**Aerosol Atmospheric Rivers:
Climatology, Event Characteristics, and Detection Algorithm Sensitivities**

24 **Abstract**

25 Leveraging the concept of atmospheric rivers (ARs), a detection technique based on a widely
26 utilized global algorithm to detect ARs (Guan and Waliser, 2019, 2015; Guan et al., 2018) was
27 recently developed to detect aerosol atmospheric rivers (AARs) using the Modern-Era
28 Retrospective analysis for Research and Applications, Version 2 reanalysis (Chakraborty et al.,
29 2021a). The current study further characterizes and quantifies various details of AARs that were
30 not provided in that study, such as AARs' seasonality, event characteristics, vertical profiles of
31 aerosol mass mixing ratio and wind speed, and the fraction of total annual aerosol transport
32 conducted by AARs. Analysis is also performed to quantify the sensitivity of AAR detection to
33 the criteria and thresholds used by the algorithm. AARs occur more frequently over, and
34 typically extend from, regions with higher aerosol emission. For a number of planetary-scale
35 pathways that exhibit large climatological aerosol transport, AARs contribute up to a maximum
36 of 80% to the total annual transport depending on the species of aerosols. Dust (DU) AARs are
37 more frequent in boreal spring, sea salt AARs are often more frequent during the boreal winter
38 (summer) in the Northern (Southern) Hemisphere, carbonaceous (CA) AARs are more frequent
39 during dry seasons and often originate from the global rainforests and industrial areas, and
40 sulfate AARs are present in the Northern Hemisphere during all seasons. For most aerosol types,
41 the mass mixing ratio within AARs is highest near the surface. However, DU and CA AARs
42 over or near the African continent exhibit peaks in their aerosol mixing ratio profiles around 700
43 hPa. AAR event characteristics are mostly independent of species with mean length, width, and
44 length/width ratio around 4000 km, 600 km, and 7-8, respectively.

45

46

47 **1. Introduction**

48 As an important component of atmospheric composition, aerosols have considerable impacts
49 on the convective lifetime and precipitation (Chakraborty et al., 2016; Fan et al., 2016; Stevens
50 and Feingold, 2009; Rosenfeld et al., 2008; Andreae and Rosenfeld, 2008; Rosenfeld et al., 2016,
51 2014; Seinfeld et al., 2016; Rosenfeld et al., 2013) of convection, the radiation budget via direct
52 and indirect effects (Chylek and Wong, 1995; Kim and Ramanathan, 2008; Huang et al., 2006;
53 Lohmann and Feichter, 2001; Takemura et al., 2005), and the hydrological cycle (Chakraborty et
54 al., 2018; Rosenfeld et al., 2008). In particular, their interactions with cloud microphysics and
55 radiative forcing remain highly uncertain, constituting a large uncertainty in the assessment of
56 climate radiative forcing (IPCC, 2013b, a). Aerosols can also influence a plant's photosynthesis.
57 Aerosols are known to increase the amount of diffuse radiation (Xi and Sokolik, 2012). The
58 implications for plants are that along with decreasing the direct beam photosynthetically active
59 radiation (PAR), the presence of aerosols would lead to greater diffused PAR, which means
60 illumination of a greater portion of plant canopies, including shaded leaves, for which direct
61 PAR was not accessible previously (Niyogi et al., 2004; Knohl and Baldocchi, 2008; Gu et al.,
62 2003). Moreover, aerosols degrade the air quality and visibility, thus pose direct and negative
63 impacts on human health (Gupta and Christopher, 2009; Martin, 2008; Wang and Christopher,
64 2003; Li et al., 2017a).

65 With the advent of satellites capable of providing global-scale observations, it has become
66 clear that aerosol loading in the atmosphere is not limited to regions just near their emission
67 sources, but are also transported across continental areas and large expanses of the ocean
68 — emphasizing a source-receptor relationship among these impacts of aerosols. In addition, in-
69 situ measurements have been conducted to detect aerosol transport events over various regions of

70 the world, even in the remote polar regions (Gohm et al., 2009a; Tomasi et al., 2007a; Wang et
71 al., 2011a; Rajeev et al., 2000a; Bertschi et al., 2004a; Qin et al., 2016a; Ackermann et al., 1995;
72 Fast et al., 2014a). Many studies have previously investigated the long-range aerosol transport
73 events between various regions of the world (Prospero, 1999; Sciare et al., 2008; Abdalmogith
74 and Harrison, 2005; Swap et al., 1996; Kindap et al., 2006a; Weinzierl et al., 2017) including
75 inter-continental transport events. Many regions have been studied including the transport events
76 from the Sahara Desert to the United States (Prospero, 1999), Europe to Istanbul (Kindap et al.,
77 2006b), East Asia to California (Fan et al., 2014), and South Africa to the South Atlantic region
78 (Swap et al., 1996). Many other studies have investigated aerosol aging and chemical processes
79 during the transport events (Febo et al., 2010; Kim et al., 2009; Mori et al., 2003; Markowicz et
80 al., 2016; Song and Carmichael, 1999) including the secondary organic aerosol formation and
81 depicted the impact of the long-range aerosol transport on clouds (Wang et al., 2020a; Garrett
82 and Hobbs, 1995), precipitation (Fan et al., 2014), radiation (Ramanathan et al., 2007), and air
83 quality events including the PM_{2.5} level (Han et al., 2015; Chen et al., 2014; Prospero et al.,
84 2001; Febo et al., 2010). Apart from the studies using satellite and in-situ measurements, climate
85 models have often been used to understand aerosol transport (Takemura et al., 2002; Chen et al.,
86 2014; Ackermann et al., 1995; Fast et al., 2014). As mentioned above, many of these studies
87 used different approaches and methodologies and thus comparing one region to the another
88 around the globe or depicting one species' character of extreme events to another species with a
89 common framework is difficult. Although these studies identify aerosol transport events across
90 the globe, a clear picture about the identification of the extreme aerosol transport events (see
91 methods) using long-term climatological observational data sets, their climatology and major

92 transport pathways, and fractional contribution of those extreme transport events to the global
93 annual transport were lacking.

94 Leveraging the concept of atmospheric rivers (ARs) (Ralph et al., 2020; Zhu and Newell,
95 1994) and a widely used global AR detection algorithm (Guan and Waliser, 2019, 2015; Guan et
96 al., 2018), our previous study developed an aerosol atmospheric rivers (AARs) detection
97 algorithm (Chakraborty et al., 2021a). As with ARs that were studied around the globe using
98 different algorithms in different places, including global change studies, it was hard to get a
99 consistent assessment based on one homogeneous method of identifying the transport events. A
100 value of this study comes from the extension of a well-developed algorithm and applied
101 uniformly around the globe and across species. That study applied the new AAR detection
102 algorithm to five primary aerosol species represented in the MERRA-2 reanalysis – dust (DU),
103 sulfate (SU), sea salt (SS), and organic and black carbon (CA), and showed that aerosols can be
104 transported long distances by AARs, i.e. narrow and elongated channels of very high values of
105 vertically-integrated aerosol transport. It should be noted that aerosol transport and the fractional
106 contribution from AARs is detected over certain regions or the major transport pathways of the
107 globe. For example, except SS aerosols, AARs of other species are not detected over the tropical
108 equatorial regions, especially over the oceans. Moreover, it was found that along major transport
109 pathways, AARs are detected about 20-30 days per year and can be responsible for up to a
110 maximum of 40-80%, depending on the species of aerosols, of the total annual aerosol transport
111 (Fig. 3, Chakraborty et al., 2021a).” That study also illustrated that AAR events can have
112 profound impacts on local air quality conditions.

113 Owing to the relatively large contribution AARs have on the total annual aerosol transport in
114 many regions across the world, and the impacts that AARs can have on regional air quality

115 conditions, it is important to further investigate and quantify the roles AARs play within the
116 climate system and the impacts they have on air quality. For example, our previous study did not
117 characterize and show the vertical profiles of aerosol mass flux and wind of AARs for each
118 aerosol species. However, such information is crucial to improving the understanding of the
119 impacts of aerosols on the global radiative budget since multiple studies have revealed that the
120 aerosols' radiative impact depends on the aerosol composition and their vertical distribution
121 (Keil and Haywood, 2003; McComiskey and Feingold, 2008; Satheesh and Ramanathan, 2000;
122 Mishra et al., 2015). With that motivation in mind, the current study explores the AAR concept
123 further, characterizing and quantifying additional important features of AARs that were not
124 provided in Chakraborty et al. (2021a). These include 1) characteristics of individual AARs such
125 as length, width, length/width ratio, transport strength, and dominant transport direction, 2)
126 seasonal variations, 3) relationship to the spatial distribution of surface emissions, 4) vertical
127 profiles of wind, aerosol mixing ratio, and aerosol mass fluxes, and 5) the major planetary-scale
128 aerosol transport pathways AARs contribute to. As with Chakraborty et al (2021a), we carry out
129 this analysis utilizing the Modern-Era Retrospective analysis for Research and Applications,
130 Version 2 (MERRA-2) reanalysis during 1997-2014, and for all five aerosol species represented:
131 DU, SS, SU, OC, and BC; the latter two are combined into carbonaceous aerosols (CA) in
132 Figures 1 and 2 (Buchar et al., 2017; Gelaro et al., 2017; Randles et al., 2017).

133 **2. Data**

134 For this study, we use the MERRA-2 aerosol reanalysis (Global Modeling and Assimilation
135 Office (GMAO), 2015a) (Global Modeling and Assimilation Office (GMAO), 2015a) that has a
136 horizontal resolution of $0.5^\circ \times 0.625^\circ$ and a temporal resolution of 1 hour (Randles et al., 2017).
137 In particular, most of the analysis is based on the zonal and meridional components of the

138 vertically-integrated aerosol mass flux data. The MERRA-2 aerosol reanalysis data capture the
139 global aerosol optical depth reasonably well and are validated against 793 Aerosol Robotic
140 Network (AERONET) stations' aerosol measurements (Gueymard and Yang, 2020). For
141 example, we have used the variables dust mass flux in the zonal (DUFLUXU) and meridional
142 (DUFLUXV) directions to compute integrated aerosol transport (IAT) values for dust at each
143 grid. MERRA-2 aerosol data have previously been used in studies investigating aerosol
144 microphysical effect and global aerosol transport (Xu et al., 2020; Sitnov et al., 2020;
145 Chakraborty et al., 2021a). Our previous study using MERRA-2 data successfully detected
146 AARs over various regions of the globe, and the AERONET stations located either in the
147 receptor regions or along the path of AARs have shown a substantial increase in the aerosol
148 optical thickness during AAR events (Chakraborty et al., 2021a).

