>3</sub> during  
26 haze aggravating processes remain unclear, and will be explored in this study by using  
27 the WRF-Chem model, which is improved to include ground-based (traffic, soil, and  
28 indoor emissions, and the NO<sub>2</sub> heterogeneous reaction on ground surface (Het<sub>ground</sub>))  
29 and aerosol-related (the NO<sub>2</sub> heterogeneous reaction on aerosol surfaces (Het<sub>aerosol</sub>) and  
30 nitrate photolysis (Phot<sub>nitrate</sub>)) potential HONO sources. The results indicate that  
31 ground-based HONO sources producing HONO enhancements showed a rapid

32 decrease with height, while the NO+OH reaction and aerosol-related HONO sources  
33 decreased slowly with height. Phot<sub>nitrate</sub> contributions to HONO concentrations  
34 enhanced with aggravated pollution levels, the enhanced HONO due to Phot<sub>nitrate</sub> in  
35 hazy days was about one order of magnitude larger than in clean days and Phot<sub>nitrate</sub>  
36 dominated HONO sources (~30–70% when the ratio of the photolysis frequency of  
37 nitrate (J<sub>nitrate</sub>) to gas nitric acid (J<sub>HNO<sub>3</sub></sub>) equals 30) at higher layers (>800 m). Compared  
38 with that in clean days, the Phot<sub>nitrate</sub> contribution to the enhanced daily maximum 8-h  
39 averaged O<sub>3</sub> was increased by over one magnitude during the haze aggravating process.  
40 Phot<sub>nitrate</sub> contributed only ~5% of the surface HONO in daytime with a J<sub>nitrate</sub>/J<sub>HNO<sub>3</sub></sub>  
41 ratio of 30 but contributed ~30–50% of the enhanced O<sub>3</sub> near the surface in NCP in  
42 hazy days. Surface O<sub>3</sub> was dominated by volatile organic compounds-sensitive  
43 chemistry, while O<sub>3</sub> at higher altitude (>800m) was dominated by NO<sub>x</sub>-sensitive  
44 chemistry. Phot<sub>nitrate</sub> had a limited impact on nitrate concentrations (<15%) even with a  
45 J<sub>nitrate</sub>/J<sub>HNO<sub>3</sub></sub> ratio of 120. The above results suggest that more field studies of J<sub>nitrate</sub> in  
46 the atmosphere are still needed.

47

## 48 1. Introduction

49 Nitrous acid (HONO) is an important source of the hydroxyl radical (OH) through  
50 its photolysis (R1), and contributes ~20–80% of the primary OH production (Alicke et  
51 al., 2002; Hendrick et al., 2014; Kim et al., 2014).

53        Although it has passed forty years since the first detection of HONO in the  
54        atmosphere (Perner and Platt, 1979), the sources of HONO (especially daytime) and  
55        the dynamic parameters of HONO formation mechanisms are still not well understood  
56        (Ge et al., 2021), the current air quality models with the default gas-phase reaction (the  
57        reverse reaction of R1) always severely underestimate HONO observations, resulting  
58        in low atmospheric oxidation capacity and underestimation of secondary pollutants like  
59        ozone (O<sub>3</sub>) (Li et al., 2010, 2011; Sarwar et al., 2008; Zhang et al., 2016, 2019a).

60        HONO sources can be generally classified into three categories, i.e., direct  
61        emissions, homogeneous and heterogeneous reactions. Direct emissions are mainly  
62        from traffic (Kramer et al., 2020; Kurtenbach et al., 2001; Liao et al., 2021), soil  
63        (Kubota and Asami, 1985; Oswald et al., 2013; Wu et al., 2019; Xue et al., 2021),  
64        biomass burning (Cui et al., 2021; Rondon and Sanhueza, 1989; Theys et al., 2020) and  
65        indoor combustion processes (Klosterkother et al., 2021; Liu et al., 2019; Pitts et al.,  
66        1985). The reaction of nitric oxide (NO) with OH is usually thought as the dominant  
67        homogeneous reaction and is important during daytime but could be neglected at night  
68        due to low OH concentrations. The heterogeneous reactions mainly include nitrogen  
69        dioxide (NO<sub>2</sub>) hydrolysis and reduction reactions on various humid surfaces  
70        (Finlayson-Pitts et al., 2003; Ge et al., 2019; Gómez Alvarez et al., 2014; Ma et al.,  
71        2013; Marion et al., 2021; Sakamaki et al., 1983; Tang et al., 2017; Yang et al., 2021b)  
72        and nitrate photolysis (Romer et al., 2018; Zhou et al., 2003), and are usually thought  
73        as the main contributor to HONO concentrations in the atmosphere.

74        Among those potential HONO sources, the photolysis of nitrate to produce HONO

75 in the atmosphere has received extensive attention over the past several years, and the  
76 nitrate photolysis frequency ( $J_{\text{nitrate}}$ ) is still argued. In the laboratory studies, some  
77 researchers (Bao et al., 2018; Ye et al., 2016, 2017) showed that nitrate photolysis was  
78 an important HONO source, the measured  $J_{\text{nitrate}}$  was 1–3 orders larger than the gaseous  
79 nitric acid ( $\text{HNO}_3$ ) photolysis frequency ( $J_{\text{HNO}_3}$ ) and could reach up to  $10^{-4} \text{ s}^{-1}$ , and a  
80 number of substances including humic acid (Yang et al., 2018), sulfate (Bao et al., 2020)  
81 and  $\text{TiO}_2$  (Xu et al., 2021) might enhance the reaction significantly; while Shi et al.  
82 (2021) found that the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio was  $<10$  when using suspended submicron  
83 particulate sodium and ammonium nitrate rather than  $\text{PM}_{2.5}$  samples. In the field studies  
84 combining with model simulations, Kasibhatla et al. (2018) compared  $\text{NO}_x$   
85 observations in Cape Verde Atmospheric Observatory with GEOS-Chem (Goddard  
86 Earth Observing System-Chemistry) model simulations and reported a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio  
87 of 25–50, Romer et al. (2018) reported a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of  $<30$  based on observations  
88 of  $\text{NO}_x$  ( $= \text{NO} + \text{NO}_2$ ) and  $\text{HNO}_3$  over the Yellow Sea and a box model simulation.  
89 Adopting a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of  $\sim 120$  could greatly improve daytime surface HONO  
90 simulations (contributed  $\sim 30\text{--}40\%$  of noontime HONO) by using the Community  
91 Multiscale Air Quality model (CMAQ) in the Pearl River Delta (Fu et al., 2019) or a  
92 box model in the Yangtze River Delta (Shi et al., 2020), while a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 30  
93 produced negligible HONO in clean periods ( $\sim 2\%$ ) and slightly higher HONO in heavy  
94 haze periods ( $\sim 8\%$ ) in the North China Plain (NCP) by using a box model (Xue et al.,  
95 2020) and  $\sim 1\%$  by using CMAQ model in urban Beijing (Zhang et al., 2021). Recently,  
96 Zheng et al. (2020) evaluated the effect of three  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios (1, 10 and 100) on

97 heterogeneous sulfate formation by using CMAQ and large uncertainties of simulated  
98 sulfate concentrations were reported, so more efforts are needed to better understand  
99 the impact of nitrate photolysis on HONO concentrations, atmospheric oxidation  
100 capacity and other secondary pollutant concentrations.

101 A number of potential HONO sources (e.g., direct emissions, NO<sub>2</sub> heterogeneous  
102 reactions and nitrate photolysis) have been coupled into several air quality models (An  
103 et al., 2013; Fu et al., 2019; Guo et al., 2020; Li et al., 2010, 2011; Sarwar et al., 2008;  
104 Tang et al., 2015; Xu et al., 2006; Zhang et al., 2019a, 2019b, 2020a, 2021, 2022) to  
105 improve HONO simulations. The improved HONO sources can produce more OH,  
106 which is favorable for the formation of O<sub>3</sub> (Fu et al., 2019; Guo et al., 2020; Li et al.,  
107 2010; Xing et al., 2019; Zhang et al., 2016, 2019a, 2022). O<sub>3</sub> can directly damage plants  
108 and threaten human health (Avnery et al., 2011a, b; Feng et al., 2015, 2019; Mills et al.,  
109 2007, 2018; Richards et al., 1958; Selin et al., 2009; Wilkinson et al., 2012), an  
110 increasing trend of O<sub>3</sub> concentrations in China has been widely reported in recent years  
111 (Chen et al., 2020a; Li et al., 2020; Lu et al., 2020; Ma et al., 2016; Maji and Namdeo,  
112 2021), made O<sub>3</sub> pollution be a severe concern. A co-occurrence of high PM<sub>2.5</sub> and O<sub>3</sub>  
113 concentrations has been frequently found in China over the past few years and  
114 researchers speculated the significant role of HONO in producing O<sub>3</sub> enhancements  
115 (Feng et al., 2021; Fu et al., 2019; Tie et al., 2019; Yang et al., 2021a), but the HONO  
116 difference in O<sub>3</sub> formation during clean and hazy days is still unclear, and the relative  
117 contribution of each potential HONO source to O<sub>3</sub> enhancements during haze  
118 aggravating processes with a co-occurrence of high PM<sub>2.5</sub> and O<sub>3</sub> concentrations is still

119 unknown to the best of our knowledge.

120 In this study, time series of pollutants including HONO, O<sub>3</sub>, and nitrate were  
121 collected in NCP in Oct.11–31 of 2018, in which high concentrations of PM<sub>2.5</sub>  
122 accompanying by high O<sub>3</sub> concentrations were found at least twice in haze events, thus  
123 the specific role of each of potential HONO sources coupled into the Weather Research  
124 and Forecasting model with Chemistry (WRF-Chem) in O<sub>3</sub> formation will be explored  
125 during these haze events. The relative contribution of each potential HONO source to  
126 surface-averaged and vertical-averaged concentrations of HONO and O<sub>3</sub> will be  
127 quantified and the uncertainty in key potential HONO sources (e.g., J<sub>nitrate</sub>) will be  
128 discussed, in order to find the key HONO sources resulting in O<sub>3</sub> enhancements in NCP  
129 in different pollution levels (especially during haze aggravating processes).

## 130 **2. Data and methods**

### 131 **2.1 Observed data**

132 The field observation was carried out during October 11–31, 2018, and the  
133 observation site was located in the west campus of Beijing University of Chemical  
134 Technology (BUCT, 116°18'37" E, 39°56'56" N) in Beijing. BUCT is an urban site  
135 close to the third ring road of Beijing, with large human activities, including vehicle  
136 emissions. Instruments were set on the 5th floor of the main teaching building. HONO  
137 was measured with a home-made water-based long-path absorption photometer (Chen  
138 et al., 2020b). A set of on-line commercial analyzers (Thermo 48i, 42i, 49i, 43i) was  
139 used for measurements of CO, NO<sub>x</sub>, O<sub>3</sub>, and SO<sub>2</sub>. The chemical composition of PM<sub>2.5</sub>

140 was analyzed with a Time-of-Flight Aerosol Chemical Speciation Monitor (ToF-ACSM,  
141 Aerodyne). An online Single Photon Ionization Time-of-Flight Mass Spectrometer  
142 (SPI-ToF-MS, Hexin) was used for the detection of a large variety of volatile organic  
143 compounds (VOCs) (Gao et al., 2013). Surface observations of O<sub>3</sub>, NO<sub>2</sub>, PM<sub>2.5</sub> and  
144 PM<sub>10</sub> at 95 sites in NCP were obtained from <https://quotsoft.net/air/>, issued by the China  
145 Ministry of Ecology and Environment; surface meteorological observations at 284 sites  
146 in NCP were taken from the National Climatic Data Center, China Meteorological  
147 Administration (**Fig.1**).

148 The vertical HONO observations was not available during the Oct.11–31 of 2018  
149 at the BUCT site, we used the observed vertical HONO concentrations from Meng et  
150 al. (2020) at urban Beijing in December of 2016 to validate our simulation of vertical  
151 HONO concentrations, which were also used by Zhang et al. (2021) in their CMAQ  
152 model validation.

