## 17 18 **Abstract:**

19 Peroxyacetyl nitrate (PAN) acting as a typical indicator of photochemical pollution can redistribute  
20 NO<sub>x</sub> and modulate O<sub>3</sub> production. Coupled with the observation-based model (OBM) and a generalized  
21 additive model (GAM), the intensive observation campaigns were conducted to reveal the pollution  
22 characteristics of PAN and its impact on O<sub>3</sub>, the contributions of influencing factors to PAN formation  
23 were also quantified in this paper. The F-values of GAM results reflecting the importance of the  
24 influencing factors showed that ultraviolet radiation (UV, F-value=60.64), O<sub>x</sub> (O<sub>x</sub>=NO<sub>2</sub>+O<sub>3</sub>, 57.65), and  
25 air temperature (T, 17.55) were the main contributors in the PAN pollution in spring, while the significant  
26 effects of O<sub>x</sub> (58.45), total VOCs (TVOCs, 21.63) and T (20.46) were found in autumn. The PAN  
27 formation rate in autumn was 1.58 times higher than that in spring, relating to the intense photochemical  
28 reaction and meteorological conditions. Model simulations revealed that acetaldehyde oxidation (46±4%)  
29 contributed to the dominant formation pathway of PA (hence PAN), followed by methylglyoxal oxidation  
30 (28±3%) and radical cycling (19±3%). The PAN formation was highly VOC-sensitive, as surplus NO<sub>x</sub>  
31 (compared with VOCs abundance) prevented NO<sub>x</sub> from being the limiting factor photochemical  
32 formation of secondary pollution. At our site, PAN promoted and inhibited O<sub>3</sub> formation under high and  
33 low RO<sub>x</sub> levels, respectively. The PAN promoting O<sub>3</sub> formation mainly occurred during the periods of  
34 11:00-16:00 (local time) when the favorable meteorological conditions (high UV and T) stimulated the  
35 photochemical reactions to offer RO<sub>x</sub> radicals, which accounted for 17% of the whole monitoring periods  
36 in spring and 31% in autumn. The analysis of PAN formation mechanism and its positive or negative

37 effect on ozone [provided scientific insights into](#) photochemical pollution [mechanism under various](#)  
38 [pollution scenarios](#) in coastal areas.

## 44 **1 Introduction**

45 Peroxyacetyl nitrate ( $\text{CH}_3\text{C}(\text{O})\text{O}_2\text{NO}_2$ , PAN) is a key product of photochemical smog (Penkett and  
46 Brice, 1986; Li et al., 2019). PAN is generated through photochemical reactions of precursors emitted by  
47 human activities only, and the atmospheric PAN is a reliable and scientific indicator of photochemical  
48 pollution (Lonneman et al., 1976; Han et al., 2017). In the surface atmosphere, the level of PAN is much  
49 lower than that of ozone ( $\text{O}_3$ ), but its biological toxicity is about one or two magnitudes greater than that  
50 of  $\text{O}_3$  (Temple and Taylor, 1983). Additionally, PAN acts as a temporary reservoir for  $\text{NO}_x$  and radicals,  
51 and can transport to remote regions to redistribute  $\text{NO}_x$  and intervene in  $\text{O}_3$  production at regional or even  
52 global scale (Kleindienst, 1994; Atkinson et al., 2006; Fischer et al., 2010).

53 The reaction of peroxyacetyl radical ( $\text{CH}_3\text{C}(\text{O})\text{O}_2$ , PA) with  $\text{NO}_2$  is [the only](#) formation pathway of  
54 PAN (Han et al., 2017; Xue et al., 2014). PAN affects radical chemistry and modulates  $\text{O}_3$  production  
55 mainly by affecting PA radical, which is one of the most abundant organic peroxy radicals in the  
56 troposphere (Tyndall et al., 2001). Only a small group of oxygenated volatile organic compounds (OVOCs)  
57 (i.e. acetaldehyde ( $\text{CH}_3\text{CHO}$ ), methacrolein (MACR), methyl vinyl ketone (MVK), methyl ethyl ketone  
58 (MEK), and methylglyoxal (MGLY)) can directly produce PA radical to generate PAN (Xue et al., 2014;  
59 Zhang et al., 2015). [A large proportion of](#) these OVOCs (the second-generation precursors of PAN) are  
60 mainly transformed by oxidation reactions from some hydrocarbons such as ethane, propene, isoprene,  
61 and aromatics (the first-generation precursors of PAN) (Xu et al., 2021; [Qian et al., 2019](#)). The main and  
62 direct PAN destruction is thermal decomposition, and the indirect sinks of PAN were the reactions of PA  
63 with  $\text{NO}$ ,  $\text{HO}_2$ , and  $\text{RO}_2$  (Wolfe et al., 2014; Zeng et al., 2019).