149 To examine the vertical profiles of aerosol amount, wind and aerosol mass fluxes (i.e. Figure
150 4), we use MERRA-2 3-hourly, instantaneous, aerosol mixing ratio data (inst3_3d_aer_Nv, last
151 accessed : June 2021) that provide aerosol mass mixing ratio at 72 vertical levels. To assess the
152 information about the zonal and meridional wind, we use MERRA-2's associated meteorological
153 fields (inst3_3d_asm_Nv, last accessed : June 2021) with the same resolution as the aerosol mass
154 mixing ratio data (Randles et al., 2017). In addition, we also use MERRA-2 time-averaged,
155 single-level, assimilated aerosol diagnostics (Global Modeling and Assimilation Office
156 (GMAO), 2015b) datasets (MERRA-2 tavgU_2d_adg_Nx) to describe the spatial distribution of
157 the emissions of aerosol particles at the surface to examine the relationship between source
158 regions and frequency of occurrence of AARs. MERRA-2 accounts various sources for
159 emissions (Randles et al., 2017). Dust emissions in MERRA-2 use a map of potential dust source
160 locations. Emissions of both DU and SS are wind driven for each size bin and parameterized. Sea

161 salt emission is estimated using the sea surface temperature and the wind speed dependency
162 with sea salt emission parameterization depends on the friction velocity. For SS, lake emissions
163 are also considered. SU aerosol emissions derive from both natural and anthropogenic
164 sources. Inventories for sulfate includes volcanic sulfur dioxide (SO₂) emissions as well as those
165 from the aircraft, energy-sectors, and anthropogenic aerosol sources. Emissions of CA and SU
166 aerosols in MERRA-2 come from various inventories over the time. From 2010, the Quick Fire
167 Emissions Dataset version 2.4-r6 is used. Locations of fires are obtained from MODIS level-2
168 fire and geolocation products. Please see table 1 of Randles et al., 2017 for details. Before that
169 MERRA-2 utilizes the Global Fire Emission Dataset from MODIS. MERRA-2 also applies
170 biome-dependent correction factors, fractional contributions of emissions from different forests
171 with applying correction to the monthly mean emissions that cover 1980–96 and are based on
172 Advanced Very High Resolution Radiometer, the Along Track Scanning Radiometer, and the
173 Total Ozone Mapping Spectrometer Aerosol Index.

174

175 **3. Methodology**

176 The AR detection algorithm designed by (Guan and Waliser, 2015)) was to detect and study
177 ARs based on a combination of criteria related to the intensity, direction, and geometry of
178 vertically integrated water vapor transport (IVT). The algorithm and associated AR detection
179 databases (based on multiple reanalysis products) have been widely used by the AR research
180 community (Chapman et al., 2019; Dhana Laskhmi and Satyanarayana, 2020; Edwards et al.,
181 2020; Gibson et al., 2020; Guan et al., 2020; Guan and Waliser, 2019; Huning et al., 2019;
182 Jennrich et al., 2020; Nash and Carvalho, 2019; Sharma and Déry, 2020; Wang et al., 2020;

183 Zhou and Kim, 2019). Details about the AAR algorithm and the modifications made to the AR
184 algorithm to make it applicable for AARs are provided below.

185 In the initial AAR algorithm (Chakraborty et al., 2021a), we detect AARs daily at four-time
186 steps (00, 06, 12, and 18 hours UTC) for a period of 18 years during 1997-2014 and separately
187 for each aerosol species. To compute total IAT over each grid cell at each time step for any
188 species (n) of aerosols we calculate $IAT_n = \sqrt{IATU_n^2 + IATV_n^2}$ where IATU and IATV denote
189 the vertically integrated aerosol mass flux in the zonal and meridional directions, respectively.
190 We are interested in identifying extreme transport events; thus, we first compute the 85th
191 percentile of the IAT magnitude over each grid cell during 1997-2014. Grid cells with IAT
192 magnitude less than the 85th percentile threshold are discarded. The remaining grid cells serve as
193 input to the following five steps to 1) isolate objects (i.e., contiguous areas) of enhanced IAT
194 with values above the 85th percentile; 2) check the consistency of the IAT directions at each grid
195 cell within an IAT object, to retain only those objects where at least 50% of the grid cells have
196 IAT directions within 45° of the direction of the mean IAT of the entire object; 3) retain the
197 stronger 50% of those objects detected in the previous step based on the object-mean IAT; 4)
198 retain objectives only if the direction of object-mean IAT is within 45° of the along-river axis to
199 ensure that the direction of the aerosol transport is aligned with the river; 5) apply length and
200 length-to-width ratio criteria and retain only those objects longer than 2000 km an aspect ratio
201 greater than 2. At the end of these steps, the objects that remain are referred to as AARs and are
202 further characterized in this study. We also show the sensitivity of the detection of AARs to key
203 threshold values used in the above steps in Figure 9.

204 In developing the AAR detection algorithm (Chakraborty et al., 2021a), only three changes
205 were made to the original AR detection algorithm. In step 1 of the AR moisture algorithm, a

206 fixed lower limit of IVT, specifically $100 \text{ kg m}^{-1} \text{ s}^{-1}$, is applied globally to facilitate detection of
 207 ARs in polar regions where IVT is extremely weak climatologically due to the very cold, dry
 208 atmosphere. We found that this additional filter is not needed for AAR detection. In addition,
 209 given the strong meridional moisture gradient between the tropics and extratropics, ARs are
 210 primarily recognized as the dominant means to transport water vapor poleward (Zhu and Newell,
 211 1998). Accordingly, the AR algorithm is designed to detect IVT objects with notable transport in
 212 the poleward direction. However, since there is no similar and dominant planetary gradient in
 213 aerosol concentration in the north-south direction, we removed this constraint on meridional IAT
 214 for AARs and instead applied a constraint on the total IAT (i.e., zonal and meridional
 215 components combined). Finally, Chakraborty et al. (2021a) computed the climatological 85th
 216 percentile threshold IAT values for each month based on the 5 months centered on that month, as
 217 in the original AR algorithm (Guan and Waliser, 2015). However, it was found that a 3-month
 218 window better resolves the annual cycle of IAT and meanwhile still retains sufficient sampling
 219 over the period of 1997–2014. For example, the IAT 85th percentile for February is calculated
 220 using the IAT values four times each day during January-March of 1997-2014.

221 AAR frequency at each grid cell is calculated as percent of time steps AARs are detected at
 222 that grid cell, and expressed in units of days/year for annual means (by multiplying the
 223 percentage by 365 days/year) and days/season for seasonal means (by multiplying the percentage
 224 by 91 days/season). The mean zonal and meridional IAT associated with AARs over each grid
 225 cell at latitude φ and longitude λ are calculated as:

$$226 \text{Mean IATU}(\varphi, \lambda) = \sum_1^N \text{IATU}(\varphi, \lambda)/N \text{ and } \text{Mean IATV}(\varphi, \lambda) = \sum_1^N \text{IATV}(\varphi, \lambda)/N$$

227 where N is the number of times AARs were detected over that grid cell.

228 To obtain the fraction of total (i.e., regardless of AAR or non-AAR) annual transport
 229 conducted by AARs of five different aerosol species, we first temporally integrate IATU and
 230 IATV over all the time steps when AARs were detected over a grid cell at latitude φ and
 231 longitude λ as

$$232 \quad \text{Total IATU}(\varphi, \lambda) = \int_0^T \text{IATU}(\varphi, \lambda, t) dt \quad (1a)$$

$$233 \quad \text{Total IATV}(\varphi, \lambda) = \int_0^T \text{IATV}(\varphi, \lambda, t) dt \quad (1b)$$

234

235 where dt is the duration between each time step (6 hours), and T is the total duration for 18 years.

236 Based on that, the magnitude of annual AAR IAT, which is a scalar quantity, at each grid cell is

$$237 \quad \text{Total_AAR_annual_IAT}_{\varphi, \lambda} = \sqrt{\text{Total IATU}(\varphi, \lambda)^2 + \text{Total IATV}(\varphi, \lambda)^2} / 18.$$

238 Similarly, we compute $\text{Total_all_annual_IAT}_{\varphi, \lambda}$ for all the time steps (i.e., AAR and non-AAR

239 combined). Next, since the annual AAR IAT and annual total IAT are not expected to be in the

240 same exact direction, we project the former onto the latter. For that, the directions of the two

241 vectors are obtained as

$$242 \quad \beta_{\text{All}} = \tan^{-1}(\text{Total IATU}(\varphi, \lambda) / \text{Total IATV}(\varphi, \lambda)) \text{ for all events} \quad (2a).$$

$$243 \quad \beta_{\text{AAR}} = \tan^{-1}(\text{Total IATU}(\varphi, \lambda) / \text{Total IATV}(\varphi, \lambda)) \text{ for AAR events} \quad (2b).$$

244 Finally, the fraction of total annual transport conducted by AARs is obtained as $\text{Frac}_{\varphi} =$

$$245 \quad \text{Total_AAR_annual_IAT}_{\varphi, \lambda} \times \cos(\beta) / \text{Total_all_annual_IAT}_{\varphi, \lambda}, \text{ where } \beta = \beta_{\text{All}} - \beta_{\text{AAR}}.$$

246 **4. Results**

247 **4.1 Overall aerosol transport and surface emission**

248 To provide a background for characterizing the seasonality of AARs, we first illustrate the

249 seasonal variability of the overall aerosol transport (i.e., regardless of AAR conditions) during

250 1997-2014 (Fig. 1). Here, we combine black carbon (BC) and organic carbon (OC) aerosols,

Figure 1. MERRA-2 vertically integrated aerosol transport (IAT, $10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$) in 4 seasons (DJF: December-February; MAM: March-May; JJA: June-August, and SON: September-November) during 1997-2014.