153

## 154 **2.2 Model description**

155 The improved WRF-Chem (version 3.7.1), which contained six potential HONO  
156 sources, i.e., traffic ( $E_{\text{traffic}}$ ), soil ( $E_{\text{soil}}$ ), and indoor ( $E_{\text{indoor}}$ ) emissions, nitrate photolysis  
157 in the atmosphere ( $\text{Phot}_{\text{nitrate}}$ ), and NO<sub>2</sub> heterogeneous reactions on aerosol ( $\text{Het}_{\text{aerosol}}$ )  
158 and ground ( $\text{Het}_{\text{ground}}$ ) surfaces (Zhang et al., 2019a), was used in this study.  $\text{Phot}_{\text{nitrate}}$   
159 was newly added in WRF-Chem (R2) following the work of Fu et al. (2019), Ye et al.  
160 (2017), and Zhou et al. (2003):

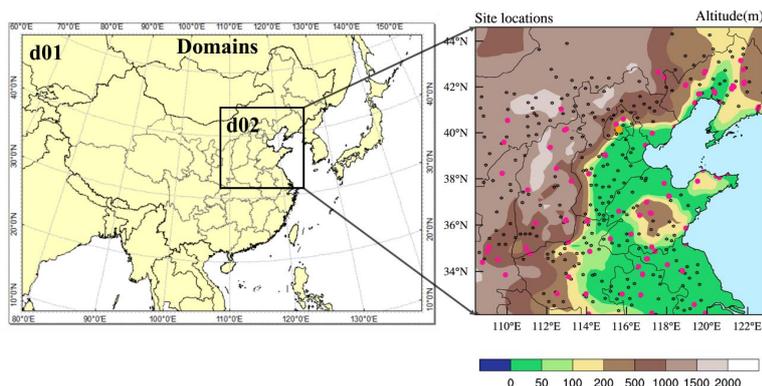

162 The uptake coefficient ( $\gamma$ ) of  $\text{NO}_2$  on aerosol surfaces, and the yield ( $f$ ) of HONO from  
163  $\text{NO}_2$  reaching the ground surface were improved from previous studies (Li et al., 2010;  
164 Liu et al., 2014; Zhang et al., 2019a) and calculated by:

$$165 \quad \gamma = 5 \times 10^{-6} \times \left(1 + \frac{SR}{\alpha}\right) \quad (\text{R3})$$

$$166 \quad f = 0.08 \times \left(1 + \frac{SR}{\alpha}\right) \quad (\text{R4})$$

167 where SR denotes solar radiation ( $\text{W m}^{-2}$ ),  $\alpha$  is an adjusted parameter and set as 100,  
168 thus  $\gamma$  and  $f$  became continuous functions during the whole day ( $\gamma$  and  $f$  enhanced by  
169 one order of magnitude and reached  $5 \times 10^{-5}$  and 0.8 when SR reached  $900 \text{ W m}^{-2}$  at  
170 noontime, respectively).

171 The physical and chemical schemes used in this study are given in **Table 1**. Two  
172 domains were adopted, domain one contains  $82 \times 64$  grid cells with a horizontal  
173 resolution of 81 km, domain two contains  $51 \times 51$  grid cells with a horizontal resolution  
174 of 27 km (**Fig.1**), both with 17 vertical layers encompassing from the surface to 100  
175 hPa. The observational sites are shown in the right panel of **Fig.1**, including one HONO  
176 observation site (the orange dot in urban Beijing), 95 observation sites of  $\text{PM}_{2.5}$ ,  $\text{NO}_2$   
177 and  $\text{O}_3$  (pink dots) and 284 meteorological monitoring sites (black dots).

178

179 **Figure 1** Domains of WRF-Chem used in this study (left panel), and the locations of one HONO  
180 observation site (the orange dot in urban Beijing), 95 environmental monitoring (PM<sub>2.5</sub>, NO<sub>2</sub> and  
181 O<sub>3</sub>) sites (deep pink dots), and 284 meteorological observation sites (black dots) in domain 2 (right  
182 panel).

183

184 The anthropogenic emissions in East Asia in 2010 were taken from the MIX emission  
185 inventory (Li et al., 2017) (<http://www.meicmodel.org/>), including both gaseous and  
186 aerosol species, i.e., SO<sub>2</sub>, NO<sub>x</sub>, CO, VOCs, NH<sub>3</sub>, PM<sub>10</sub>, PM<sub>2.5</sub>, BC, OC and CO<sub>2</sub>, and  
187 were provided monthly by five sectors (power, industry, residential, transportation, and  
188 agriculture) at a resolution of 0.25° × 0.25°. VOC emissions were speciated into model-  
189 ready inputs according to the MOZART chemical mechanism to build the WRF-Chem  
190 emission files. The anthropogenic emissions in China were replaced by employing the  
191 MEIC 2016 (the Multi-resolution Emission Inventory for China) developed by  
192 Tsinghua University. The NH<sub>3</sub> emissions in China were from Dong et al. (2010),  
193 biomass burning emissions were from Huang et al. (2012) and biogenic emissions were  
194 calculated using the Model of Emissions of Gases and Aerosols from Nature (MEGAN)  
195 (Guenther et al., 2012). Due to the sharp reduction of anthropogenic emissions in recent  
196 years, the default emission inventory was systematically overestimated in autumn of  
197 2018, especially for SO<sub>2</sub> and PM<sub>2.5</sub> concentrations. Based on the comparison of  
198 simulations and observations (the urban Beijing site plus other 95 pollutant monitoring  
199 sites in NCP), we cut off 80% of SO<sub>2</sub> emissions, 50% of NH<sub>3</sub> emissions, 30% of toluene  
200 emissions, and 50% of PM<sub>2.5</sub> and PM<sub>10</sub> emissions. The cut-off emissions are largely

201 close to the emission reductions in east China during 2013 to 2017 (Zhang and Geng,  
202 2019). The revised emissions significantly improved regional PM<sub>2.5</sub> simulations in NCP  
203 **(Fig.S1)**, and the simulations of gases and PM<sub>2.5</sub> in urban Beijing **(Fig.S2)**.

204 The National Centers for Environmental Prediction (NCEP) 1° × 1° final reanalysis  
205 data (FNL) (<https://rda.ucar.edu/datasets/ds083.2/>) were used in this study to obtain the  
206 meteorological initial and boundary conditions every 6 h. The global simulations of  
207 MOZART-4 (<https://www.acom.ucar.edu/wrf-chem/mozart.shtml>) were used as the  
208 chemical initial and boundary conditions (every 6 h).

209

210 **Table 1** Physical and chemical options in WRF-Chem used in this study

Options	WRF-Chem
Advection scheme	Runge-Kutta 3rd order
Boundary layer scheme	YSU
Cloud microphysics	Lin et al. (1983)
Cumulus parameterization	New Grell scheme
Land-surface model	Noah
Long-wave radiation	RRTM
Short-wave radiation	Goddard
Surface layer	Revised MM5 Monin-Obukhov scheme
Aerosol option	MOSAIC
Chemistry option	Updated MOZART mechanism
Photolysis scheme	F-TUV

211

212 Totally 23 simulation scenarios were performed in this study (**Table 2**), in which  
213 the base case only considered the default homogeneous reaction (OH + NO → HONO),  
214 case 6S contained six potential HONO sources while case A, B, C, D, E and F contained  
215 each of the six potential HONO sources, respectively. Other 15 cases (A\_double,  
216 A\_half, ..., Nit\_120, D\_NO<sub>2</sub> and D\_HONO) were used to evaluate the uncertainties of  
217 the six potential HONO sources (**Table 2**). All of the cases were simulated with a spin-

218 up of 7 days.  $J_{\text{nitrate}}$  and  $J_{\text{HNO}_3}$  denote the photolysis frequency of nitrate and gas nitric  
 219 acid in the atmosphere, respectively; the enhancement factor for  $F_{\text{double}}$  was 1.25  
 220 rather than 2.0 to avoid the production rate of HONO from  $\text{NO}_2$  reaching the surface  
 221 exceeding 100%, while  $0.33\text{NO}_2$  in  $D_{\text{NO}_2}$  or  $0.67\text{HONO}$  in  $D_{\text{HONO}}$  referred to the  
 222 assumed products of the nitrate photolysis in R2.

223

224 **Table 2.** Simulation scenarios designed in this study.

Case	HONO sources
Base	Default ( $\text{OH} + \text{NO} \rightarrow \text{HONO}$ )
6S	Default + $E_{\text{traffic}}$ + $E_{\text{soil}}$ + $E_{\text{indoor}}$ + $\text{Phot}_{\text{nitrate}}$ ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ ) + $\text{Het}_{\text{aerosol}}$ + $\text{Het}_{\text{ground}}$
A	Default + $E_{\text{traffic}}$
B	Default + $E_{\text{soil}}$
C	Default + $E_{\text{indoor}}$
D	Default + $\text{Phot}_{\text{nitrate}}$ ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ )
E	Default + $\text{Het}_{\text{aerosol}}$
F	Default + $\text{Het}_{\text{ground}}$
-----	
A_double	Default + $2 \times E_{\text{traffic}}$
A_half	Default + $0.5 \times E_{\text{traffic}}$
B_double	Default + $2 \times E_{\text{soil}}$
B_half	Default + $0.5 \times E_{\text{soil}}$
C_double	Default + $2 \times E_{\text{indoor}}$
C_half	Default + $0.5 \times E_{\text{indoor}}$
E_double	Default + $\text{Het}_{\text{aerosol}}$ ( $2 \times \gamma$ )
E_half	Default + $\text{Het}_{\text{aerosol}}$ ( $0.5 \times \gamma$ )
F_double	Default + $\text{Het}_{\text{ground}}$ ( $1.25 \times f$ )
F_half	Default + $\text{Het}_{\text{ground}}$ ( $0.5 \times f$ )
Nit_1	Default + $\text{Phot}_{\text{nitrate}}$ ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 1$ )
Nit_7	Default + $\text{Phot}_{\text{nitrate}}$ ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 7$ )
Nit_120	Default + $\text{Phot}_{\text{nitrate}}$ ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 120$ )
D_NO <sub>2</sub>	Only $0.33\text{NO}_2$ produced in $\text{Phot}_{\text{nitrate}}$ for case D
D_HONO	Only $0.67\text{HONO}$ produced in $\text{Phot}_{\text{nitrate}}$ for case D

225 **3.Results**

226 **3.1 Comparison of simulations and observations**

227 **3.1.1 Meteorological factors**

228 The statistical metrics of simulated meteorological parameters at 284 sites in NCP

229 including air temperature (T), relative humidity (RH) and wind speed (WS) were  
230 comparable with the previous modelling results of other researchers (**Table 3**), the  
231 simulated wind direction (WD) bias within  $45^\circ$  accounted for  $\sim 56\%$ , and the bias within  
232  $90^\circ$  accounted for  $\sim 80\%$ , suggesting that the simulated WD captured the main observed  
233 WD.

234

235 **Table 3.** Performance metrics (index of agreement (IOA), RMSE (root-mean-square error) and  
236 MB (mean bias)) of WRF-Chem simulated air temperature, relative humidity, wind speed and  
237 direction at 284 meteorological sites in the North China Plain during Oct. 11–31 of 2018. The  
238 definition of the metrics used in this study is given in **Text S1**.

	IOA	RMSE	MB	Reference
<b>T (°C)</b>	<b>0.97</b>	<b>1.4</b>	<b>-1.1</b>	<b>This work</b>
	0.90	2.5	0.2	(Wang et al., 2014)

### 239 3.1.2 Pollutant concentrations at the BUCT site

240 Time series of the observational data at the BUCT site are shown in **Fig.2**, the gray  
241 shaded periods stand for three haze aggravating processes, while the cyan shaded period  
242 denotes typical clean days, respectively. The hourly largest observations of O<sub>3</sub> ( $\sim 50$ – $75$

243 ppb) and  $PM_{2.5}$  ( $\sim 100\text{--}200\ \mu\text{g}/\text{m}^3$ ) were both relatively higher in hazy days than in clean  
244 days, especially for the first two haze events (the  $O_3$  concentrations in the third haze  
245 event was relatively lower due to the higher  $NO_x$  concentrations in urban area).

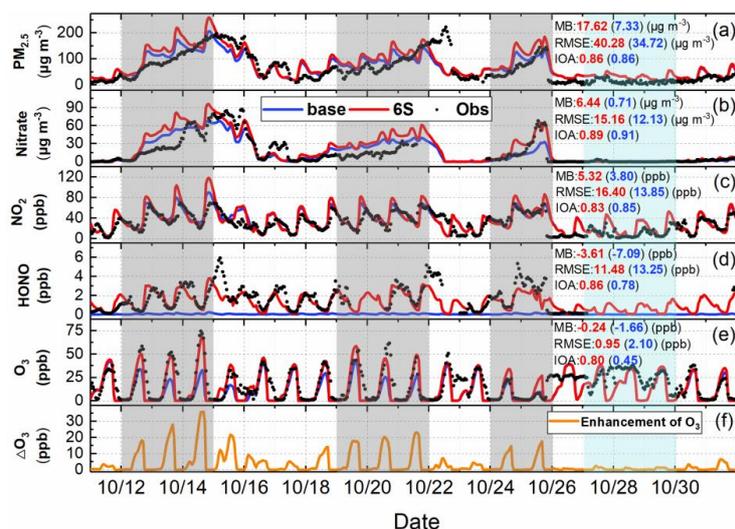

246 The observed  $PM_{2.5}$  and nitrate trends at the BUCT site were well simulated  
247 (**Fig.2a&b**), and  $NO_2$  simulations generally agreed with the observations (**Fig.2c**).  
248 Hourly and diurnal HONO simulations at the BUCT site (**Fig.2d&3a**) were  
249 significantly improved in the 6S case (mean is 1.47 ppb) compared with the base case  
250 (mean is 0.05 ppb). The normalized mean bias (NMB) was remarkably reduced to -  
251 14.22% (6S) from -97.11% (Base), and the index of agreement (IOA) was improved  
252 significantly to 0.86 (6S) from 0.78 (Base) (**Fig.2d**).