64 Some studies on the distribution and sources of PAN have been conducted in urban, suburban, and  
65 remote regions around the world (Grosjean et al., 2002; Marley et al., 2007; Roberts et al., 2001). The  
66 PAN levels in cities are higher than that in rural and remote areas, and that in background areas such as  
67 oceans and mountains can be as low as tens of pptv (Gaffney et al., 1999; Moore et al., 2009). Despite the  
68 growing concerns about photochemical pollution in China, PAN measurements and analysis of its

69 photochemical mechanism are still sparse (Zeng et al., 2019). At present, the observations of PAN were  
70 mainly distributed in Beijing, Guangzhou, and Hong Kong (Xue et al., 2014; Yuan et al., 2018; Zeng et  
71 al., 2019). Xue et al. (2014) reported that anthropogenic VOCs were the most important precursors of  
72 PAN in urban areas, and isoprene was the predominant precursor in suburban regions. In Zeng et al. (2019)  
73 study, carbonyls were the most significant contributors to PAN production, followed by aromatics and  
74 BVOCs. In addition, some researchers found that atmospheric PAN suppressed local O<sub>3</sub> formation in  
75 autumn (Zeng et al., 2019). Recently, negative and positive impacts of PAN photochemistry on O<sub>3</sub>  
76 production were captured under the low and high NO<sub>x</sub> conditions, respectively (Zeng et al., 2019; Liu et  
77 al., 2021). However, the PAN formation and its influencing mechanism on O<sub>3</sub> production are still complex  
78 and unclear (Hu et al., 2020; Zhang et al 2019; Xu et al., 2018). Long-term field measurements and model  
79 simulations could help to verify the mechanisms under various pollution scenarios and environmental  
80 conditions.