251 denoted as CA, owing to their similar sources and seasonality (BC and OC are accounted for
 252 separately in subsequent analysis of AARs). Dust IAT (first column, Fig. 1) is higher during the
 253 MAM and JJA seasons. Global deserts, such as the Sahara Desert, Gobi Desert, and Taklamakan
 254 Desert and the Middle East act as a significant source of dust aerosols year-round (Fig. 2A)
 255 emitting more than $2 \times 10^{-9} \text{ kg m}^{-2} \text{ s}^{-1}$ of dust, primarily in the northern Spring. The sea-salt IAT
 256 (second column, Fig.1) increases during the winter seasons of the Northern and Southern
 257 Hemispheres due to the increased mean westerly flow and storm activities during these seasons.
 258 Annual maps of SS emission (Fig. 2B) show that a large number of SS aerosols are emitted over
 259 the global oceans, especially over the tropical oceans because of the convective activities and in

260 the midlatitudes where synoptic storm activities are dominant. Sulfate IAT (SU, third column,
 261 Fig. 1) is high over a region between China and the North Pacific Ocean region, extending up to
 262 the western US, during all seasons with the lowest SU IAT values in JJA. The large SU IAT
 263 values (Figure 2C) are likely due to high emissions of SO₂ over China (Dai et al., 2019; Wang et
 264 al., 2013) coupled with strongly varying synoptic flows. A secondary region of higher amount of
 265 SU IAT is also detected between the eastern US and the northwestern Atlantic Ocean as a high
 266 amount of SO₂ is emitted east of the Rocky Mountains, particularly over the Ohio valley (Fig.

Figure 2. Annual surface emission ($\text{kg m}^{-2} \text{s}^{-1}$) of (A) DU, (B) SS, (C) SO₂ and (D) CA (BC+OC) aerosol species during 1997-2014 from the MERRA-2 data.

267 2C). Figure 2C also shows some SO₂ is emitted due to global shipping activities.

268 Globally, boreal and rainforests are the most significant contributors to the CA aerosols (Fig.
 269 2D). Accordingly, it appears that the Congo rainforest dominates the Amazon rainforest in terms
 270 of CA IAT (right column, Fig. 1). The Amazon rainforest region has higher IAT during its dry
 271 and transition seasons, and lower IAT in the wet season. Similarly, the Congo rainforest releases

272 a high amount of CA aerosols during the dry season (JJA) and another peak in the Sahel during
273 DJF (Fig. 2D). An increase in dry period CA IAT might be due to the increased vegetative stress,
274 forest fire, and agricultural burning over these two regions. However, it is interesting to note that
275 the Congo rainforest also emits CA aerosols during the boreal autumn (SON) rainy season,
276 which is the stronger of the two rainfall seasons in this region, but not during the MAM rainy
277 season. In MAM, the tropical rainforests over eastern India, Myanmar, and southern China have
278 higher CA IAT values. Emissions from the boreal forests appear to be less than that of the
279 rainforests. Over most of the midlatitudes in the Northern Hemisphere, the emissions of CA
280 aerosols (Fig. 2D) (also IAT values, Fig. 1D) is less than that over the global rainforests and
281 China in all four seasons (Fig. 1). As a result, although CA (OC and BC) AARs are more
282 frequent over the midlatitude region, the mean IAT by those rivers are less than those AARs that
283 originate from the global rainforests and China (Chakraborty et al., 2021a). These results point
284 out the existence of seasonality and variability in the overall aerosol emission and transport. As a
285 result, we expect the frequency and intensity of AARs might also vary among different seasons
286 in accordance with the distribution of surface emissions.

287 **4.2 AAR frequency and intensity**

288 To illustrate characteristics of individual AAR objects, Fig. 3 shows examples of AARs of
289 each species, including the location, shape, and transport direction and magnitude. Also indicated
290 in the figure is the length and width of each illustrated AAR. Figure 3A shows all the DU AARs
291 detected on 25th June, 2008 at 1200 UTC. Many of those DU AARs are detected between the
292 Sahara Desert and the Caribbean, the middle east region and Europe, over the central US, and
293 over the Patagonia region. Figure 3D shows details of one DU AAR (encircled in Fig. 3A) that
294 extends from the western boundary of the Sahara Desert to the southern US and Caribbean and

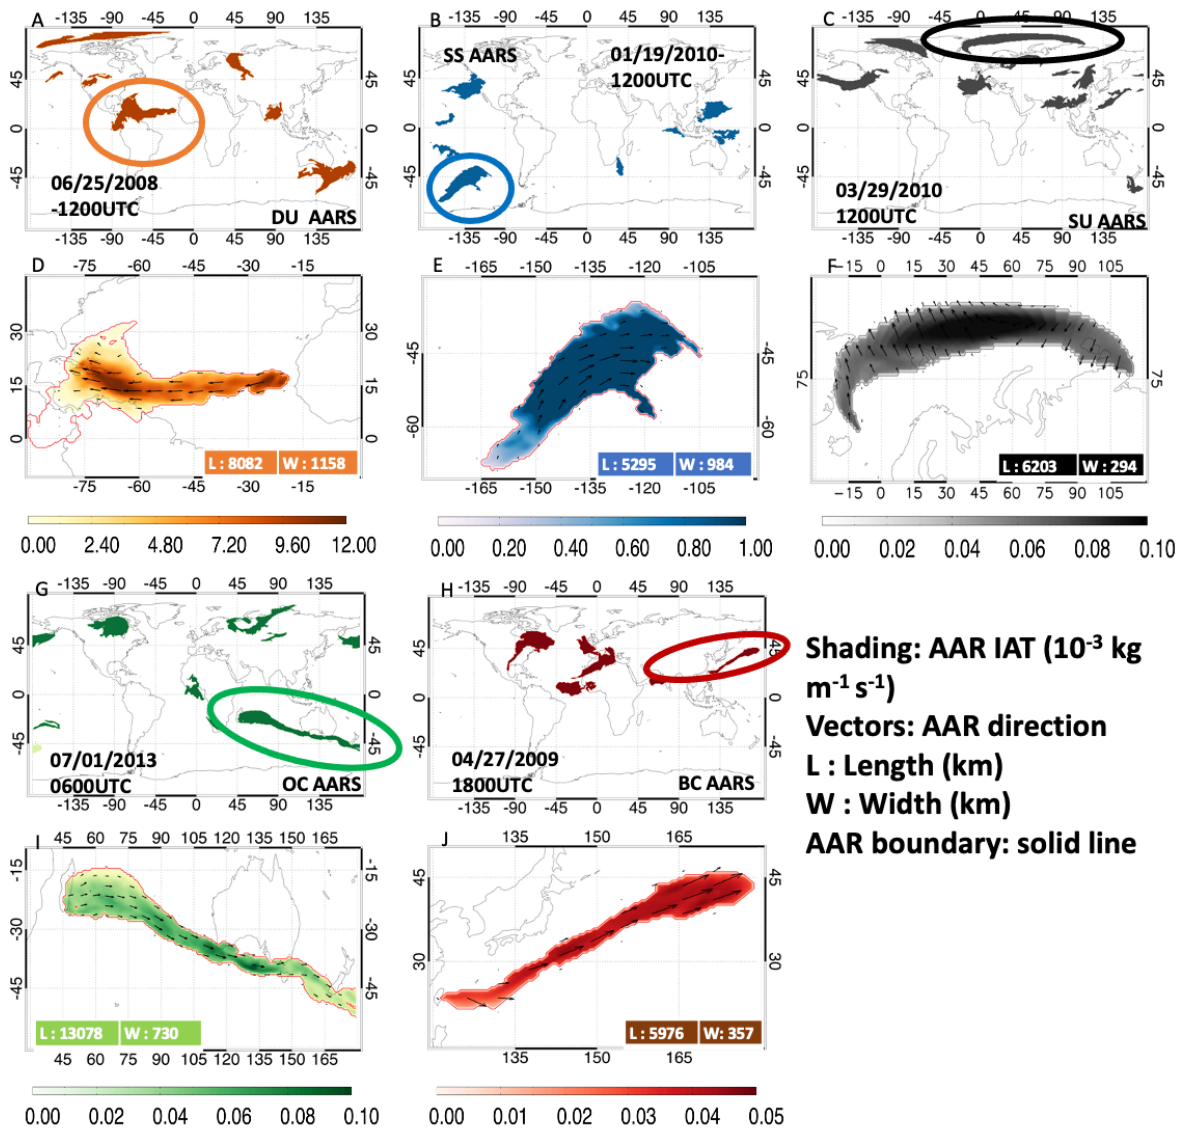

Figure 3: Detection of five different species of aerosols atmospheric rivers. Each panel in the 1st and 3rd rows show all AARs detected for a given species at an arbitrary time step; see bottom of each panel for the aerosol species and time stamp. Each panel in the 2nd and 4th rows shows detail (see legend) of a specific AAR from the corresponding panel above.

295 has IAT values greater than $12 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$. The AAR is 8082 km long and 1158 km wide.

296 Similarly, we show details of one SS AAR (Fig. 3E) with a length of 5295 km and a width of

297 984 km (IAT $\sim 1.0 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$) over the Southern Ocean among other AARs detected on 19th

298 January 2010 at 1200 UTC (Fig. 2B). Unlike DU AARs, SS AARs are located mostly over the

299 ocean (see also Fig. 4) and carry the extratropical AR signature. SS AARs over the tropical
300 regions appear to be smaller than the extratropical AARs in Figure 3B.