253 As for  $O_3$ , noticeable improvements could be found at the BUCT site after  
254 considering the six potential HONO sources, especially in hazy days (**Fig.2e&f**). The  
255 mean bias (MB) was improved to -3.61 ppb (6S) from -7.09 ppb (Base), and the IOA  
256 was improved to 0.80 (6S) from 0.45 (Base) (**Fig.2e**). Specially, the 6S case  
257 significantly enhanced daytime hourly  $O_3$  by 15–35 ppb compared with the base case  
258 and the simulated  $O_3$  was very close to the observations in hazy days (**Fig.2e**). Larger  
259 daytime  $O_3$  enhancements were accompanied with higher  $PM_{2.5}$  concentrations during  
260 haze aggravating processes, while in clean days the daytime enhanced  $O_3$  due to the  
261 potential HONO sources was mostly  $< 5$  ppb (**Fig.2e&f**). The diurnal  $O_3$  pattern during  
262 the first two haze aggravating processes is presented in **Fig.3b**, significant  
263 improvements in daily maximum 8-h (10:00–17:59) averaged (DMA8)  $O_3$  (18.8 ppb)  
264 occurred at the BUCT site after considering the six potential HONO sources, and the

265 NMB of DMA8 O<sub>3</sub> was remarkably improved to -2.38% (6S) from -47.14% (Base).

266

267

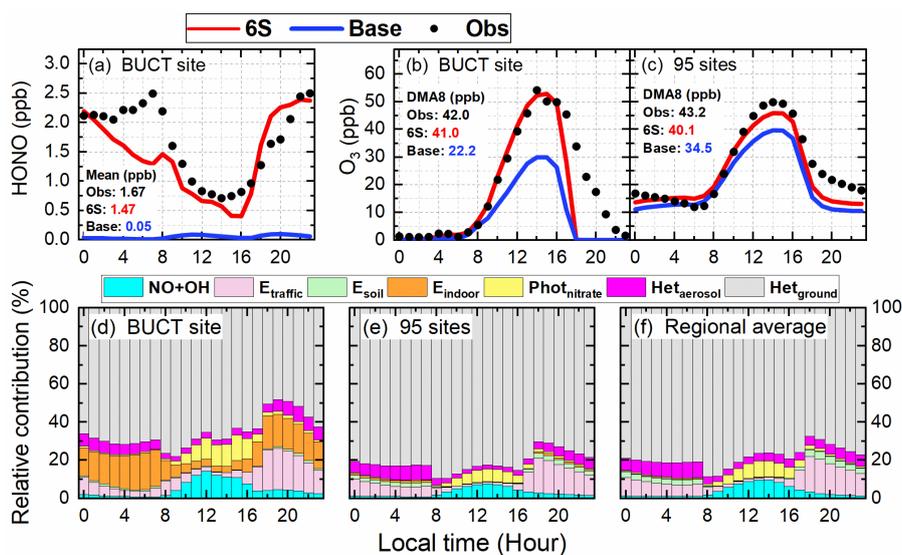

268 **Figure 2** Comparison of simulated (Base and 6S cases) and observed hourly concentrations of PM<sub>2.5</sub>,

269 nitrate, NO<sub>2</sub>, HONO and O<sub>3</sub> (a–e), and the hourly enhanced concentrations of O<sub>3</sub> (ΔO<sub>3</sub>) (f) caused

270 by the six potential HONO sources (6S minus Base) at the BUCT site during Oct.11–31 of 2018.

271

272

273

274 **Figure 3** Comparison of diurnal mean simulations (Base and 6S cases) and observations of HONO  
275 during the study period (a) and O<sub>3</sub> during the first two haze events at the BUCT site (b), and O<sub>3</sub>  
276 averages at the 95 NCP monitoring sites during the study period (c); and the relative contributions  
277 of each of the six potential HONO sources and the reaction of OH with NO to surface HONO  
278 concentrations for the 6S case at the BUCT site (d), at the 95 monitoring sites (e) and in the whole  
279 NCP region (f). The calculated 24-h mean HONO concentrations and DMA8 O<sub>3</sub> concentrations  
280 were given in panels (a) – (c).

281

282 The relative contribution of each HONO source near the surface at the BUCT site  
283 for the 6S case is shown in **Fig.3d**. Briefly, Het<sub>ground</sub> was the largest source during  
284 daytime and nighttime (~50–70%), consistent with the results of Zhang et al. (2021).  
285 Phot<sub>nitrate</sub> ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ ) and the NO+OH reaction contributed similarly ~1–12%  
286 during daytime. E<sub>traffic</sub> was important during nighttime (~10–20%) but small during  
287 daytime (<5%). The contribution of Het<sub>aerosol</sub> to HONO concentrations was minor (~2–

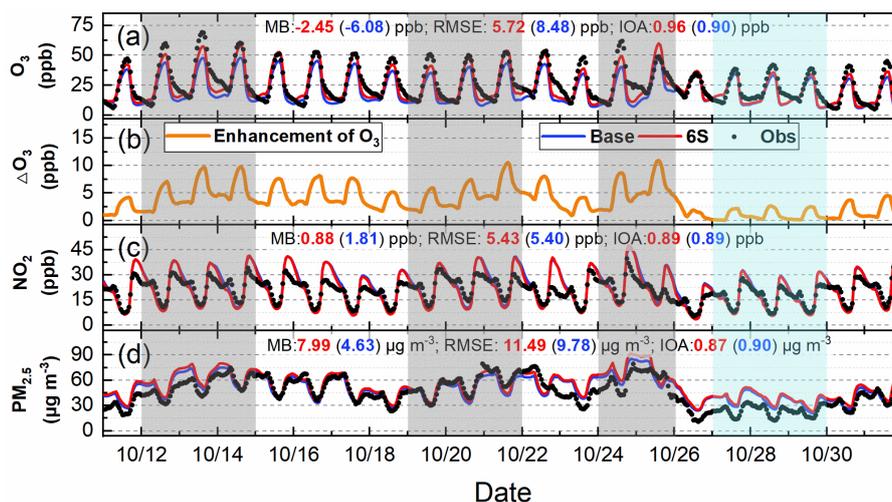

288 3%) in daytime and ~6–10% in nighttime.  $E_{\text{soil}}$  could be neglected while the  
289 contribution of  $E_{\text{indoor}}$  was close to that of  $E_{\text{traffic}}$  in urban Beijing. The relative  
290 contribution of the potential HONO sources in this study was comparable with the result  
291 of Fu et al. (2019) by using CMAQ, except for the contribution of  $\text{Phot}_{\text{nitrate}}$  due to the  
292 different  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios (30 in our study and ~120 in Fu et al. (2019)).

293

### 294 **3.1.3 Pollutant concentrations in NCP**

295 The 95-site-averaged hourly simulations and observations of  $\text{O}_3$ ,  $\text{NO}_2$  and  $\text{PM}_{2.5}$   
296 during the study period are shown in **Fig.4**. The six potential HONO sources  
297 significantly improved hourly  $\text{O}_3$  simulations, remarkably enhanced the daily  
298 maximum  $\text{O}_3$  by ~5–10 ppb during Oct. 11–25, and by ~2–4 ppb during Oct. 26–31  
299 (**Fig.4a&b**). The simulations of  $\text{NO}_2$  well agreed with the observations, and the mean  
300 concentrations were 22.55 (Base), 21.62 (6S) and 20.74 (Obs) ppb (**Fig.4c**). The  $\text{PM}_{2.5}$   
301 simulations generally followed the observed  $\text{PM}_{2.5}$  trend but were overestimated by ~8  
302  $\mu\text{g m}^{-3}$ , with averaged concentrations of 49.94 (Base), 53.30 (6S) and 45.31 (Obs)  $\mu\text{g}$   
303  $\text{m}^{-3}$  (**Fig.4d**), respectively.

304

305

306 **Figure 4** Comparison of 95-site-mean simulated (Base and 6S cases) and observed hourly O<sub>3</sub>(a), NO<sub>2</sub> (c)  
307 and PM<sub>2.5</sub> (d), and O<sub>3</sub> enhancements due to the six potential HONO sources (6S minus Base case) (b) in  
308 the North China Plain during Oct.11–31 of 2018.

309

310 The 95-site-averaged diurnal simulations and observations of O<sub>3</sub> are presented in  
311 **Fig.3c**, O<sub>3</sub> simulations showed a remarkable improvement when the six potential  
312 HONO sources were considered, the six potential HONO sources produced a mean  
313 enhancement of 5.7 ppb in DMA8 (10:00–17:59) O<sub>3</sub> and improved the NMB from -  
314 20.32% to -7.16% at the 95 sites in NCP. The 95-site-averaged diurnal simulations and  
315 observations of NO<sub>2</sub> and PM<sub>2.5</sub> during the study period are demonstrated in **Fig. S3**.  
316 NO<sub>2</sub> simulations generally followed the observed trend but were underestimated during  
317 04:00 to 16:00 and overestimated after 18:00 (**Fig.S3a**), PM<sub>2.5</sub> simulations agreed with  
318 the observed diurnal pattern but were overestimated for both cases during the whole  
319 day (**Fig.S3b**).

320 The relative contribution of each HONO source near the surface at the 95 NCP sites

321 for the 6S case is shown in **Fig.3e**.  $E_{\text{ground}}$  was the dominant source during daytime  
322 and nighttime (~70–80%).  $E_{\text{nitrate}}$  ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ ) and the NO+OH reaction nearly  
323 equaled and contributed ~2–8% during daytime (~5% on average).  $E_{\text{traffic}}$  was important  
324 during nighttime (~10–15%) but small during daytime (<3%). The contribution of  
325  $E_{\text{aerosol}}$  to HONO concentrations was <3% in daytime and <10% in nighttime.  $E_{\text{soil}}$   
326 contributed ~3% in nighttime but could be neglected in daytime. The contribution of  
327  $E_{\text{indoor}}$  was too small to be noticed at the 95 NCP sites, implying that this source was  
328 noticeable only in megacities. The relative contribution of each HONO source in the  
329 whole NCP region (all grid cells in domain two except for the seas) is presented in  
330 **Fig.3f**, the results were quite similar with those at the 95 sites (**Fig.3f**), thus the results  
331 of the 95 sites were representative for the whole NCP region. To further understand the  
332 role of potential HONO sources in haze aggravating processes in regional  $\text{O}_3$   
333 concentrations, the 95 site-averaged surface/vertical HONO concentrations and their  
334 impacts during a typical haze event (Oct. 19–21) and a clean period (Oct. 27–29) were  
335 analyzed and shown in the following sections.

336

### 337 **3.2 Spatial distribution of enhanced DMA8 $\text{O}_3$ by potential HONO sources**

#### 338 **3.2.1 General patterns of enhanced DMA8 $\text{O}_3$**

339 **Fig.S4** shows surface-averaged and zonally-averaged DMA8  $\text{O}_3$  enhancements due  
340 to the six potential HONO sources in NCP during the study period (Oct. 11–31) and three  
341 haze events (Oct.12–14, Oct.18–21 and Oct.24–25). The overall surface DMA8  $\text{O}_3$

342 enhancement decreased gradually from south (6–10 ppb) to north (2–6 ppb) (**Fig.S4a**)  
343 and could reach 10–20 ppb under unfavorable meteorological conditions during haze  
344 events (**Fig.S4b–d**). For the first two haze events, the anti-cyclone in the Shandong  
345 peninsula carried pollutants being transported from the southeastern NCP to the western  
346 (108–112°E) and northern (39–41°N) NCP, and the six potential HONO sources led to  
347 a DMA8 O<sub>3</sub> enhancement of 10–20 ppb (**Fig.S4b**) and 10–15 ppb (**Fig.S4c**) in Beijing,  
348 respectively. For the third haze event, two air masses were converged to form a transport  
349 channel from south to north, the O<sub>3</sub> enhancement caused by the six potential HONO  
350 sources can reach 10–18 ppb in the southern NCP and decreased to 6–10 ppb in the  
351 northern NCP along the transport channel. Vertically, the DMA8 O<sub>3</sub> enhancements were  
352 2–8 ppb during the whole period (**Fig.S4e**) and increased to 6–12 ppb in these haze  
353 events (**Fig.S4f–h**). The enhanced O<sub>3</sub> near the surface (0–100 m) was slightly smaller  
354 than that at higher altitude (**Fig.S4f–h**), due mainly to the stronger titration of O<sub>3</sub> by  
355 NO near the surface. The above results demonstrated that the six potential HONO  
356 sources significantly enhanced surface and vertical O<sub>3</sub> concentrations in NCP,  
357 especially during haze events.