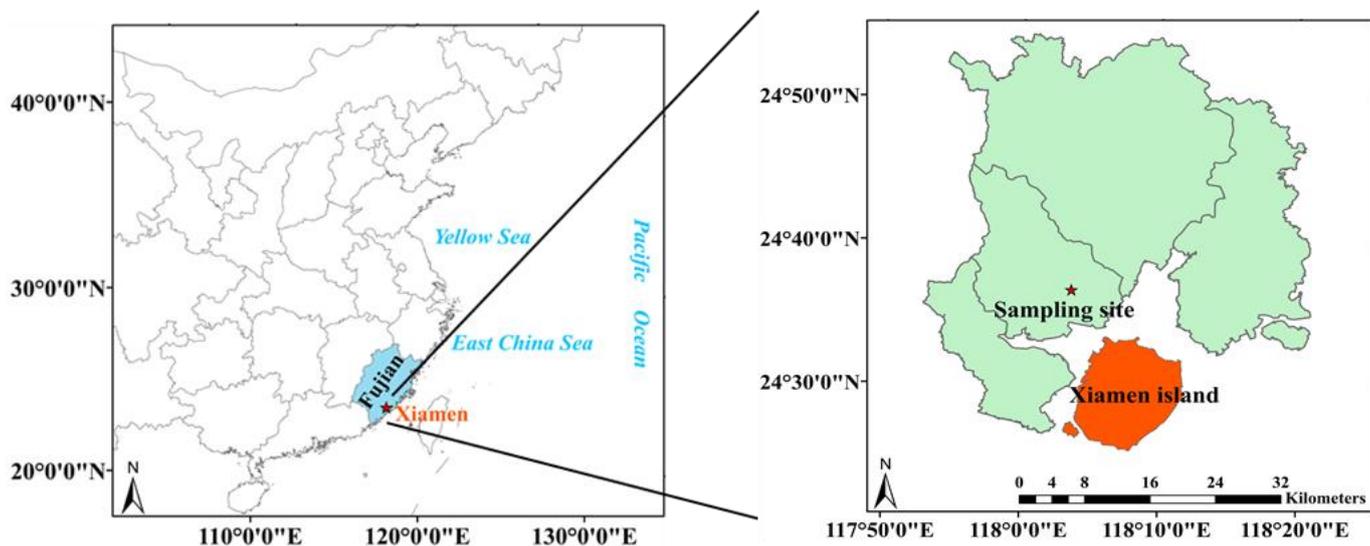

81 Xiamen is located in the coastal region of Southeast China under the East Asian monsoon control,  
82 belonging to the subtropical marine climate (Liu et al., 2020a; Liu et al., 2020b). In spring, north cold  
83 airflow and south warm airflow formed the quasistationary front causing atmospheric stagnation. In  
84 autumn, under the control of the west pacific subtropical high (WPSH), favorable meteorological  
85 conditions enhanced the formation and accumulation of photochemical pollutants (Wu et al., 2020). Our  
86 previous studies focused on the occurrence and pollution characteristics of PAN (Hu et al., 2020). In this  
87 study, an observation-based model coupled to the Master Chemical Mechanism (OBM-MCM) was used  
88 to better understand PAN photochemistry in spring and autumn, and a generalized additive model (GAM)  
89 was adopted to quantify the complex nonlinear relationships of PAN with its precursors and  
90 environmental factors (Hua et al., 2021). The study aims to explore (1) the PAN formation mechanism  
91 and sensitivity analysis, (2) the impacts of PAN on O<sub>3</sub> formation and radical chemistry, (3) the relationship  
92 between PAN and influencing factors under different pollution scenarios.

93

## 94 **2 Materials and methods**

### 95 **2.1 Observation site**

96

97  
98  
99 **Fig. 1. Location of Xiamen and the observation site.**

100 Observations were carried out at the Atmospheric Environment Observation Supersite (AEOS, 24.61°  
101 N, 118.06° E; Fig. 1), located on the rooftop of around a 70 m high building in the Institute of Urban  
102 Environment, Chinese Academy of Sciences. The observations site is surrounded by highways,  
103 educational institutions, and residential buildings, which was characterized by rapidly urbanizing  
104 development area. When the prevailing wind direction was southerly winds, our observation site is  
105 downwind of the densely populated downtown (Xiamen island) (Hu et al., 2020; Liu et al., 2022). The  
106 field observations were continuously conducted from March 15 to November 4, 2020. The photochemical  
107 pollution events mainly appeared during spring and autumn in Xiamen, and we preferred to choose the  
108 periods with relatively high O<sub>3</sub> and PAN levels, then the measured data of 53 days in each season was  
109 chosen after excluding some special circumstances, such as extreme synoptic situations and instrument  
110 calibration.

## 111 2.2 Measurement techniques

112 PAN was monitored using a PAN analyzer (PANs-1000, Focused Photonics Inc., Hangzhou, CN)  
113 containing gas chromatography with electron capture detector (GC-ECD). During the observation period,  
114 multi-point standard curve calibration was conducted once a month, and single-point calibration was  
115 conducted every week, respectively. In the calibration mode of the PAN analyzer, the Mass Flow  
116 Controller (MFC) controls the flow rate of NO, acetone and zero gas separately. The PAN standard gas is  
117 generated by the reaction of NO and acetone under ultraviolet light irradiation, and the sample is diluted  
118 to the required calibration mixing ratio for injection analysis. PAN was detected every 5 min and the  
119 detection limit was 50 pptv. The uncertainty and precision of PAN measurement were ±10% and 3%,  
120 respectively.