301 A number of SU AARs occurred in the polar region due to the Eyjafjallajökull volcanic
302 eruption (Fig. 3C). The volcano, located in Iceland, erupted on the 20th March 2010, causing
303 disruption to the aviation industry
304 (https://volcanoes.usgs.gov/volcanic_ash/ash_clouds_air_routes_eyjafjallajokull.html). In Figure
305 3F, we show details of one of these SU AARs on the 29th March 2010. The SU AAR is 6203 km
306 long and 294 km wide and transported a large amount of SU aerosols (IAT $\sim 0.1 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$)
307 into and across the polar region. It is important to notice that MERRA-2 did not include the ash
308 aerosols that were co-emitted with the SO₂ plumes that were eventually converted into sulfate
309 aerosols by gaseous and aqueous processes. In April 2010, our algorithm detected ~ 80 SU AARs
310 (at every six hours of interval i.e., 20 SU AAR days) originating over that region and
311 propagating to different directions.

312 Herein forth, we separately show the CA rivers as OC and BC rivers, especially because BC
313 AARs can significantly impact the radiative forcing compared to OC AARs and because the
314 mean mass of aerosols being transported by the OC is about five times that of BC AARs (Fig. 4).
315 Figure 3G shows examples of OC AARs detected on the 1st July 2013. We show details of one
316 OC AAR that stretches from Madagascar to New Zealand in Figure 3I. The OC AAR is 13078
317 km long and 730 km wide and flows west over the Indian Ocean with IAT of $\sim 0.1 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$.
318 ¹. Figure 3H shows a few BC AARs detected on 27th April 2009. BC AARs often originate near
319 the China-northwestern Pacific Ocean region (see also Fig. 4). We show the details of one such
320 BC AAR in Figure 3J. It is to be noted that the IAT values of BC AARs are smaller than the OC

321 AARs; however, they might play a significant role in the atmospheric radiation budget owing to
 322 the capability of BC aerosols to absorb solar energy.

Figure 4. Annual climatological AAR frequency (days/year; shading) and IAT (arrows; kg m⁻¹ s⁻¹) during 1997-2014 based on MERRA-2. (A) Dust; (B) Sea salt; (C) Sulfate; (D) Organic carbon; (E) Black carbon. Scales for the IAT vectors are provided in the lower right side of each plot.

323 To illustrate the overall climatology of AARs, Figure 4 shows the annual mean frequency of
 324 occurrence (shading; days per year) and the mean IAT (arrows; kg m⁻¹ s⁻¹) associated with AARs.
 325 Figure 4A shows that a strong anticyclonic motion over the Sahara Desert is associated with
 326 many DU AARs, consistent with the annual DU emission (Fig. 2A) and seasonal DU IAT (Fig. 1
 327 – leftmost column) over that region. Around 30 AAR days/year (shades) carry on average 3-15 x
 328 10⁻³ k gm⁻¹ s⁻¹ (vectors) of dust from the Sahara Desert over the North Atlantic Ocean and reach
 329 the southern US and the Caribbean regions. A similar number of AARs also transport aerosols
 330 towards Europe and the middle east region. A relatively high number of DU AARs are detected
 331 over China, Mongolia, and Kazakhstan; however, the mean transport over these regions by

332 AARs is lower (IAT $\sim 1 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$) than those originating from the Sahara Desert. The
333 Southern Hemispheric deserts also emit numerous AARs but with a smaller amount of dust
334 transport as the dust emission (Fig. 2A) and IAT (Fig. 1) are low over there. Overall, the Sahara
335 Desert dominates any other deserts in the world regarding the formation of the strongest and
336 most intense DU AARs.

337 Figure 4B shows the climatological maps of SS AARs. SS AARs are mostly located over the
338 global oceans, especially over the tropical and subtropical trade wind regions. The SS AARs in
339 the midlatitudes carry the signature of the storm tracks, and have distributions similar to ARs
340 (Guan and Waliser, 2015). Every year, in the midlatitude region, 30-40 ARs are detected
341 (Chakraborty et al, 2021a), whereas ~ 20 AAR days/year occur in the mid-latitudes with mean
342 IAT of $\sim 2 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$. The distributions between ARs and SS AARs are not quite the same;
343 the SS AARs are biased equatorward toward the trade winds. In comparison, tropical SS AARs
344 are more frequent but have less IAT than the midlatitude SS AARs. Around 30 SS AARs have
345 mean IAT of $\sim 1 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$ over the tropical region.

346 It is important to note SU AARs are more frequent (~ 40 days/year, Fig. 4C) in the Northern
347 Hemisphere than in the Southern Hemisphere, consistent with the predominance of emissions of
348 SO_2 over China, Europe, and the eastern US (Fig. 2C) owing to anthropogenic emissions as well
349 as biogenic activities in these regions. It is important to note that MERRA-2 aerosols data don't
350 account for biogenic sources like Carbonyl Sulfide in the version of the data we have used for
351 this study. The SU AAR hotspot regions over the Southern Hemisphere include pathways from
352 the southern edges of the global rainforests to the South Indian, South Atlantic, and Southern
353 Oceans. Mean IAT ($\sim 0.2 \times 10^{-3} \text{ kg m}^{-1} \text{ s}^{-1}$) by SU AARs is lower than that of the DU and SS
354 AARs. Many BC and OC AARs originate from the global rainforests, such as the Congo and

355 Amazon, and from the regions that are susceptible to biomass burning and CA aerosol emissions,
356 such as Europe, the eastern US, industrialized areas over eastern China, and north India.
357 Annually, 20-40 BC or OC AARs are generated from these regions. It appears that BC AARs are
358 more numerous than the OC AARs; however, OC AARs have larger IAT than BC AARs.

359 **4.3 Vertical profiles of AAR aerosol mass flux and wind**

360 To understand the anomalous atmospheric conditions that account for an AAR event, it is
361 important to know the relative contribution of the two quantities that make up these IAT
362 extremes, namely the aerosol mixing ratio and the wind speed. Also, as mentioned before, the
363 altitude of aerosol particles within AARs can be of importance due to aerosol impacts on the
364 radiation budget, convective anvil lifetime (Bister and Kulmala, 2011), cloud formation (Froyd
365 et al., 2009; Khain et al., 2008), and air quality near the surface. Here, we characterize the
366 vertical profiles of the AARs at a number of different locations with high AAR frequency (see
367 the inset map in the middle column; based on Fig. 4). For example, the orange box over the
368 Sahara-Caribbean pathway experiences a presence of 25-30 AARs per year (Fig. 4A). Based on
369 our analysis between 1997-2014, the profiles shown in Figs. 5A, 5B, and 5C shows the mean and
370 standard deviation of ~400-500 AARs.

371 It is important to keep in mind that the aerosol vertical structure in MERRA-2 is not directly
372 constrained by measurements, and are chiefly determined by the injection height of the emissions
373 as well as turbulent and convective transport processes parameterized in the model. Evaluation of
374 the vertical structure of MERRA-2 aerosols appears in Buchard et al. (2017). Buchard et al.
375 (2017) has attempted to use Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation
376 (CALIPSO) to examine the vertical structure of aerosols in MERRA-2. The left column of Fig. 5
377 shows composite vertical profiles of aerosol mass fluxes for each aerosol species; both those for