358

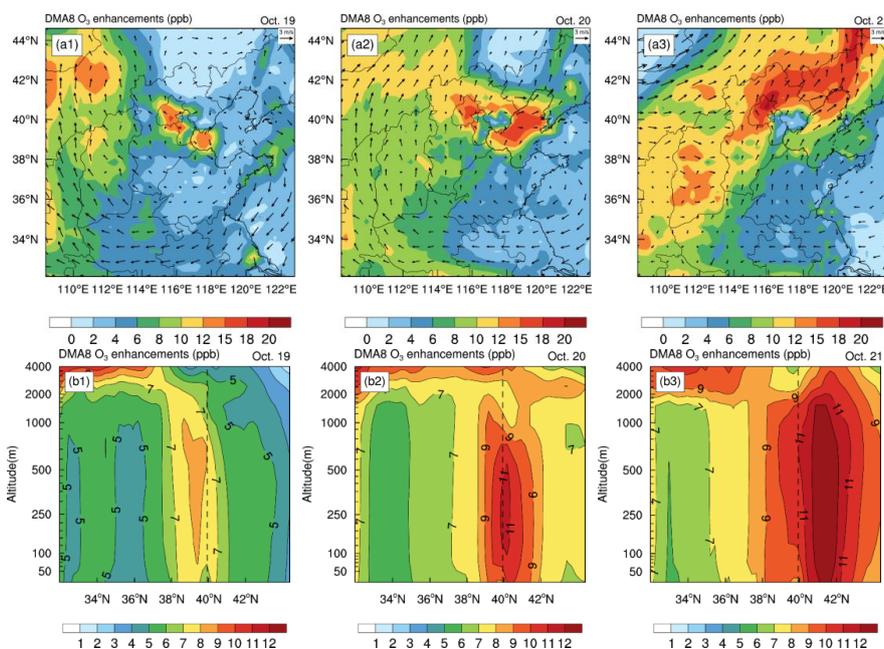

### 359 **3.2.2 During a typical haze aggravating process and a clean period**

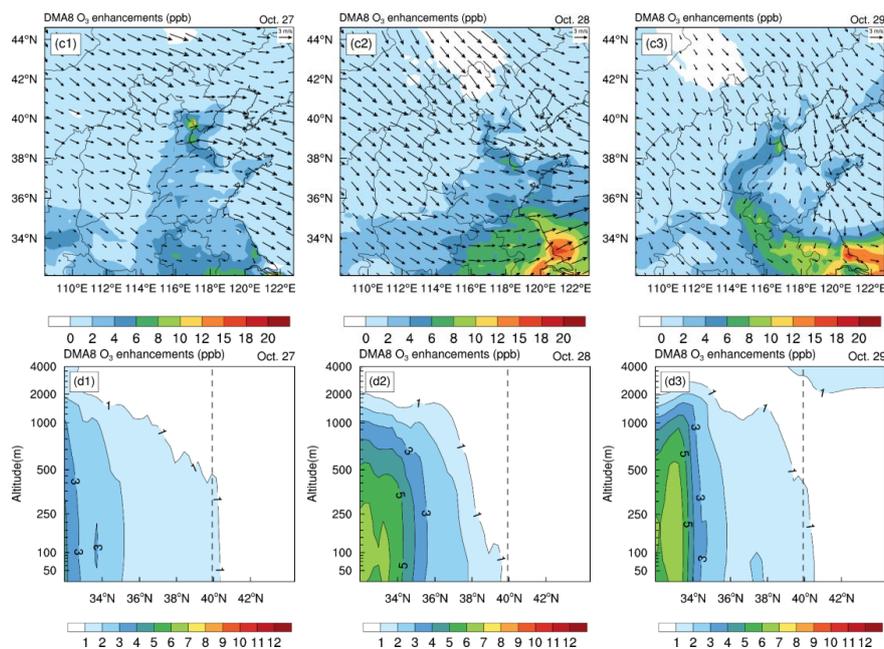

360 **Fig.5** demonstrates surface-averaged and zonally-averaged DMA8 O<sub>3</sub>  
361 enhancements due to the six potential HONO sources in NCP during a typical haze  
362 aggravating process (Oct.19–21, 2018) and a clean period (Oct.27–29, 2018). The

363 increasing trend of DMA8 O<sub>3</sub> enhancements can be clearly seen from Oct.19 to Oct.21  
364 near the surface and in the vertical direction. During the haze aggravating process, the  
365 surface DMA8 O<sub>3</sub> enhancements were ~2–10 ppb (Oct.19), ~6–12 ppb (Oct.20) and  
366 ~8–15 ppb (Oct.21), respectively, and the vertical DMA8 O<sub>3</sub> enhancements were ~4–7  
367 ppb (Oct.19), ~6–10 ppb (Oct.20), and ~8–15 ppb (Oct.21), respectively; while during  
368 clean days, the surface/vertical DMA8 O<sub>3</sub> enhancements were usually <4 ppb. The six  
369 potential HONO sources significantly enhanced surface and vertical O<sub>3</sub> concentrations  
370 in NCP during haze aggravating processes, the detailed role of potential HONO sources  
371 on vertical HONO concentrations and their impacts were given in the next section.

372

375

376

377 **Figure 5** Surface-averaged (a1–a3, c1–c3) and zonally-averaged (b1–b3, d1–d3) DMA8 O<sub>3</sub>

378 enhancements due to the six potential HONO sources in the North China Plain during a typical haze

379 aggravating process (Oct.19–21, 2018) and a clean period (Oct.27–29, 2018). The dashed line

380 denotes the latitude of the BUCT site.

381

### 382 3.3 Vertical variations of potential HONO sources and their impacts

#### 383 3.3.1 Potential HONO sources and their impacts on HONO concentrations

384 A number of studies have conducted vertical HONO observations abroad

385 (Kleffmann et al., 2003; Ryan et al., 2018; Sorgel et al., 2011; VandenBoer et al., 2013;

386 Villena et al., 2011; Wang et al., 2020; Wong et al., 2011, 2012; Zhang et al., 2009) and

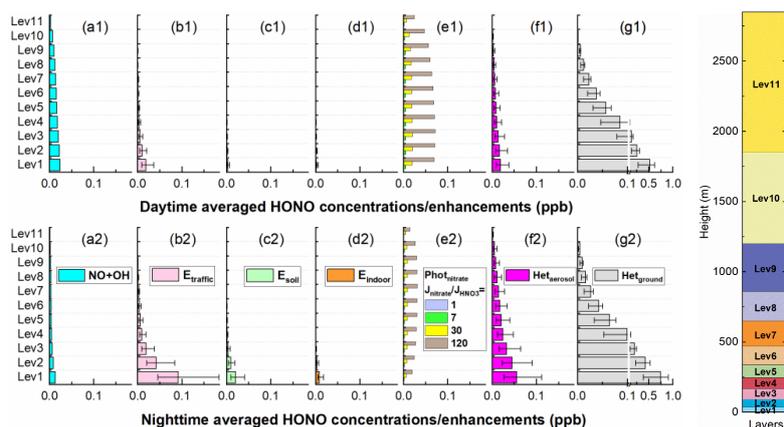

387 in China (Meng et al., 2020; Wang et al., 2019; Xing et al., 2021; Zhu et al., 2011), a

388 decreasing trend of HONO with height was mostly observed among these studies, and  
389 our simulations also reproduced this vertical variation and were comparable with  
390 another model simulation by Zhang et al. (2021) whom using the CMAQ model  
391 (**Fig.S5**). For a deep understanding of the role of each considered HONO source in  
392 HONO concentrations at different heights, we assessed the contributions of each  
393 potential HONO source to HONO concentrations at different heights (**Fig.6**) during  
394 Oct.11–31 of 2018.

395 Generally, the impacts of ground-based potential HONO sources ( $E_{\text{traffic}}$ ,  $E_{\text{soil}}$ ,  
396  $E_{\text{indoor}}$  and  $H_{\text{etground}}$ ) on HONO concentrations decreased rapidly with height, while the  
397 NO+OH reaction and aerosol related HONO sources ( $Phot_{\text{nitrate}}$  and  $H_{\text{et_aerosol}}$ ) decreased  
398 slowly with height (**Fig.6**). During daytime the NO+OH reaction,  $Phot_{\text{nitrate}}$  and  $H_{\text{etground}}$   
399 were the three main HONO sources, while during nighttime  $E_{\text{traffic}}$ ,  $H_{\text{et_aerosol}}$  and  
400  $H_{\text{etground}}$  were the three main contributors to HONO concentrations (**Fig.6**). The HONO  
401 concentrations via the NO+OH reaction and  $Phot_{\text{nitrate}}$  were higher during daytime. The  
402 impact of  $E_{\text{soil}}$  in the NCP was small, however, Xue et al. (2021) found strong HONO  
403 emissions in NCP agricultural fields after fertilization, suggesting that this source may  
404 have a remarkable enhancement on regional HONO and secondary pollutants in crop  
405 growing seasons.

406

407

408 **Figure 6** The 95-site-averaged daytime/nighttime HONO concentrations/enhancements at different  
409 heights when the NO+OH reaction (a1&a2) and each of the six potential HONO sources (b1–  
410 g1&b2–g2) were considered during Oct.11–31 of 2018, the error bar denotes the uncertainties of  
411 each potential HONO source in HONO concentrations (**Table 2**). The right panel denotes the  
412 approximate height of each vertical layer above the ground.

413

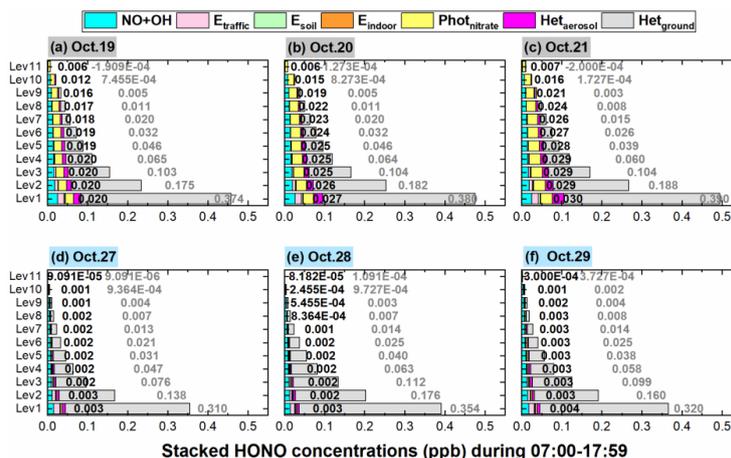

414 The comparison of HONO concentrations/enhancements during a haze aggravating  
415 process and a clean period is shown in **Fig.7&8**. Generally, daytime HONO  
416 concentrations increased in haze aggravating processes and were higher than those in  
417 clean days. Het<sub>ground</sub> was the dominant source of the surface HONO in both hazy and  
418 clean days and contributed 80–90% of daytime averaged HONO concentrations (**Fig.8**),  
419 however, its relative contribution decreased with height, especially in haze aggravating  
420 processes (**Fig.8**). Although the contribution of the NO+OH reaction to daytime HONO  
421 was small near the surface, its relative contribution to HONO increased with height,  
422 especially in clean days (**Fig.8**). As for Phot<sub>nitrate</sub>, a much larger enhancement could be  
423 found in hazy days compared with clean days. In clean days the daytime enhanced

424 HONO by  $\text{Phot}_{\text{nitrate}}$  was only 1–3 ppt in general and its contribution to daytime HONO  
425 was usually <10%, while in the haze aggravating process, the enhanced HONO  
426 concentration by  $\text{Phot}_{\text{nitrate}}$  was about one order of magnitude higher than that in clean  
427 days and  $\text{Phot}_{\text{nitrate}}$  became the dominant HONO source (~30–70%) at higher altitude,  
428 and both HONO concentrations and  $\text{Phot}_{\text{nitrate}}$  contributions increased with the air  
429 pollution aggravation (**Fig.7a–c**, **Fig.8a–c**). The contributions of direct emission  
430 sources were small and decreased when  $\text{PM}_{2.5}$  increased, compared with those  
431 heterogeneous reactions. Higher concentrations of  $\text{NO}_2$ , nitrate, and  $\text{PM}_{2.5}$  favored  
432 heterogeneous formation of HONO, while direct emission sources were relatively  
433 invariable under different pollution levels.

434 Based on our results, nitrate concentrations increased with the haze aggravating  
435 processes (**Fig.2b**), as a positive feedback effect, the elevated nitrate could in turn  
436 enhance HONO formation and further enhance the atmospheric oxidation capacity  
437 during daytime. Considering  $J_{\text{nitrate}}$  was still unclear, sensitivity tests were conducted  
438 and presented in the discussion section.

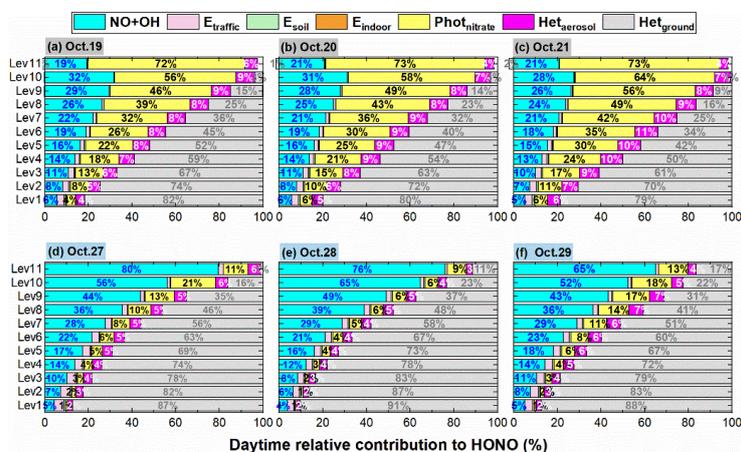

439

440

441 **Figure 7** The 95-NCP-site-averaged daytime HONO concentrations at different heights when the  
 442 NO+OH reaction and the six potential HONO sources were included during a typical haze  
 443 aggravating process of Oct.19–21 (a–c) and a clean period of Oct.27–29 (d–f) of 2018. The first  
 444 column numbers in black in each graph are for Phot<sub>nitrate</sub>, and the second column numbers in gray  
 445 are for Het<sub>ground</sub>.