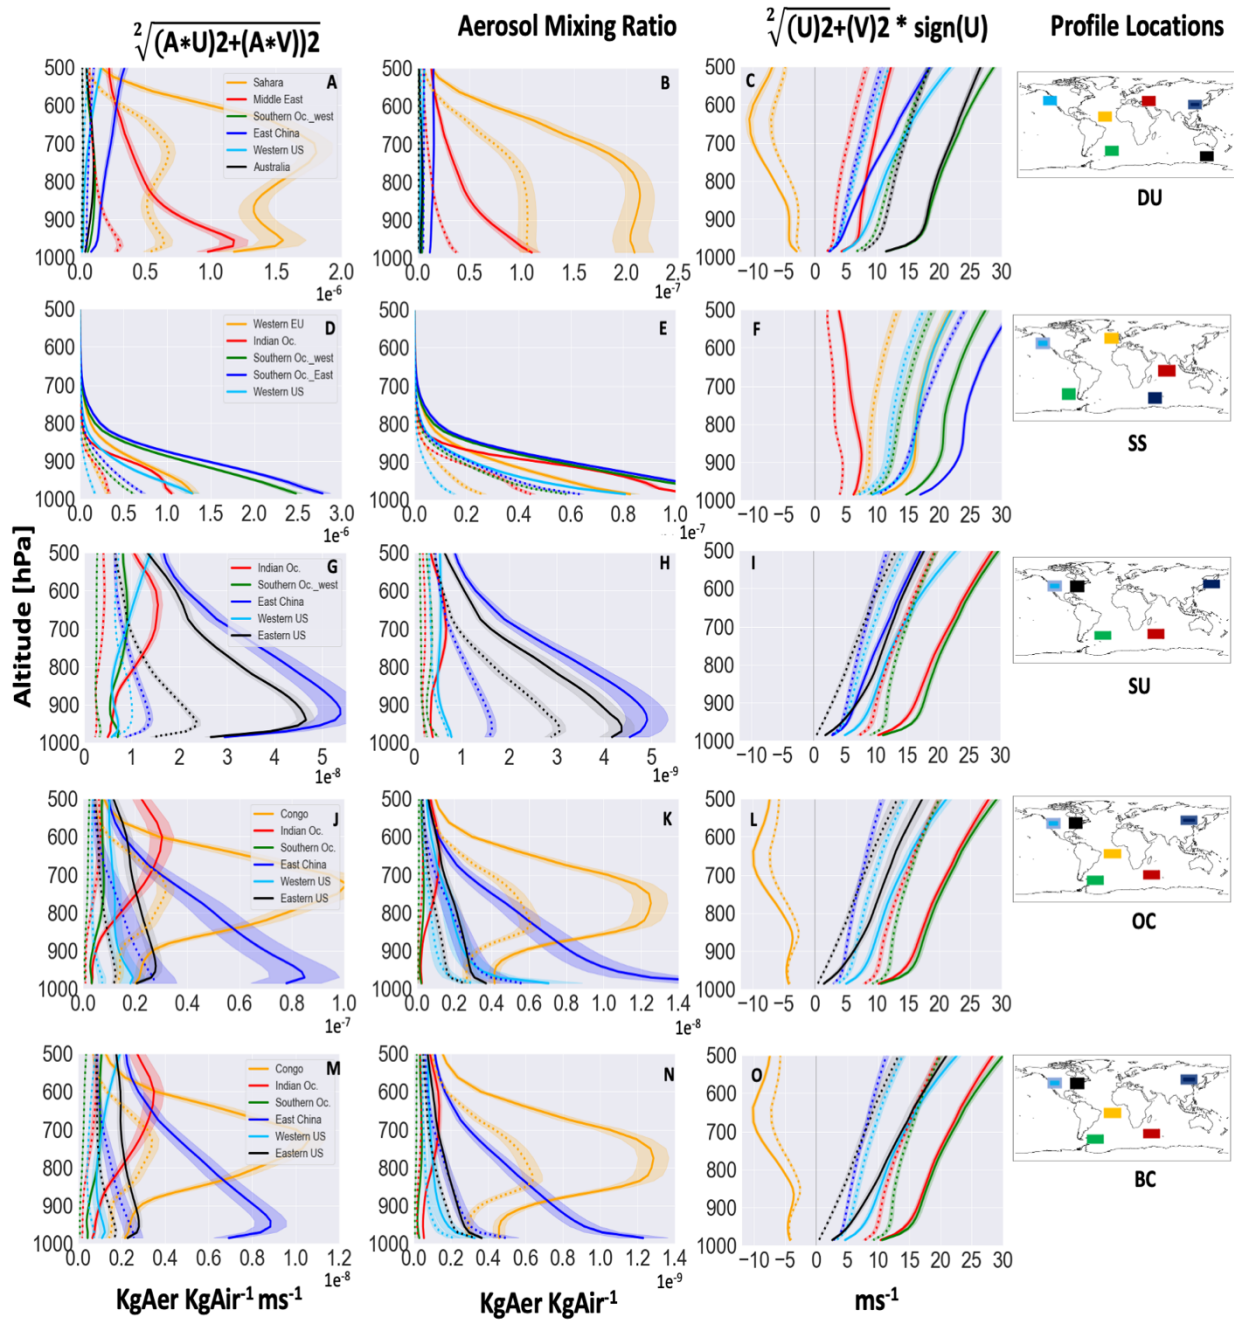

Figure 5. Average vertical profiles of (left) aerosol mass fluxes, (center) aerosols mixing ratio, and (right) wind speed over a number of locations for AAR events (solid) and All (dotted) time steps. Please see the AAR frequency maps in the inset of the middle panel for the locations chosen to calculate the profiles. In the right column, a sign convention (see column title) is used to highlight the general east-west direction of the wind speed profiles.

378 AARs (solid) and for all time steps regardless of AAR conditions (dotted) are shown for

379 comparison. Mean fluxes of the synoptic AAR events is larger than the overall annual mean over
380 all the regions, not unexpected since AARs represent the extreme transport events. For DU
381 AARs (Fig. 5A), the strongest transport is observed between the Sahara Desert and North
382 Atlantic/Caribbean (orange) as well as western Europe/middle-east (red) pathways. Flux values
383 decreases with altitude within AARs that transport aerosols from the Sahara Desert to the
384 Europe/Middle East region (red). However, AARs that transport aerosols from the Sahara Desert
385 to the North Atlantic region (orange) have peak IAT values near 750 hPa. There is also a
386 secondary peak at the 960 hPa (Fig. 5A). The aerosol mixing ratio (Fig. 5B) slightly decreases
387 from the surface up to a height of 960 hPa and then increases above it. This might suggest the
388 influence of the gravitational force and settlement on the aerosol mixing ratio as observed in
389 many of the aerosol mixing ratio profiles of other species over other regions (for example, the
390 red line showing the aerosol mixing ratio profile for the Sahara to European pathway). However,
391 a smaller peak in the wind profile (Fig. 5C) around 950 hPa indicates the influences from the
392 low-level jets and the seasonal variations of trans-Atlantic dust transport that have not been
393 studied yet. A detailed seasonal analysis is required to understand the existence of the smaller
394 peak at 960 hPa. However, the presence of the African easterly jet-north or AEJ-N above,
395 centering 600-700 hPa, further lifts the aerosols and attain a peak around 750 hPa.

396 We also show the vertical aerosol mixing ratio profiles (middle column) and the wind
397 profiles (right column) separately to help disentangle their influences on the aerosol flux profiles.
398 Given the very few globally gridded datasets to use for this purpose, we have relied on the data
399 provided in the MERRA2 data, which in this case is provided as aerosol mixing ratio. Figure 5B
400 shows that high aerosol levels inside AARs over the Sahara Desert to Caribbean pathway extend
401 vertically up to the 700 hPa with a peak around 750 hPa, unlike any other regions analyzed. The

402 third column, which shows the mean wind speed profile $\sqrt{U^2+V^2}$ multiplied by the sign of the
403 zonal wind to show the east-west direction of the AARs, confirms the influence from the AEJ-N
404 (Cook, 1999; Wu et al., 2009) on AARs' wind profile that peaks around 650 hPa and lifts
405 aerosols over this region (Fig. 4C). Higher flux values near the surface are due to a high aerosol
406 mixing ratio, but as altitude increases higher flux values inside AARs is contributed by both the
407 aerosol lifting and the high zonal wind speed of AEJ-N between the Sahara Desert and the North
408 Atlantic Ocean region. Other regions like the Southern Ocean (near South America), Australia,
409 eastern China, and western US have less aerosol mixing ratio as compared to the Sahara to the
410 North Atlantic Ocean/Caribbean and Sahara to Europe/Middle east pathways. Wind speed
411 contributes to larger flux values as altitude increases over some of these locations near eastern
412 China, the Southern Ocean, Australia, and the western US, however, their flux values are less
413 than those taking off the Sahara Desert.

414 Aerosol flux and mass mixing ratio profiles for SS species (Figs. 5D and 5E) decreases with
415 altitude. This is because the SS particles are typically found within the boundary layer (Gross
416 and Baklanov, 2007) and are larger in size, and often form due to high wind speed and surface
417 evaporation along the storm tracks and may not travel long distances outside the storm tracks
418 (Sofiev et al., 2011; May et al., 2016). The largest aerosol mixing ratio and IAT values are
419 observed over the Southern Ocean consistent with the persistent and year-round AAR activities
420 over there.

421 Consistent with the SO₂ emission (Fig. 2C), eastern China (blue line) dominates in terms of
422 SU aerosol mass mixing ratio by a factor of 5 as compared to the other regions (Fig. 5H)
423 analyzed and shown here. The aerosol mixing ratio (Fig. 5H) and the flux values (Fig. 5G)
424 increase with height, attain a peak around 900 hPa over there, probably exhibiting the impact of

425 the boundary layer inversion effect on the accumulation of the pollutants (Li et al., 2017b).
426 Above 900 hPa, both the aerosols mass mixing ratio and flux values gradually decrease.
427 However, SU aerosol mass mixing ratio decrease when those AARs reach the western US by 5
428 times (Figs. 5H). Owing to the fact that the eastern US originates many SU AARs than can
429 contribute to a transatlantic transport driven by strong westerly winds, we have also computed
430 the IAT profiles of SU AARs generated over there. Figures 5G and 5H show that AARs over the
431 eastern US Also have a high IAT (Fig. 5G) and aerosol mass mixing ratio (Fig. 5H). Flux
432 profiles and aerosols mixing ratio over the Indian Ocean (red) and Southern Ocean (green) show
433 different behavior. Aerosols appear to be continental in origin and are lifted to attain a peak
434 concentration around 650 hPa. Contribution from wind speed (Fig. 5I) as compared to aerosol
435 mixing ratio (Fig. 5H) appears to be less on the SU flux profiles (Fig. 5G) since the wind speed
436 associated with AARs is the highest over the Indian and Southern Ocean, but the largest flux
437 values are associated with the AARs over the eastern China region which have the largest
438 aerosol mass mixing ratio.

439 Next, we examine the vertical profiles of CA AARs over the Congo basin, the western US,
440 the eastern China, the Indian Ocean, and the Southern Ocean. As in the case of dust aerosols over
441 the Sahara Desert to North Atlantic transport pathway (Fig. 5A, orange line), both the OC and
442 BC AARs off the Congo basin show elevated flux values around 700 hPa (Figs. 5J and 5M). It is
443 to be noted that the wind speed within AARs peaks around 650 hPa – suggesting the influence
444 from the AEJ-South (Adebiyi and Zuidema, 2016; Chakraborty et al., 2021b; Das et al., 2017) on
445 the AARs' wind profile (Figs. 7K and 7N) that might be responsible for the peaks in the aerosol
446 mixing ratio profiles around 750 hPa (Figs. 5L and 5O) instead of the exponential profiles as
447 observed in most of other regions. AARs over eastern China (blue) also carry a large amount of

448 near-surface aerosol particles that contribute to large BC and OC IAT values in this region.
449 However, when those AARs reach the western US, the amount of BC and OC aerosol mass
450 mixing ratio significantly decreases by ~ 8 times, presumably because of the settlement and
451 removal of the aerosol particles during the transport. As compared to SU AARs, the IAT values
452 and aerosol mass mixing ratio of OC and BC AARs over the eastern US is significantly lower
453 (3-4 times less) than those originating from China and the Congo rainforest. Wind speed appears
454 to have less influence on the flux profiles since the Indian Ocean and the Southern Ocean has the
455 largest (smallest) wind speed (flux values) associated with the AARs.

456 **4.4 Fraction of total annual transport accounted for by AARs**

457 It is apparent from Figure 5 that the mean IAT averaged over AAR time steps is greater than
458 the mean IAT averaged from all time steps. This is not surprising since AARs detected by our
459 algorithm represent the extreme transport events (see Section 2 for definition and methodology).
460 Considering that the original analysis on water vapor ARs (Zhu and Newell, 1998) highlighted
461 that 90% of the poleward transport of water vapor in the midlatitudes occurred in a relatively
462 small number of extreme transport events (i.e. ARs), a similar question can be raised here for
463 AARs. Specifically, what fraction of the total annual aerosol transport is accounted for by the 20-
464 40 AAR days that occur each year on average (Fig. 4)? Also, do AARs transport a higher
465 fraction of the total global annual transport over the major aerosol transport pathways, and is this
466 dependent on aerosol species? In Figure 6, we show the fraction of total annual IAT accounted
467 for by AARs (shades), counting only the component of AAR transport in the direction of the
468 total annual transport (arrows). Figure 6A shows that annually, ~ 40000 - 100000 kg m^{-1} of DU
469 IAT is transported by All events (i.e. considering all data points in the record) that originate from
470 the Sahara Desert. Near the equator, the fractional transport by AARs (F_{AAR}) is around $\sim 20\%$

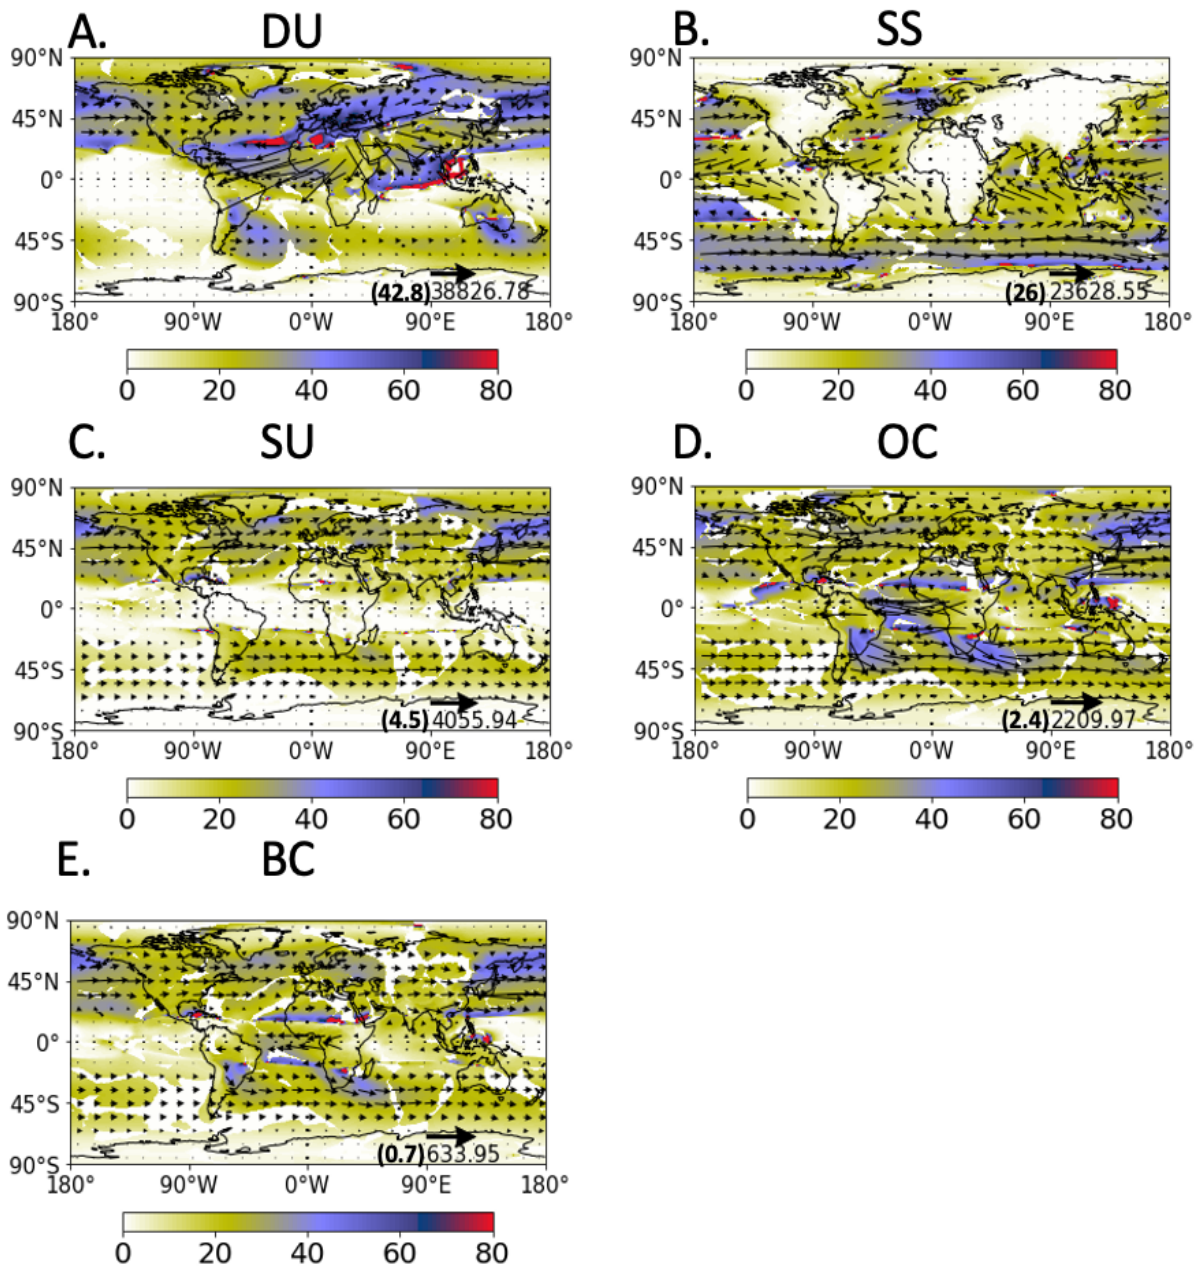

Figure 6. Fraction of annual total IAT transport (arrows; (tons) kg m^{-1}) accounted for by AARs (%) (shading) of five different aerosol species.

471 over the Atlantic Ocean in the direction of the Amazon rainforest (Fig. 6A), which is realized
 472 within ~ 30 AAR days per year (see Fig. 4A). In this same longitude sector, F_{AAR} gradually
 473 increases with latitude and reaches up to 80% around $35^\circ\text{-}40^\circ\text{ N}$ where AARs act to transport

474 dust from the Sahara Desert to Europe and the middle-east region. Over Mongolia and China, the
475 total annual IAT is $\sim 20000\text{-}40000\text{ kg m}^{-1}$ and about 30-40 AAR days per year (Fig. 4A)
476 contribute up to $\sim 40\text{-}50\%$ of that transport. In the Southern Hemisphere, Patagonia and South
477 American drylands give rise to $\sim 4000\text{ kg m}^{-1}$ of annual dust transport and AARs contribute to a
478 maximum of 20-40% of that transport in about 20-30 AAR events per year (Fig. 4A). Over some
479 regions far from the dust source region, such as over the maritime continent, the annual IAT
480 value is very less by All events (Fig. 6A). About 5 AARs (shading, Fig. 4A) with very small
481 object-mean IAT values (arrows, Fig. 4A) are observed over there each year. It appears that
482 although AARs are not frequent (~ 5 AARs/year) over there, they are responsible for 80-100% of
483 the total annual transport.

484 SS AARs are far more frequent over the oceans than over the land, (Figure 4B) with peak
485 frequencies of about 30 AAR days per year occurring over the subtropical trade wind regions,
486 Southern Ocean and northern Atlantic Ocean. In these regions, the total annual IAT is about
487 $10000\text{-}20000\text{ kg m}^{-1}$, and F_{AAR} is about $\sim 20\text{-}30\%$ in the subtropical regions, reaching a maximum
488 of $\sim 50\%$ over the Southern Ocean and the North Atlantic Ocean (Fig. 6B).

489 AARs for other species of aerosols can contribute to a maximum of 40% of the total annual
490 IAT over their major transport pathways. For example, the ~ 30 SU AAR days per year that
491 originate over China (Fig. 4C) transport $\sim 30\text{-}40\%$ of the total annual aerosol transport ($\sim 2500\text{ kg}$
492 m^{-1}) over the northern Pacific Ocean. F_{AAR} associated with OC (BC) AARs is reaches a maximum
493 of 40% (30%) between the Congo basin and the tropical Atlantic Ocean. Over China and the
494 North Pacific Ocean, South Africa and the Southern/Indian Oceans, south China and the west
495 Pacific Ocean, and Amazon and the South Atlantic Ocean/Southern Ocean F_{AAR} can reach up to a

496 maximum of 40%. Higher F_{AAR} is also observed, despite low total annual IAT, over the northern
497 part of the Sahel region for both BC and OC AARs.