446

447

448 **Figure 8** The 95-NCP-site-averaged relative contributions of the NO+OH reaction and each of the  
 449 six potential HONO sources to daytime HONO concentrations at different heights during a typical

450 haze aggravating process of Oct.19–21 (a–c) and a clean period of Oct.27–29 (d–f) of 2018. The  
451 first column numbers in blue in each graph are for the NO+OH reaction, the second column numbers  
452 in black are for  $\text{Phot}_{\text{nitrate}}$ , the third column numbers in white are for  $\text{Het}_{\text{aerosol}}$ , and the fourth column  
453 numbers in gray are for  $\text{Het}_{\text{ground}}$ .

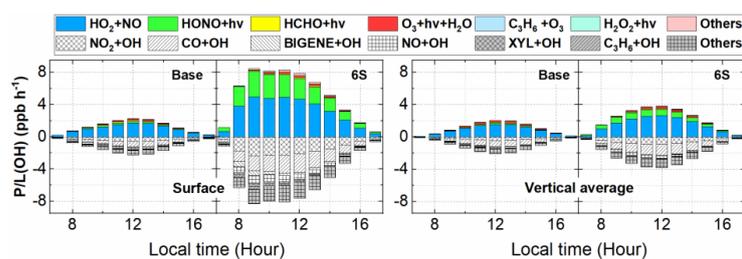

454

### 455 3.3.2 Enhanced OH and its production rate

456 **Fig.9** demonstrates daytime variations of OH production ( $P(\text{OH})$ ) and loss ( $L(\text{OH})$ )  
457 rates near the surface and in the vertical-averaged layer (from ground to the height of  
458 2.5km) at the 95 NCP sites for the Base and 6S cases during Oct.11–31, 2018. Near the  
459 surface, daytime  $P(\text{OH})$  and  $L(\text{OH})$  were significantly enhanced by ~320% for the 6S  
460 case (mean was  $5.27 \text{ ppb h}^{-1}$ ) compared with the base case (mean was  $1.26 \text{ ppb h}^{-1}$ ).  
461 After adding the six potential HONO sources in case 6S, the daytime  $P(\text{OH})$  via HONO  
462 and  $\text{O}_3$  photolysis was  $1.81 \text{ ppb h}^{-1}$  and  $0.10 \text{ ppb h}^{-1}$ , respectively, HONO photolysis  
463 was the main source of the primary formation of OH, while the secondary formed OH  
464 via  $\text{HO}_2+\text{NO}$  ( $3.14 \text{ ppb h}^{-1}$ ) was the dominant source of the total OH formation.  
465 Vertically, daytime  $P(\text{OH})$  or  $L(\text{OH})$  was enhanced by ~105% for the 6S case (mean  
466 was  $2.21 \text{ ppb h}^{-1}$ ) compared with the base case (mean was  $1.08 \text{ ppb h}^{-1}$ ), the daytime  
467  $P(\text{OH})$  via the photolysis of HONO and  $\text{O}_3$  and via the  $\text{HO}_2+\text{NO}$  reaction was  $0.48 \text{ ppb}$   
468  $\text{h}^{-1}$ ,  $0.12 \text{ ppb h}^{-1}$  and  $1.52 \text{ ppb h}^{-1}$ , respectively. In short, the six potential HONO sources  
469 accelerated OH production and loss rates remarkably near the surface and noticeably in  
470 the considered vertical layers.

471

472

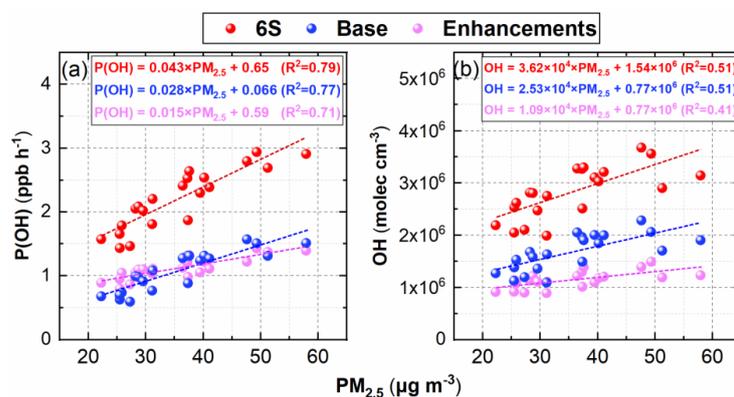

473 **Figure 9** Diurnal mean variations of OH production (P(OH)) and loss (L(OH)) rates including major  
474 production and loss reactions near the surface and in the vertically-averaged layer (from ground to  
475 the height of 2.5km) at the 95 NCP sites for the Base and 6S cases during Oct.11–31, 2018.

476

477 **Fig.10** shows the linear relationships between daytime-averaged P(OH) and PM<sub>2.5</sub>  
478 concentrations and between daytime-averaged OH and PM<sub>2.5</sub> concentrations from  
479 ground to the height of 2.5km at the 95 NCP sites during Oct. 11–31 of 2018. Both  
480 P(OH) for the two cases (Base and 6S) and the enhanced P(OH) due to the six potential  
481 HONO sources showed a strong positive correlation ( $R>0.8$ ) with PM<sub>2.5</sub> concentrations  
482 at the 95 NCP sites, and the enhanced P(OH) for the 6S case reached 0.043 ppb h<sup>-1</sup> per  
483 1 μg m<sup>-3</sup> of a PM<sub>2.5</sub> enhancement. Similarly, high positive correlation ( $R>0.6$ ) could be  
484 found between OH and PM<sub>2.5</sub> concentrations, the OH concentrations and enhancements  
485 due to the six potential HONO sources were both higher in hazy days than those in  
486 clean days, and the enhancement of OH reached  $3.62 \times 10^4$  molec cm<sup>-3</sup> per μg m<sup>-3</sup> of  
487 PM<sub>2.5</sub> for case 6S. These results were consistent with a recent field study reported by  
488 Slater et al. (2020), who found that the OH observed in haze events was elevated in  
489 central Beijing in November–December of 2016. Furthermore, two observations

490 confirmed the key role of HONO in producing primary OH despite the lower photolysis  
491 frequency in haze aggravating processes (Slater et al., 2020; Tan et al., 2018), consistent  
492 with our simulations (**Fig.S6** shows the relationship between surface PM<sub>2.5</sub> and  
493 photolysis frequencies of NO<sub>2</sub>, HONO and HNO<sub>3</sub> in this study).

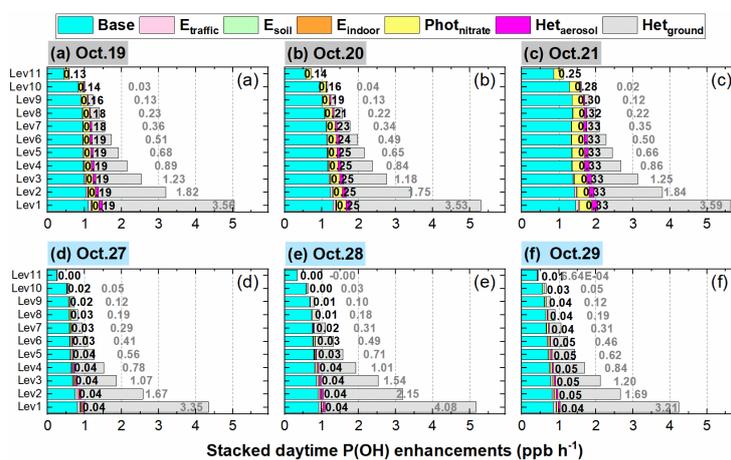

494  
495 **Figure 10** The linear relationships between daytime-averaged P(OH) and PM<sub>2.5</sub> concentrations (a)  
496 and between daytime-averaged OH and PM<sub>2.5</sub> concentrations (b) from ground to the height of 2.5km  
497 at the 95 NCP sites during Oct. 11–31 of 2018.

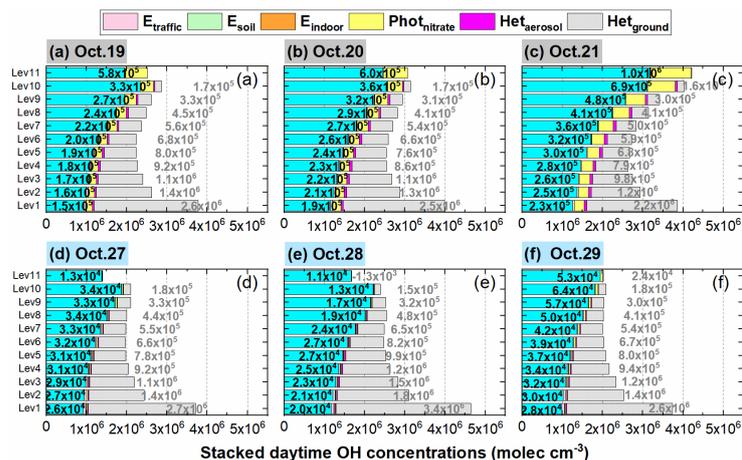

498  
499 **Fig.11&12** show the detailed comparisons of P(OH) and OH enhancements during  
500 a haze aggravating process and a clean period. It can be seen that both P(OH) and OH  
501 were enhanced in hazy days compared with clean days, and P(OH) and OH increased  
502 with the aggravated haze pollution. Among the six potential HONO sources, Het<sub>ground</sub>  
503 was the largest contributor to the enhanced P(OH) and OH near the surface, but its  
504 contribution was relatively stable under different pollution levels and was attenuated  
505 rapidly with height in both hazy and clean days; the contribution induced by Phot<sub>nitrate</sub>  
506 was remarkably increased in haze aggravating processes and was about one order of

507 magnitude higher than that in clean days; Het<sub>aerosol</sub> also increased with the pollution  
 508 levels but with relatively small values, while the impact of other three direct emission  
 509 sources of HONO was quite small.  
 510

511 Stacked daytime P(OH) enhancements (ppb h<sup>-1</sup>)  
 512 **Figure 11** The 95-NCP-site-averaged daytime P(OH) for the base case and the enhancements due  
 513 to the six potential HONO sources during a typical haze aggravating process of Oct.19–21 (a–c)  
 514 and a clean period of Oct.27–29 (d–f) of 2018. The first column number in black in each graph is  
 515 for Phot<sub>nitrate</sub>, and the second column number in gray is for Het<sub>ground</sub>.  
 516

517

518 **Figure 12** The 95-NCP-site-averaged daytime OH concentrations for the base case and the  
 519 enhancements due to the six potential HONO sources during a typical haze aggravating process of  
 520 Oct.19–21 (a–c) and a clean period of Oct.27–29 (d–f) of 2018. The first column number in black  
 521 in each graph is for  $\text{Phot}_{\text{nitrate}}$ , and the second column number in gray is for  $\text{Het}_{\text{ground}}$ .

522

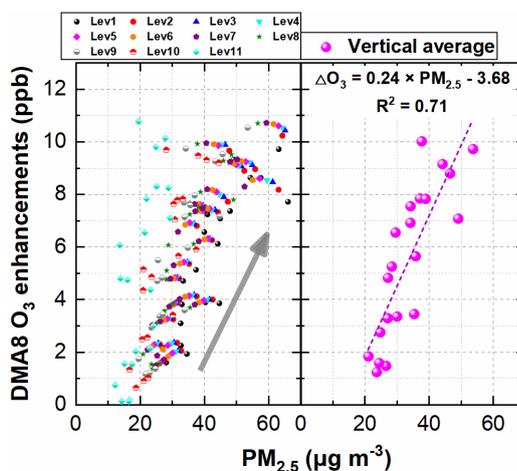

### 523 3.2.3 Enhanced DMA8 O<sub>3</sub>

524 **Fig.13** demonstrates the linear relationship between DMA8 O<sub>3</sub> enhancements and  
 525 daytime PM<sub>2.5</sub> concentrations in each vertical layer (a) and the averaged vertical layer  
 526 for the considered eleven layers (b) at the 95 NCP sites during Oct. 11–31 of 2018. A  
 527 good correlation ( $R > 0.8$ ) between DMA8 O<sub>3</sub> enhancements and daytime PM<sub>2.5</sub>  
 528 concentrations in the vertical averaged layer suggests that the enhanced O<sub>3</sub> due to the  
 529 six potential HONO sources was larger in polluted days and increased during the haze  
 530 aggravating processes. The enhanced DMA8 O<sub>3</sub> was  $< 2 \text{ ppb}$  when PM<sub>2.5</sub> was  $< 20 \mu\text{g}$   
 531  $\text{m}^{-3}$ , and was  $> 10 \text{ ppb}$  when PM<sub>2.5</sub> was  $> 60 \mu\text{g} \text{ m}^{-3}$  on average, with a mean DMA8 O<sub>3</sub>

532 enhancement of 0.24 ppb per  $\mu\text{g m}^{-3}$  of  $\text{PM}_{2.5}$ .

533

534

535 **Figure 13** The linear relationship between DMA8 O<sub>3</sub> enhancements and daytime  $\text{PM}_{2.5}$

536 concentrations in each vertical layer (a) and the averaged vertical layer for the considered eleven

537 layers (b) at the 95 NCP sites during Oct. 11–31 of 2018.