498 **4.5. AAR seasonality**

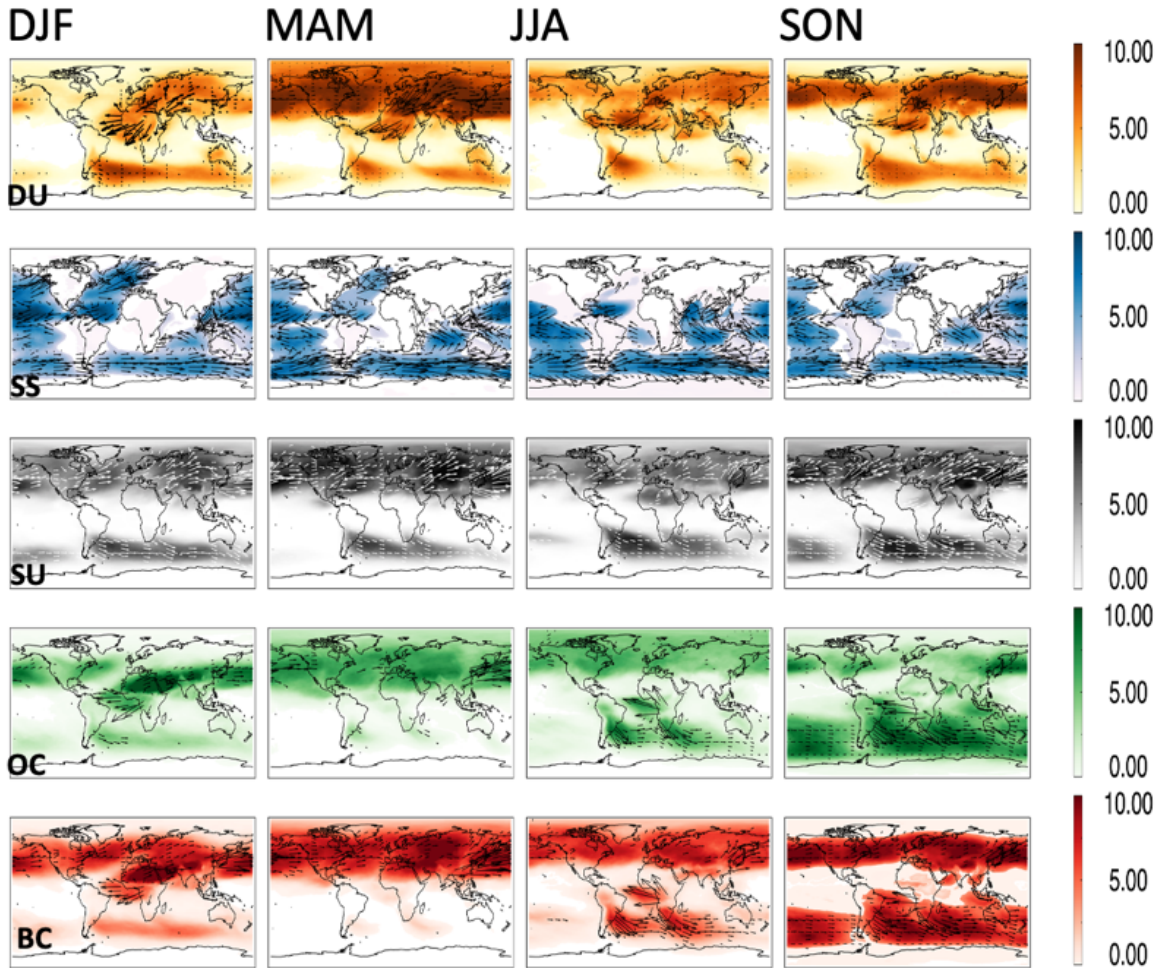

Figure 7. Seasonal variations of AAR frequency (days/season) and IAT (arrows) for five different species of aerosols.

499 Figure 7 shows AAR frequency along with the direction and magnitude of the mean AAR
500 IAT during four different seasons. DU AARs (shading) originate during all the seasons over the
501 Sahara Desert. DU AAR IAT (arrows) is higher during DJF and MAM over the Sahara Desert
502 owing to a stronger anticyclonic motion in the boreal winter and spring. The largest number of
503 DU AARs are generated during the MAM season when the DU IAT is the highest (Figure 1) and

504 widely spread across the Northern Hemisphere. In JJA and SON, DU AARs appear to have
505 lower IAT (shorter arrows), but are more frequent than in the DJF season. The frequency of SS
506 AARs also depends on the season. A higher number of SS AARs are detected over the eastern
507 Pacific Ocean and the west coast of the US, north Atlantic Ocean, and Europe in DJF and MAM.
508 In JJA, no SS AARs are detected over there. Over the Southern Ocean, SS AARs with large IAT
509 are more frequent during austral winter or MAM and JJA. In comparison, tropical SS AARs are
510 present year-round.

511 SU AARs in the Northern Hemisphere are more (less) frequent in MAM (JJA) and can be
512 related to the seasonal variations in IAT there (Figure 1). The frequency of occurrences of SU
513 AARs is higher during SON compared to DJF while their IAT values are larger in DJF. This
514 might be because of the readiness of sulfate aerosols to form CCNs and their hygroscopic nature.
515 The occurrences of intense AR-related precipitation in DJF over the extratropical region in the
516 Northern Hemisphere might cause scavenging and wet removal of SU aerosols when the AARs
517 and ARs coexist. A detailed investigation considering AR-AAR interactions is needed in future
518 studies to better understand the coexistence and influence of AARs and ARs.

519 Over the Congo rainforest, several OC AARs occur during its dry season (also when CA
520 IAT is high, Fig. 1). A similar frequency of occurrences of OC AARs is also observed during the
521 dry season over the Amazon rainforest. Many OC AARs occur east of China during the DJF and
522 MAM season when the IAT values are large over there (Fig. 1). Many BC and OC AARs are
523 generated over the global rainforests during their dry seasons.

524 **4.6 Basic characteristics of individual AARs and algorithm sensitivities**

525 In this section, we characterize basic features of AARs (Fig. 8), including those related to
526 geometry and IAT intensity and directions, and discuss and show the sensitivity of various AAR

AAR Characteristics ; ★ Mean

Figure 8. Histograms of characteristics of individual AARs. The “★” symbol denotes the mean. (A) Length. (B) Width. (C) Aspect ratio. (D) Magnitude of mean IAT. (E) Coherence of the IAT direction. (F) Direction of mean IAT.

527 features to algorithm specifications and thresholds (Fig. 9). Fig. 8A shows that the frequency of
 528 AARs decreases monotonically as AAR length increases for all aerosol species. The mean
 529 lengths of DU, SS, SU, OC, BC AARs are 4264 km, 3722 km, 4121 km, 4528 km, and 4378 km,
 530 respectively. Fig. 8B shows that AAR widths exhibit a skewed distribution, unlike AAR lengths,
 531 implying an optimum or common value for AAR widths around 400 km. The mean width of DU,
 532 SS, SU, OC, BC AARs is 586 km, 642 km, 542 km, 625 km, and 589 km, respectively. When

533 considered together in the form of the aspect ratio of AARs, i.e., length/width ratio, the
534 distribution is also a skewed distribution (Fig. 8C). The lengths typically 7-8 times their widths
535 due to the skewness of the distribution. DU and SS AARs are the two species having the largest
536 object-mean IAT values (Fig. 8D). While on average, DU AARs have IAT ~ 1.65 and 1.3×10^{-3}
537 $\text{kg m}^{-1} \text{s}^{-1}$, respectively, SU, OC, and BC AARs have smaller IAT (Fig. 8D). Average object-
538 mean IAT for SU, OC, and BC AARs are 0.1, 0.1, and $0.016 \times 10^{-3} \text{ kg m}^{-1} \text{s}^{-1}$, respectively. The
539 frequency of object-mean IAT for BC AARs decreases sharply and seldom reaches beyond $0.1 \times$
540 $10^{-3} \text{ kg m}^{-1} \text{s}^{-1}$. SU (OC) AARs attain a maximum object-mean IAT values around $0.1 \times 10^{-3} \text{ kg}$
541 $\text{m}^{-1} \text{s}^{-1}$ with a maximum frequency of ~ 0.6 (0.4).

542 The coherence of IAT directions (Fig. 8E) is computed as a fraction of the number of grid
543 cells with IAT directed within 45° of the direction of the object-mean IAT to all the grid cells
544 within that AAR. A large value implies that a larger fraction of the grid cells has IAT directed in
545 the same overall direction as the AAR. AARs of all the species have the mean coherence of IAT
546 directions between 0.91 (DU) and 0.94 (SU). The distribution of the direction of the object-mean
547 IAT implies that the AARs are mostly directed in the zonal direction (Fig. 8F). Relative to North,
548 peak frequencies near 90° and between 250° - 310° imply that the AARs are either westerly or
549 easterly in nature. A few westerly AARs also transport aerosols in the northeastward (45° - 90°)
550 and southeastward (90° - 135°) directions. A wider peak between 250° - 310° implies that most of
551 the easterly AARs also have meridional components in the southwestward and northwestward
552 directions. The average values of object-mean IAT direction for all the species of AARs are $\sim 90^\circ$
553 (westerly) and between 260 - 270° (easterly). These results show that the AARs mostly transport
554 aerosols in the zonal direction as compared to ARs that have notable transport of water vapor in
555 the meridional direction (Guan and Waliser, 2015).

Figure 9. Sensitivity of AAR detection to threshold values used for three key parameters (corresponding to the three columns; see legend for the parameter being tested and the three values chosen for each test parameter) in the detection algorithm for five aerosol species (corresponding to the five rows; see panel title for the aerosol species). Shown are histograms of mean IAT of individual AARs detected. For example, the left column shows results based on perturbing the IAT percentile threshold (85th, 90th, and 95th percentiles) while keeping the length (2000 km) and aspect ratio (2) thresholds unchanged from the main analysis presented earlier.

556 Finally, Figure 9 shows the sensitivity of AAR detection in our algorithm to three primary

557 thresholds that define the geometry (length and aspect ratio) and grid-wise IAT limits (to identify
558 the extreme transport) of AARs. The results presented above in this study are based on a length
559 limit of 2000 km, aspect ratio limit of 2, and a pixel-wise IAT limit of the 85th percentile.
560 Keeping the length and aspect ratio limits fixed, while increasing the IAT limit to the 90th and
561 95th percentile values, yields fewer number of AARs detected (top row). On the other hand,
562 relaxing the length limit to 1750 km and 1500 km greatly increases the number of AARs
563 detected (middle row). Relaxing the aspect ratio limit to 1.5 and 1 does not significantly alter the
564 number of AARs detected, suggesting that the other limits applied (such as length greater than
565 2000 km) already effectively removes IAT objects that are not elongated. It appears from Figure
566 9 that grid-wise IAT thresholds pose a large sensitivity to AARs detection as the number of
567 AARs detected is reduced roughly by half as we increase that threshold to the 95th percentile
568 from the 85th percentile used in our main analysis.

569 Figure 10 shows the sensitivity of the average global area coverage of all AARs to AAR
570 algorithm parameters. Each bar represents the area-weighted global mean AAR frequency or a
571 spatial-temporal measure of the amount of time/space that there is an AAR. Annually, AARs
572 cover 3.42 % of the global area, respectively. Upon relaxing the length limits to 1750 (1500) km
573 increases the number of detections of AARs, thus the areal coverage of AARs increases to 3.56%
574 (3.76%). On the other hand, increasing the pixel-wise IAT limit to 90th and 95th percentile
575 reduces the areal coverage to 2.44% and 1.13%, respectively. Relaxing the aspect ratio doesn't
576 have any impact on AAR's areal coverage. ARs, on the other hand, account for ~2% more of the
577 Earth's surface area than AARs (not shown), likely because the filter based on object-mean
578 IVT direction in the AR algorithm preferentially filtered out smaller objects compared to the
579 revised filter in the AAR algorithm based on IAT magnitude.