538

539 **Fig.14** shows the 95-NCP-site-averaged DMA8 O<sub>3</sub> enhancements due to the six

540 potential HONO sources during a typical haze aggravating process of Oct.19–21 and a

541 clean period of Oct.27–29 of 2018. A significant enhancement of DMA8 O<sub>3</sub> can be

542 found during the haze aggravating process compared with during clean days. The

543 enhanced DMA8 O<sub>3</sub> was ~5.5 ppb (Oct.19), ~ 7 ppb (Oct.20) and ~ 10 ppb (Oct.21),

544 respectively, during the haze aggravating process, while that was usually ~2 ppb in

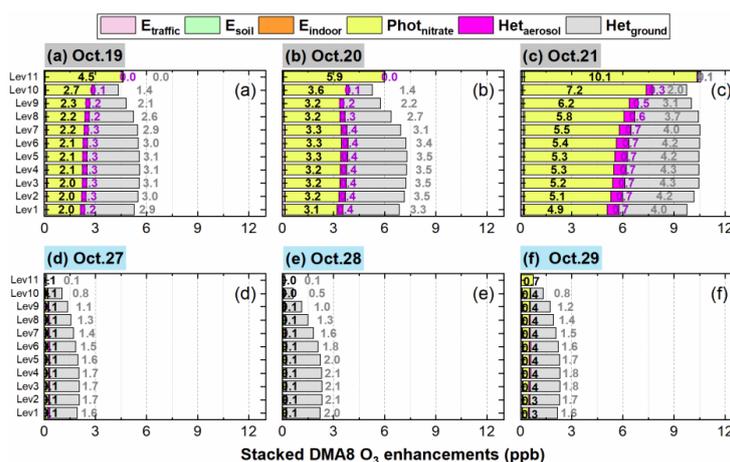

545 clean days.

546 In clean days,  $\text{Het}_{\text{ground}}$  was the dominant contributor (~1.5–2 ppb) to the enhanced

547 DMA8 O<sub>3</sub> among the six potential HONO sources, the contribution of  $\text{Phot}_{\text{nitrate}}$  to the

548 enhanced DMA8 O<sub>3</sub> was ~0.1–0.4 ppb, while that of the other four sources was minor.  
 549 When it comes to the comparison between the haze aggravating process (Oct.19–21)  
 550 and clean days, the DMA8 O<sub>3</sub> enhancements induced by Het<sub>ground</sub> were doubled and  
 551 reached ~3–4 ppb; the contribution of Phot<sub>nitrate</sub> to the enhanced DMA8 O<sub>3</sub> substantially  
 552 increased and reached ~2–4.5 ppb (Oct.19), ~3–6 ppb (Oct.20) and ~5–10 ppb (Oct.21),  
 553 respectively; Het<sub>aerosol</sub> showed an increasing contribution to the enhanced DMA8 O<sub>3</sub>  
 554 during haze aggravating process (~0.3 ppb in Oct.19, ~0.4 ppb in Oct.20 and ~0.7 ppb  
 555 in Oct.21), while the impacts of the other three direct emission sources (E<sub>traffic</sub>, E<sub>soil</sub>, and  
 556 E<sub>indoor</sub>) on the enhanced DMA8 O<sub>3</sub> were minor.  
 557

558  
 559 **Figure 14** The 95-NCP-site-averaged DMA8 O<sub>3</sub> enhancements due to the six potential HONO  
 560 sources during a typical haze aggravating process of Oct.19–21 (a–c) and a clean period of Oct.27–  
 561 29 (d–f) of 2018. The column in black numbers in each graph is for Phot<sub>nitrate</sub>, the column in purple  
 562 numbers in each graph is for Het<sub>aerosol</sub>, and the column in gray numbers is for Het<sub>ground</sub>.  
 563

### 564 3.4 Vertical variations of O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity

565 Based on the results above, Phot<sub>nitrate</sub> could significantly enhance the DMA8 O<sub>3</sub> by  
566 one order of magnitude in the considered vertical layers (especially at elevated heights)  
567 in polluted events, but previous studies have not fully discussed. To better understand  
568 its role in vertical O<sub>3</sub> formation, the O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity was analyzed by using  
569 the P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>) ratio proposed by Sillman (1995), which is more suitable than  
570 the concentration ratio of H<sub>2</sub>O<sub>2</sub>/HNO<sub>3</sub> because of the large dry deposition velocity of  
571 the two gases in the troposphere (Sillman, 1995). A transition point of P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>)  
572 = 0.35 was suggested by Sillman (1995), when P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>) was <0.35, O<sub>3</sub> shows  
573 VOCs-sensitive chemistry (increasing VOC concentrations can significantly elevate O<sub>3</sub>  
574 levels) and when P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>) was >0.35, O<sub>3</sub> tends to NO<sub>x</sub>-sensitive chemistry  
575 (increasing NO<sub>x</sub> concentrations can significantly elevate O<sub>3</sub> levels).

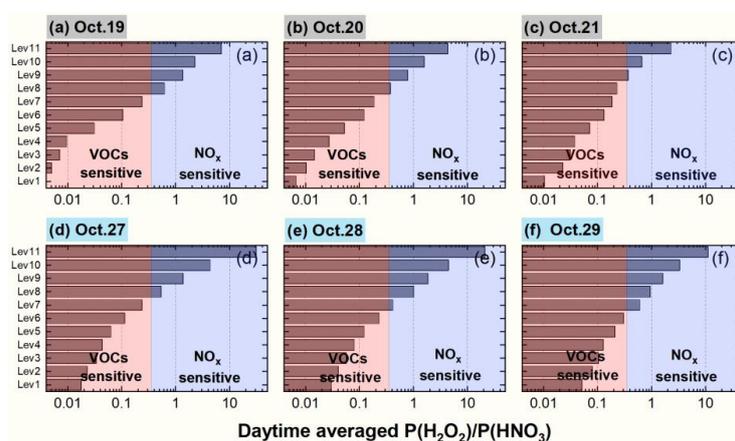

576 **Fig.15** demonstrates the 95-NCP-site-averaged P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>) ratio at each  
577 vertical layer for the 6S case during a typical haze aggravating process of Oct.19–21  
578 and a clean period of Oct.27–29 of 2018. Obviously opposite O<sub>3</sub> sensitivity appeared  
579 between the lower layers (VOCs sensitive) and the higher layers (NO<sub>x</sub> sensitive) in both  
580 clean and hazy days, and the transition point usually appeared at the eighth layer (~600–  
581 800 m).

582 The nitrate photolysis reaction is assumed to produce HONO and NO<sub>x</sub> (Zhou et al.,  
583 2003), this reaction not only enhances OH concentrations via HONO photolysis, but  
584 also directly releases NO<sub>x</sub> back into the troposphere. Considering the NO<sub>x</sub>-sensitive O<sub>3</sub>  
585 chemistry at higher layers (>800m), elevating OH and NO<sub>x</sub> concentrations are both

586 favorable for O<sub>3</sub> formation, especially in haze aggravating processes with abundant  
587 nitrate (detailed vertically enhanced O<sub>3</sub> production/loss rates induced by Phot<sub>nitrate</sub> are  
588 given in **Fig.S7**).

589

590

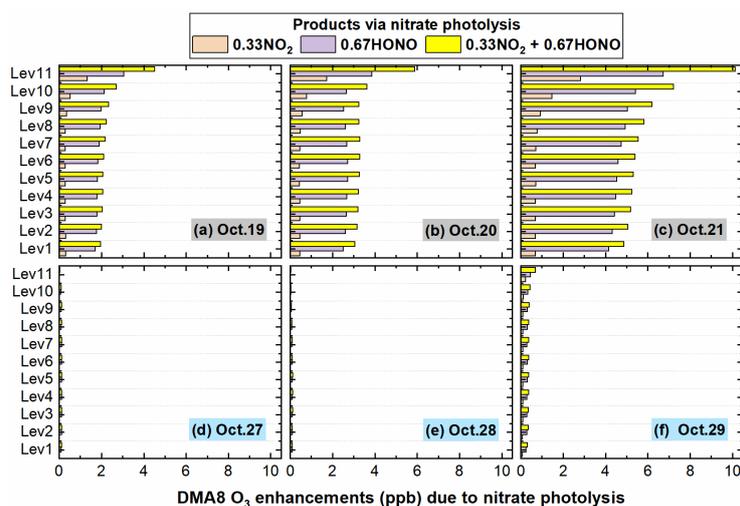

591 **Figure 15** The 95-NCP-site-averaged P(H<sub>2</sub>O<sub>2</sub>)/P(HNO<sub>3</sub>) ratio at each vertical layer for the 6S case  
592 during a typical haze aggravating process of Oct.19–21 (a–c) and a clean period of Oct.27–29 (d–f)  
593 of 2018.

594

595 The specific role of the produced HONO or NO<sub>2</sub> via the nitrate photolysis reaction  
596 (R2) in DMA8 O<sub>3</sub> enhancements were further analyzed and is shown in **Fig. 16**, the  
597 produced NO<sub>2</sub> and HONO jointly promoted O<sub>3</sub> formation and increased DMA8 O<sub>3</sub>  
598 concentrations. From the surface to ~1200m (Level 9), the DMA8 O<sub>3</sub> enhancements for  
599 case D\_HONO was ~5 times those for case D\_NO<sub>2</sub>, while at ~2000 m (Level 11) the  
600 DMA8 O<sub>3</sub> enhancements for case D\_HONO was ~2 times those for case D\_NO<sub>2</sub>. A  
601 balance exists between the propagation of the free radical interconversion cycle and the  
602 rate of termination of the cycle for the O<sub>3</sub> formation chemistry (Gligorovski et al., 2015),

603 considering the 0.67 and 0.33 yields (ratio is 2) for the two products, we could conclude  
604 that the impact of produced HONO on O<sub>3</sub> enhancements was larger than produced NO<sub>2</sub>  
605 near the surface, while at higher altitude (>2000 m) the impacts of the two products  
606 were similar.  
607

608  
609 **Figure 16** The 95-NCP-site-averaged DMA8 O<sub>3</sub> enhancements due to nitrate photolysis with three  
610 product scenarios (cases D\_NO<sub>2</sub>, D\_HONO and D) during a typical haze aggravating process of  
611 Oct.19–21 (a–c) and a clean period of Oct.27–29 (d–f) in 2018.

612

## 613 4. Discussion

### 614 4.1 Vertical variations of potential HONO sources

615 The relative contribution of potential HONO sources near the surface,  
616 corresponding to the first model layer (0 to ~35 m) in our simulation, was quantified in

617 previous modelling studies (Fu et al., 2019; Xue et al., 2020; Zhang et al., 2021),  
618 however, for those potential HONO sources, their relative contributions to HONO  
619 concentrations near and above the surface should be different. Based on our results  
620 (Figs.7&8), the effects of aerosol related HONO sources would be severely  
621 underestimated in hazy days when only focused surface HONO, especially for nitrate  
622 photolysis. Near the surface in NCP, the daytime contribution of Phot<sub>nitrate</sub> to HONO  
623 concentrations in hazy days was only ~4–6%, but this source contributed ~35–50% of  
624 the enhanced DMA8 O<sub>3</sub> (**Fig.14a–c**); above the eighth layer (~800 m), this source  
625 contributed ~50–70% of HONO concentrations and ~50–95% of the enhanced DMA8  
626 O<sub>3</sub> (**Fig.14a–c**).

627 A recent observation in urban Beijing reported vertical HONO concentrations from  
628 three heights above the surface and found that extremely high HONO concentrations  
629 occurred at 120 m (~5 ppb) and 240 m (~3 ppb) rather than near the surface (~1.2 ppb)  
630 during 12:00 in a typical hazy day (Zhang et al., 2020b). The observation was unusual  
631 at noontime under strong convection conditions, inconsistent with those most previous  
632 observations indicating a HONO decrease trend with height, especially with the  
633 observational results of Zhu et al. (2011) and Meng et al. (2020) and simulated results  
634 of Zhang et al. (2021) at the same observational site (including our simulations in  
635 **Fig.S5**). The contributions of different HONO sources at each layer were analyzed by  
636 using a box model, but ~80–90% of the noontime HONO at higher layers could not be  
637 explained by the known HONO formation mechanisms (Zhang et al., 2019c). The box  
638 model neglected the vertical convection, so the ground related HONO sources had no

639 contribution to HONO concentrations at the higher layers, thus their HONO simulations  
640 were actually underestimated compared with our results and the previous studies of  
641 Wong et al. (2011) and Zhang et al. (2021).

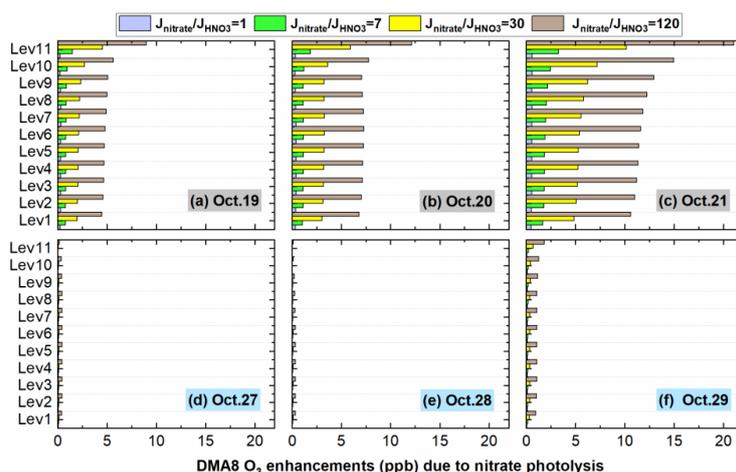

642

#### 643 **4.2 Uncertainties of $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratios and their impacts**

##### 644 **4.2.1 Uncertainties of $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratios in DMA8 O<sub>3</sub> enhancements**

645 Based on our results,  $\text{Het}_{\text{ground}}$  and  $\text{Phot}_{\text{nitrate}}$  were the two major contributors to the  
646 enhanced DMA8 O<sub>3</sub>, especially for  $\text{Phot}_{\text{nitrate}}$  in hazy days with higher PM<sub>2.5</sub>  
647 concentrations. The uncertainties of  $\text{Phot}_{\text{nitrate}}$  (four  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios) in O<sub>3</sub>  
648 enhancements were analyzed and are shown in **Fig.17** (the uncertainties for  $\text{Het}_{\text{ground}}$   
649 are given in **text S2**). During the haze aggravating process, the enhanced DMA8 O<sub>3</sub>  
650 increased from ~0.3 to ~0.5 ppb, from ~0.9 to ~2 ppb, from ~2 to ~6 ppb, and from ~5  
651 to ~12 ppb, with the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio being 1, 7, 30, 120, respectively, and the enhanced  
652 O<sub>3</sub> increased with altitude. In clean days, the impact of  $\text{Phot}_{\text{nitrate}}$  on O<sub>3</sub> enhancements  
653 was small (<1 ppb) even with a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 120.

654

655

656 **Figure 17** The 95-NCP-site-averaged DMA8 O<sub>3</sub> enhancement induced by nitrate photolysis with

657 four  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios (1, 7, 30 and 120) during a typical haze aggravating process of Oct.19–21

658 (a–c) and a clean period of Oct.27–29 (d–f) of 2018.

659

#### 660 4.2.2 Uncertainties of $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratios in nitrate concentrations

661 We found considerable enhancements in O<sub>3</sub> concentrations induced by nitrate

662 photolysis, yet it is still unclear that to what extent nitrate photolysis could influence

663 nitrate concentrations. The overall nitrate concentrations for the base case and the

664 nitrate enhancements induced by the potential HONO sources decreased with rising

665 altitude except for  $\text{Phot}_{\text{nitrate}}$  (**Fig.S8a**).  $\text{Het}_{\text{ground}}$  enhanced nitrate concentrations by  $\sim 1.5$

666  $\mu\text{g m}^{-3}$  near the surface and the enhancements decreased to  $< 0.5 \mu\text{g m}^{-3}$  above the eighth

667 model layer ( $\sim 800\text{m}$ ); the nitrate enhancements due to  $\text{Het}_{\text{aerosol}}$  and  $E_{\text{traffic}}$  near the

668 surface were  $\sim 0.2$  and  $\sim 0.1 \mu\text{g m}^{-3}$ , respectively, and were  $< 0.1$  and  $< 0.04 \mu\text{g m}^{-3}$  above

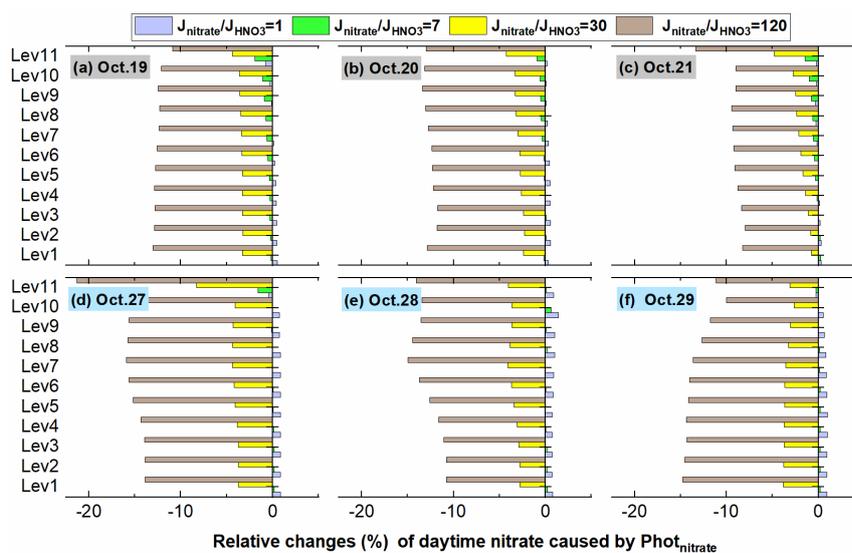

669 the sixth model layer ( $\sim 500\text{m}$ ). For  $\text{Phot}_{\text{nitrate}}$ , the overall impact of four  $J_{\text{nitrate}}/J_{\text{HNO}_3}$

670 ratios on nitrate concentrations is shown in **Fig.S8b**, a smaller  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 1 or  
671 7 had a limited impact on nitrate concentrations of  $\sim 0\text{--}0.05 \mu\text{g m}^{-3}$ , a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio  
672 of 30 slightly decreased nitrate concentrations by  $\sim 0.2 \mu\text{g m}^{-3}$ , while the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$   
673 ratio of 120 decreased vertical nitrate concentrations by  $\sim 0.3\text{--}0.8 \mu\text{g m}^{-3}$ . The relative  
674 nitrate changes caused by  $\text{Phot}_{\text{nitrate}}$  were calculated by the differences between four  
675 cases added  $\text{Phot}_{\text{nitrate}}$  (cases Nit\_1, Nit\_7, D and Nit\_120) and the base case, the vertical  
676 nitrate concentrations were reduced by  $\sim 0\text{--}0.4\%$  ( $J_{\text{nitrate}}/J_{\text{HNO}_3}=1$ ),  $\sim 0\text{--}2\%$  (7),  $\sim 2\text{--}5\%$   
677 (30) and  $\sim 10\text{--}14\%$  (120) at the 95 NCP sites, meaning that the  $\text{Phot}_{\text{nitrate}}$  impact on  
678 vertical nitrate concentrations is limited ( $<5\%$ ) when adopting a relatively small  
679  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio ( $< 30$ ) (**Fig.S8c**).

680 **Fig.18** shows the detailed relative nitrate changes caused by  $\text{Phot}_{\text{nitrate}}$  during a  
681 typical haze aggravating process and a clean period (corresponding concentrations were  
682 shown in **Fig.S9**), the percentage nitrate reduction was usually smaller in hazy days  
683 than in clean days, and nitrate was slightly reduced during the haze aggravating  
684 processes, the nitrate reduction was  $<5\%$  when adopting the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 30 both  
685 in clean and hazy days.

686

687

688 **Figure 18** The 95-NCP-site-averaged nitrate relative changes with four  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios (1, 7, 30  
689 and 120) compared with the base case (c) during a typical haze aggravating process of Oct.19–21  
690 (a–c) and a clean period of Oct.27–29 (d–f) of 2018.

691

### 692 4.2.3 Possible ranges of the $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio

693 From the above discussion, we can find that the enhanced OH and  $\text{O}_3$  due to  
694  $\text{Phot}_{\text{nitrate}}$  are remarkable during haze aggravating processes, and the exact value of the  
695  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio requires more studies.

696 **Fig. 19** shows diurnal patterns of surface-averaged and vertical-averaged  
697 simulations of nitrate photolysis frequency with four different  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios at the  
698 95 NCP sites during the study period. The nitrate photolysis frequency at 12:00 was  
699  $3.7 \times 10^{-7}$ ,  $2.6 \times 10^{-6}$ ,  $1.1 \times 10^{-5}$  and  $4.5 \times 10^{-5} \text{ s}^{-1}$ , when adopting a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 1, 7,  
700 30 and 120, respectively. The corresponding vertical-averaged nitrate photolysis

701 frequency was slightly larger ( $\sim 10\%$ ) and was  $4.2 \times 10^{-7}$ ,  $2.9 \times 10^{-6}$ ,  $1.3 \times 10^{-5}$  and  $5.0 \times 10^{-5}$  s<sup>-1</sup>, respectively. Adopting a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 30 in the 6S case, with the  
702  
703 corresponding  $J_{\text{nitrate}}$  of  $1.1\text{--}1.3 \times 10^{-5}$  s<sup>-1</sup>, produced  $\sim 30\text{--}50\%$  of the enhanced O<sub>3</sub> near  
704 the surface in hazy days (**Fig.13**), and  $\sim 70\text{--}90\%$  of the enhanced O<sub>3</sub> at higher layers  
705 ( $>800$  m).

706 The reported values of  $J_{\text{nitrate}}$  from previous studies are summarized in **Table 4**. The  
707 experimental  $J_{\text{nitrate}}$  values have been controversial over the past two decades and are  
708 still arguable currently. In our simulations for the 6S case, nitrate photolysis contributed  
709 from  $\sim 1\%$  (clean days) to  $\sim 5\%$  (hazy days) to surface HONO during daytime when  
710 using the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 30 in NCP, consistent with  $<8\%$  at a rural site in NCP  
711 reported by Xue et al. (2020) and  $\sim 1\%$  at urban Beijing reported by Zhang et al. (2021)  
712 using the same ratio; however, the increasing contribution of nitrate photolysis to  
713 HONO concentrations with rising altitude based on our simulations (**Fig.7**), has not  
714 been discussed in previous research. Furthermore, we found that the overall impact of  
715 nitrate photolysis to OH and O<sub>3</sub> would be severely underestimated when the  
716 contribution of nitrate photolysis to vertical HONO was excluded.

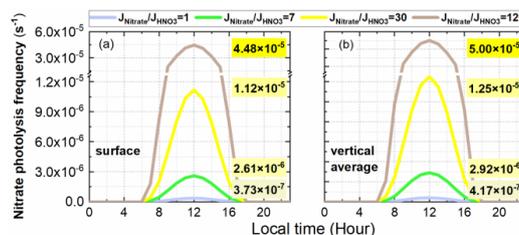

717 A larger  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 120 for nitrate photolysis ( $4.5\text{--}5.0 \times 10^{-5}$  s<sup>-1</sup> at 12:00)  
718 produced  $\sim 25\text{--}30\%$  of noontime HONO in NCP in our study (**Fig.S10**), comparable  
719 with  $30\text{--}40\%$  in previous modelling studies (Fu et al., 2019; Shi et al., 2020) when  
720 using the  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio of 118.57 ( $8.3 \times 10^{-5}/7 \times 10^{-7}$ ). In haze aggravating processes,  
721 the contribution of  $\text{Phot}_{\text{nitrate}}$  ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 120$ ) to the DMA8 O<sub>3</sub> enhancements  
722 reached  $\sim 5\text{--}10$  ppb near the surface and  $\sim 8\text{--}20$  ppb above the tenth model layer (**Fig.17**),

723 these enhancements were extremely large. In a previous modelling study by Fu et al.  
724 (2020), the daytime surface O<sub>3</sub> simulations were systematically overestimated by ~ 5  
725 ppb in NCP in winter (**Fig.S4** in Fu et al. (2020)), the inclusion of Phot<sub>nitrate</sub> ( $J_{\text{nitrate}}/J_{\text{HNO}_3}$   
726 = 118.57) in their study might cause the overestimation. From the above, a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$   
727 ratio of 120, or a  $J_{\text{nitrate}}$  value of  $\sim 4\text{--}5 \times 10^{-5} \text{ s}^{-1}$  is possibly overestimated. When adopting  
728 the maximum  $J_{\text{nitrate}}$  value of  $10^{-4} \text{ s}^{-1}$  reported by Ye et al. (2016) and Bao et al. (2018),  
729 we reasonably speculate that O<sub>3</sub> simulations will be significantly overestimated,  
730 especially at higher altitude with NO<sub>x</sub>-sensitive O<sub>3</sub> chemistry (**Figs.15**).

731 Romer et al. (2018) and Kasibhatla et al. (2018) suggested that a  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratio  
732 of 30 or smaller would be more suitable, being about the minimum value reported by  
733 Ye et al. (2016) and Bao et al. (2018), and has significantly influenced the O<sub>3</sub>  
734 simulations in haze aggravating processes. The lack of photo-catalyzer in suspended  
735 submicron particulate sodium and ammonium nitrate may cause a lower  $J_{\text{nitrate}}/J_{\text{HNO}_3}$   
736 ratio (<10) reported by Shi et al. (2021), so more chamber experiments need to be  
737 conducted by using the particles collected in the real atmosphere. Choosing a larger  
738  $J_{\text{nitrate}}$  value might cover up other ground-based unknown HONO sources, creating an  
739 illusion of good model simulations of daytime HONO, but resulting in overestimation  
740 of O<sub>3</sub> concentrations. Considering the uncertainties of NO<sub>x</sub> or VOCs emissions, which  
741 also significantly impact O<sub>3</sub> simulations, more studies are needed to find the exact value  
742 of  $J_{\text{nitrate}}$  in the real atmosphere.