Figure 10. Sensitivity of AARs' and ARs' global area coverage to threshold values used for three key parameters in the detection algorithm. For each species of AARs, the first bar shows the average global area coverage for the length limit >2000, aspect ratio > 2, and the pixel-wise IAT threshold >85%. Next two bars show the areal coverage after relaxing the length limit to 1750 and 1500 km. The fourth and the fifth bar shows the areal coverage after increasing the pixel-wise IAT limit to 90th and 95th percentile. The last two bars show the areal coverage after relaxing the aspect ratio to 1.5 and 1. Standard deviations show the variations in areal coverage by different species.

580

581 5. Conclusions

582 Using a newly developed AAR algorithm (Chakraborty et al, 2021a) based on the widely used

583 AR detection algorithm (Guan and Waliser, 2015), we examine a number of important details

584 about AARs that were not explored in Chakraborty et al. (2021a). This includes AAR seasonal

585 variations in frequency and transport values (Fig. 7), the fraction of total annual aerosol transport

586 account for by AARs (Fig. 6), a characterization of their vertical profiles (Fig. 5), relation to the

587 pattern of surface emissions (Fig. 2), along with a number of basic characteristics and

588 distributions for quantities such as AAR length, aspect ratio, object-mean IAT, the coherence of

589 the direction of IAT (Fig. 8), and sensitivities of the algorithm to the thresholds chosen for three

590 key parameters (Fig.9). To our knowledge, this study significantly advances the understanding of

591 global aerosol transport events. This study is the first to provide a common detection and
592 analytical basis for studying extreme transport events, heavily leveraging the heritage and
593 methodologies by the (water vapor) atmospheric river community. Moreover, this study
594 identifies the extreme transport events by selecting grid cells with IAT values greater than the
595 85th percentile of their climatological values and retaining the stronger 50% of those objects
596 detected based on the object-mean IAT values. This study creates a database of the AAR events
597 between 1997-2014 that will be expanded till 2020 and will provide a valuable platform for
598 aerosol transport-related research including their impacts on the climate and air quality.
599 Furthermore, the algorithm developed to detect AARs can be used to detect the real-time AAR
600 events using the nature run of the GOES FP system that provides analyses and forecasts
601 produced in real-time, using the most recent validated GEOS system
602 (https://gmao.gsfc.nasa.gov/GMAO_products/NRT_products.php).

603 The global total annual transport by All and AAR events are inhomogeneous in terms of their
604 geographic distributions. F_{AAR} varies between 0-40% for SU, OC, and BC AARs, between 0-80%
605 for DU AARs, and between 0-50% for SS AARs over various regions of the world. Our results
606 show that on average, 30-40 SU, BC, and OC AAR days every year are responsible for a
607 maximum of 30-40% of total annual aerosol transport for a given aerosol species over certain
608 major transport pathways around the globe. Over the major transport pathways of the SS (DU)
609 AARs, F_{AAR} can reach up to a maximum of 50 (80) % of the total annual aerosol transport of the
610 respective species. The inhomogeneous nature of AARs' spatial distribution and fractional
611 transport out of the annual total suggest a plausible impact of the AARs on the meridional
612 temperature gradient. The attenuation of solar energy by AARs might impact the surface
613 temperature, thus can alter the meridional temperature gradient and the thermal winds. Further

614 analysis will be conducted in the future to delineate the impacts of AARs on the global weather
615 and climate.

616 The major transport pathways by AARs are also identified in our algorithm for each of the
617 aerosol species. The source of AARs is consistent with the major aerosol emission regions of the
618 world. DU aerosols are mostly originated from the global deserts and their frequency is higher
619 during boreal autumn and spring. SS AARs are mostly located over the global oceans and carry
620 the footprint of the storms. In the midlatitudes their frequency and intensity increase during the
621 boreal (austral) winter in the Northern (Southern) Hemisphere. Tropical SS AARs are more
622 frequent, but their magnitude of aerosol transport and contribution to the annual aerosol transport
623 is less. A further investigation is needed to understand if/how tropical cyclones and midlatitude
624 storms impact SS AARs differently. CA AARs are generated over the region where biomass
625 burning is more common like India and China. CA AARs that originate from the global boreal
626 and tropical rainforests have the highest frequency as well as intensity during their dry seasons,
627 but are mostly absent or exist with a reduced frequency during their wet seasons. SU AARs are
628 present year around in the northern hemisphere with a peak frequency and intensity during the
629 dry periods-boreal spring (MAM) and autumn (SON). The frequency of SU AARs occurrences
630 reduces during the boreal summer and winter, presumably due to the summertime convective
631 precipitation events and wintertime synoptic storms. Overall, regions with frequent AAR
632 activities include the Sahara Desert to Caribbean and Europe for DU AARs, a circumpolar
633 transport around the midlatitude region in the northern hemisphere for all but SS AARs, global
634 oceans and midlatitude storm tracks over the global ocean for SS AARs, global rainforests for
635 BC and OC AARs, and from South America and Africa to the Southern Ocean for DU, BC, OC,
636 and SU AARs.

637 We have also examined the vertical structure of aerosol mixing ratio and wind inside AARs.
638 Over most of the major pathways, aerosol mixing ratio and flux values decrease with height. A
639 higher aerosol mass mixing ratio inside AARs is observed below the 700 hPa over most of the
640 regions and thus, may have a strong implication on the low cloud cover and surface irradiance.
641 Such an interaction can be complex since shallow clouds also have cooling effects as most of the
642 aerosol species do. Understanding such an interaction between shallow clouds and AARs and
643 their impacts on the cooling effect warrants further investigation. The aerosol mixing ratio (wind
644 speed) appears to contribute a large fraction of IAT below (above) 700 hPa. However, AARs
645 generated from the African continent are the exceptions. Signatures of AEJ-N on DU AARs
646 taking off the Sahara Desert and AEJ-S on BC/OC AARs originated from the Congo basin are
647 observed. Both the aerosol mixing ratio and wind speed appear to peak around 600-700 hPa,
648 leading to a higher IAT at the level. The fact that aerosols are lifted up and attain a peak mass
649 flux around the 700 hPa for AARs generated from the African continent might have a strong
650 influence on the wet season onset and rainfall mechanisms over there (Chakraborty et al.,
651 2021b). We acknowledge a source of uncertainty in the aerosol mass mixing ratio and IAT
652 profiles shown in this study from the MERRA-2 data since MERRA-2 aerosol vertical
653 distribution is also not constrained by satellite-based lidar observations. A recent study found
654 that comparison to the CALIOP VFM data detects a greater occurrence of DU aerosols in
655 MERRA-2 due to errors in MERRAero aerosol speciation (Nowotnick et al., 2015). In a future
656 study, an in-depth analysis will be performed using the observation from the ground-based and
657 air borne measurements (wherever available) and CALIPSO. For example, ORACLES mission
658 and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation can be used to study

659 the subsidence that depresses the plumes once they reach the Atlantic Ocean off the west African
660 Coast (Das et al., 2017).

661 AAR frequency of occurrence decreases monotonically with its length with the mean around
662 4000 km. However, AAR width and aspect ratio show a skewed distribution. AAR length is, on
663 average, 6-8 times the width. DU and SS AARs carry a larger amount of aerosol mass as
664 compared to SU, OC, and BC aerosols. More than 90% of all the grid cells within an individual
665 AAR have IAT directed in the same overall direction of the AAR, showing that the transport
666 occurring inside an individual AAR is largely coherent in direction. AARs are mostly oriented in
667 the zonal direction. A peak frequency of the direction of object-mean IAT is observed between
668 45° - 135° (westerly AARs) or 225° - 315° (easterly AARs). Large mean width and length (Figure
669 8A and 8B) of AARs imply that AARs have a significant amount of areal cover. AARs also
670 transport a higher aerosol mass mixing ratio, located mostly in the lower troposphere, to regions
671 far from their sources – often intercontinental 20-40 days per year on average. Our findings, thus,
672 indicate the necessity of exploring the impacts of AARs on human health since smoke as well as
673 dust particles and the secondary aerosol particles that can be generated over the AAR lifetime
674 might have a huge impact on human health, especially on lungs. The algorithm shows little to no
675 sensitivity to the aspect ratio limit chosen, but notable influence of the length limit, and strongest
676 influence of the IAT percentile limit on the detection result.

677 This study points out the necessity to analyze and investigate the impact of AARs on climate
678 and air quality. The fact that AARs can carry a greater number of aerosol particles through a
679 narrow pathway and probably can contain more aerosol particles than a moderate-high AOD
680 region suggests that their impact on radiative forcing and cloud microphysics can be stronger
681 than that have been reported and investigated so far in the literature. We have not addressed the

682 role of climate modulation on AAR activity and characteristics. Events like El Niño, La Niña,
683 Pacific Decadal Oscillation, North American Subtropical High, Madden-Julian Oscillations can
684 have a significant influence on AARs and will be addressed in future studies. A further
685 investigation is needed on the AR and AAR interaction and how ARs and cyclonic activities
686 modulate AARs in the midlatitude during the winter season of each hemisphere.

687 **Author Contribution:**

688 SC, BG, DW, and AMS designed the research and wrote the paper. SC analyzed the data.

689 **Competing Interests:**

690 The authors have no competing interests.

691 **Data and Code Availability**

692 All satellite data used in this study can be downloaded at the EOSDIS Distributed Active
693 Archive Centers (DAACs) at <https://earthdata.nasa.gov/eosdis/daacs>. References about the
694 datasets have been provided in the Data section (Sect. 2). Please contact the corresponding author
695 for any questions about how to download the data that are publicly available and codes written in
696 IDL and Python. The AAR data set will be made publicly available after the publication. The AAR
697 code is available from B.G. on request.

698 **Acknowledgements:**

699 This work was supported by the National Aeronautics and Space Administration. The
700 contribution of S.C. and D.W. was carried out on behalf of the Jet Propulsion Laboratory,
701 California Institute of Technology, under a contract with NASA. All the data are publicly
702 available and free to download. Please see reference section for the citations to all the data sets
703 used in this study. Also, details about the dataset have been included in the supplementary
704 section.