743

744

745 **Figure 19** Diurnal patterns of surface-averaged (a) and vertical-averaged (b) simulations of nitrate

746 photolysis frequency with four different  $J_{\text{nitrate}}/J_{\text{HNO}_3}$  ratios (1, 7, 30, 120) at the 95 NCP sites during

747 the study period (The nitrate photolysis frequencies at 12:00 is shown in each graph).

749

750

751 **Table 4.** Summary of studies on the nitrate photolysis frequency ( $J_{\text{nitrate}}$ ) ( $J_{\text{HNO}_3}$  denotes the photolysis  
 752 frequency of gas  $\text{HNO}_3$ )

Experimental conditions	Main conclusion	Reference
$\text{HNO}_3$ absorbed on Pyrex surface	$J_{\text{nitrate}}$ ( $1.2 \times 10^{-5} \text{ s}^{-1}$ ) is 1–2 orders of magnitude faster than in the gas and aqueous phases.	(Zhou et al., 2003)
Atmosphere simulation chamber	$J_{\text{nitrate}}$ on snow, ground, and glass surfaces, can be excluded in the chamber.	(Rohrer et al., 2005)
$\text{HNO}_3$ absorbed on glass surface	Photolysis frequency of surfaces adsorbed $\text{HNO}_3$ is > 2 orders of magnitude larger than $J_{\text{HNO}_3}$ .	(Zhu et al., 2008)
Urban grime-coated surface	$J_{\text{nitrate}}$ ( $1.2 \times 10^{-3} \text{ s}^{-1}$ ) is 4 orders of magnitude faster than in water ( $10^{-7} \text{ s}^{-1}$ ).	(Baergen and Donaldson, 2013)
Various natural/artificial surfaces	$J_{\text{nitrate}}$ ranges from $6.0 \times 10^{-6} \text{ s}^{-1}$ to $3.7 \times 10^{-4} \text{ s}^{-1}$ , 1–3 orders of magnitude higher than $J_{\text{HNO}_3}$	(Ye et al., 2016)
Adsorbed $\text{HNO}_3$ on glass surfaces	Photolysis frequency of surfaces adsorbed $\text{HNO}_3$ ( $2.4 \times 10^{-7} \text{ s}^{-1}$ ) is very low.	(Laufs and Kleffmann, 2016)
Aerosol filter samples	$J_{\text{nitrate}}$ ranges from $6.2 \times 10^{-6} \text{ s}^{-1}$ to $5.0 \times 10^{-4} \text{ s}^{-1}$ with a mean of $1.3 \times 10^{-4} \text{ s}^{-1}$ .	(Ye et al., 2017)
Nitrate aerosol in the MBL	$J_{\text{nitrate}}$ is ~10 times higher than $J_{\text{HNO}_3}$ .	(Reed et al., 2017)
$\text{PM}_{2.5}$ in Beijing	$J_{\text{nitrate}}$ ( $1.22 \times 10^{-5} \text{ s}^{-1}$ to $4.84 \times 10^{-4} \text{ s}^{-1}$ ) is 1–3 orders of magnitude higher than $J_{\text{HNO}_3}$ .	(Bao et al., 2018)
Sea-salt particulate nitrate	$J_{\text{nitrate}}$ is 25–50 times higher than $J_{\text{HNO}_3}$ .	(Kasibhatla et al., 2018)

Particles collected on filters	$J_{\text{nitrate}}$ is $\leq 30$ times $J_{\text{HNO}_3}$ .	(Romer et al., 2018)
CMAQ simulation	Nitrate photolysis contributed $\sim 30\%$ of noontime HONO with a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of $\sim 120$ .	(Fu et al., 2019)
CMAQ simulation	A $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of 100 better improved sulfate simulations than a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of 10.	(Zheng et al., 2020)
MCM Box model	Nitrate photolysis contribution to HONO was $< 8\%$ with a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of 30.	(Xue et al., 2020)
MCM Box model	Nitrate photolysis contributed $\sim 40\%$ of noontime HONO with a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of $\sim 120$ .	(Shi et al., 2020)
Smog chamber	The $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio was $< 10$ for suspended submicron $\text{NaNO}_3$ and $\text{NH}_4\text{NO}_3$ .	(Shi et al., 2021)
CMAQ simulation	Nitrate photolysis contribution to surface HONO was $\sim 1.0\%$ with a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of 30.	(Zhang et al., 2021)
WRF-Chem simulation	The relative contribution of nitrate photolysis to HONO increased with rising altitude and nitrate photolysis contributed the enhanced $\text{O}_3$ much larger in the ABL than near the surface HONO. On average, nitrate photolysis contributed $\sim 5\%$ of surface daytime HONO with a $J_{\text{nitrate}}/J_{\text{HNO}_3}$ ratio of 30 ( $\sim 1 \times 10^{-5} \text{ s}^{-1}$ ) but contributed $\sim 30\text{--}50\%$ of the enhanced $\text{O}_3$ near the surface in NCP in hazy days.	This study

753 MBL: marine boundary layer; ABL: atmospheric boundary layer.

754

## 755 5. Conclusions

756 In this study, three direct emission sources, the improved NO<sub>2</sub> heterogeneous  
757 reactions on aerosol and ground surfaces, and particulate nitrate photolysis in the  
758 atmosphere were included into the WRF-Chem to explore the key sources of HONO  
759 producing O<sub>3</sub> enhancements during typical autumn haze aggravating processes with co-  
760 occurrence of high PM<sub>2.5</sub> and O<sub>3</sub> in NCP. The six potential HONO sources produced a  
761 significant enhancement in surface HONO simulations and improved the mean HONO  
762 concentration at the BUCT site to 1.47 ppb from 0.05 ppb (improved the NMB to -  
763 14.22% from -97.11% and the IOA to 0.86 from 0.78). The improved HONO  
764 significantly enhanced the atmospheric oxidation capacity near the surface and at  
765 elevated heights, especially in hazy days, resulting in fast formation of and significant  
766 improvements of O<sub>3</sub> during haze aggravating processes in NCP. Although the photolysis  
767 frequency is usually lower during hazy days, higher concentrations of NO<sub>2</sub>, PM<sub>2.5</sub> and  
768 nitrate favored HONO formation via heterogeneous reactions, leading to stronger  
769 atmospheric oxidation capacity. The major results include:

770 (1) For the surface HONO in NCP, Het<sub>ground</sub> was the largest source during daytime  
771 and nighttime (~50–80%); the contribution of Phot<sub>nitrate</sub> ( $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ ) to surface  
772 HONO concentrations was close to that of the NO+OH reaction during daytime (~1–  
773 12%) and was ~5% for daytime average; E<sub>traffic</sub> was important during nighttime (~10–  
774 20%) but small during daytime (<5%); the contribution of Het<sub>aerosol</sub> was minor (~2–3%)  
775 in daytime and <10% in nighttime; the contribution of E<sub>soil</sub> was <3%, and E<sub>indoor</sub> could  
776 be neglected. Vertically, the HONO enhancements due to ground-based potential

777 HONO sources ( $E_{\text{traffic}}$ ,  $E_{\text{soil}}$ ,  $E_{\text{indoor}}$  and  $\text{Het}_{\text{ground}}$ ) decreased rapidly with height, while  
778 the NO+OH reaction and aerosol-related HONO sources ( $\text{Phot}_{\text{nitrate}}$  and  $\text{Het}_{\text{aerosol}}$ )  
779 decreased with height much slower. The enhanced HONO due to  $\text{Phot}_{\text{nitrate}}$  in hazy days  
780 was about one order of magnitude larger than in clean days and became the dominant  
781 HONO source ( $\sim 30\text{--}70\%$  when  $J_{\text{nitrate}}/J_{\text{HNO}_3} = 30$ ) at higher layers, and both HONO  
782 concentrations and  $\text{Phot}_{\text{nitrate}}$  contributions increased with the aggravated pollution  
783 levels.

784 (2) Near the surface, daytime OH production/loss rates were significantly enhanced  
785 by  $\sim 320\%$  for the 6S case (mean was  $5.27 \text{ ppb h}^{-1}$ ) compared with the base case (mean  
786 was  $1.26 \text{ ppb h}^{-1}$ ); vertically, daytime OH production/loss rates were enhanced by  $\sim 105\%$   
787 for the 6S case (mean was  $2.21 \text{ ppb h}^{-1}$ ) compared with the base case (mean was  $1.08$   
788  $\text{ppb h}^{-1}$ ). The enhanced OH production rate and OH due to the six potential HONO  
789 sources both showed a strong positive correlation with  $\text{PM}_{2.5}$  concentrations at the 95  
790 NCP sites, with a slope of  $0.043 \text{ ppb h}^{-1}/\mu\text{g m}^{-3}$  of  $\text{PM}_{2.5}$  and  $3.62 \times 10^4 \text{ molec cm}^{-3}/\mu\text{g}$   
791  $\text{m}^{-3}$  of  $\text{PM}_{2.5}$  from the surface to the height of 2.5 km for case 6S, respectively. The  
792 atmospheric oxidation capacity (e.g., OH) was enhanced in the haze aggravating  
793 process.

794 (3) A strong positive correlation ( $r > 0.8$ ) between enhanced  $\text{O}_3$  by the six potential  
795 HONO sources and  $\text{PM}_{2.5}$  concentrations was found in NCP, and nitrate photolysis was  
796 the largest contributor to the enhanced DMA8  $\text{O}_3$  in hazy days. Vertically, the enhanced  
797 DMA8  $\text{O}_3$  was  $< 2 \text{ ppb}$  when  $\text{PM}_{2.5}$  was  $< 20 \mu\text{g m}^{-3}$ , and that was  $> 10 \text{ ppb}$  when  $\text{PM}_{2.5}$   
798 was  $> 60 \mu\text{g m}^{-3}$  on average, with a slope of  $0.24 \text{ ppb DMA8 O}_3 \text{ enhancement } / \mu\text{g m}^{-3}$

799 of PM<sub>2.5</sub>. The surface enhanced DMA8 O<sub>3</sub> was ~5.5 ppb (Oct.19), ~7 ppb (Oct.20) and  
800 ~10 ppb (Oct.21), respectively, during a typical haze aggravating process, while that  
801 was usually ~2 ppb in clean days. The contribution of Phot<sub>nitrate</sub> to the enhanced DMA8  
802 O<sub>3</sub> was increased by over one magnitude during the haze aggravating process (up to 5–  
803 10 ppb) compared with that in clean days (~0.1–0.5 ppb), and reached ~2–4.5 ppb  
804 (Oct.19), ~3–6 ppb (Oct.20) and ~5–10 ppb (Oct.21), respectively, during a typical haze  
805 aggravating process vertically.

806 (4) Surface O<sub>3</sub> was controlled by VOCs-sensitive chemistry, while O<sub>3</sub> at higher  
807 altitude (>800m) was controlled by NO<sub>x</sub>-sensitive chemistry. The nitrate photolysis  
808 reaction enhanced OH and NO<sub>x</sub> concentrations, both favored O<sub>3</sub> formation at high  
809 altitude, especially in haze aggravating processes with abundant nitrate. The produced  
810 HONO rather than the produced NO<sub>2</sub> through nitrate photolysis had a stronger  
811 promotion for O<sub>3</sub> formation near the surface, but the impacts of the two products on O<sub>3</sub>  
812 enhancements were similar at higher altitude (~2000 m).

813 (5) Nitrate photolysis only contributed ~5% of the surface HONO in daytime with  
814 a J<sub>nitrate</sub>/J<sub>HNO<sub>3</sub></sub> ratio of 30 (~1×10<sup>-5</sup> s<sup>-1</sup>) but contributed ~30–50% of the enhanced O<sub>3</sub> near  
815 the surface in NCP in hazy days. The photolysis of nitrate had a limited impact on nitrate  
816 concentrations (reduced by <5% with J<sub>nitrate</sub>/J<sub>HNO<sub>3</sub></sub> =30, and <15% even with a  
817 J<sub>nitrate</sub>/J<sub>HNO<sub>3</sub></sub> ratio of 120), due mainly to the simultaneously enhanced atmospheric  
818 oxidation favoring the nitrate formation. Choosing a larger J<sub>nitrate</sub> value might cover up  
819 other ground-based unknown HONO sources, but overestimate vertical sources of  
820 HONO, and NO<sub>x</sub> and O<sub>3</sub> concentrations, so more studies are still needed to find the

821 exact value of  $J_{\text{nitrate}}$  in the real atmosphere.

### 823 **Data availability**

824 Data are available upon reasonable request to the corresponding authors.

825

### 826 **Author contribution:**

827 J.Z., C.L., J.A., M.G, and W.W. conceived and designed the research. J.Z. performed

828 and analyzed WRF-Chem simulations. J.Z., C.L., Y.G., and H.R. performed data

829 analyses and produced the figures. C.L., Y.Z., F.Z., X.F., C.Y., K.D., Y.L., and M.K.,

830 conducted the field observations. W.W., J.A., M.G., Y.L., and M.K. reviewed the article.

### 831 **Competing interests**

832 The authors declare that they have no conflict of interest.

833

### 834 **Acknowledgements**