121 A gas chromatography-mass spectrometer (GC-FID/MS, TH-300B, Wuhan, CN) was used for  
122 monitoring the atmospheric VOCs with a 1-hour time resolution. The instrument conducted sampling  
123 with a 30 L/min sampling rate, then samples were pre-concentrated by cooling to -160 °C in a cryogenic  
124 trap followed by heating to 100 °C, and subsequently transferred to the secondary trap by high-purity  
125 helium (He). The flame ionization detector (FID) detected the low-carbon (C2-C5) hydrocarbons by a  
126 PLOT (Al<sub>2</sub>O<sub>3</sub>/KCl) column (15 m × 0.32 mm × 6.0 μm); the other species were quantified using a DB-  
127 624 column (60 m × 0.25 mm × 1.4 μm). The instrument system can quantitatively analyze 106 VOCs in  
128 the ambient atmosphere, including 29 alkanes, 11 alkenes, one alkyne, 17 aromatics, 35 halogenated  
129 hydrocarbons, and 13 OVOCs. The single-point calibration was performed every day at 23:00 with the  
130 standard mixtures of PAMS and TO15, and multi-point calibration was performed one month. The  
131 detection limits of the measured VOCs were in the range of 0.02 ppbv to 0.30 ppbv, and the measurement  
132 precision was ≤10%.

133 Criteria air pollutants of O<sub>3</sub>, CO, SO<sub>2</sub>, and NO<sub>x</sub>, were monitored by using Thermo Instruments TEI  
134 49i, 48i, 43i, and 42i (Thermo Fisher Scientific, Waltham, MA, USA), respectively. HONO was  
135 monitored using an analyzer for Monitoring Aerosols and Gases in Ambient Air (MARGA, ADI 2080,  
136 Applikon Analytical B.V., the Netherlands). Particulate matters (PM<sub>2.5</sub>) were monitored by oscillating  
137 microbalance with tapered element (TEOM1405, Thermo Scientific Corp., MA, US), and the uncertainty  
138 of the PM<sub>2.5</sub> measurement was ±20%, respectively. The meteorological parameters (i.e. wind speed (WS),  
139 wind direction (WD), pressure (P), air temperature (T), and relative humidity (RH)) were measured by a  
140 weather station with sonic anemometer (150WX, Airmar, USA). Ultraviolet radiation (UV) was  
141 determined by a UV radiometer (KIPP & ZONEN, SUV5 Smart UV Radiometer). Photolysis frequencies  
142 including  $J(\text{O}^1\text{D})$ ,  $J(\text{NO}_2)$ ,  $J(\text{HONO})$ ,  $J(\text{NO}_3)$ ,  $J(\text{HCHO})$ , and  $J(\text{H}_2\text{O}_2)$  were analyzed by a photolysis  
143 spectrometer (PFS-100, Focused Photonics Inc., Hangzhou, China), and the uncertainty and detection  
144 limit of photolysis rates measurement were ±5% and around  $1 \times 10^{-5}$ , respectively.

145 Table S1 shows the detailed uncertainty and detection limit of instruments for trace gas observation.  
146 A schedule was applied to operate and inspect the AEOS monitoring station regularly and strictly to ensure  
147 the validity of the data. The detailed applications of the atmospheric monitoring procedure were shown  
148 in our previous studies (Wu et al., 2020; Liu et al., 2020a; Liu et al., 2020b; Hu et al., 2020).

### 150 **2.2-3 Observation-based model**

151 The OBM-MCM model is successfully used in the simulation of photochemical processes and the

152 quantification of the reaction rates, such as O<sub>3</sub>, PAN, and alkyl nitrates (RONO<sub>2</sub>) (Zeng et al. 2019). In  
 153 our study, the PAN photochemistry mechanism was simulated using this box model, and the incorporated  
 154 chemical mechanism was the latest version of MCM-v3.3.1 (<http://mcm.leeds.ac.uk/MCM/>), which  
 155 introduced 142 nonmethane VOCs and about 20000 elementary reactions (Jenkin et al., 2003; Saunders  
 156 et al., 2003). The physical process including dilution effect and dry deposition within the boundary layer  
 157 height was considered, avoiding the excessive accumulation of pollutants in the model (Li et al., 2018;  
 158 Liu et al., 2021; Xue et al., 2016). The observed data with a time resolution of 1 h of pollutants ([i.e., O<sub>3</sub>, CO, NO, NO<sub>2</sub>, HONO, SO<sub>2</sub>, and VOCs](#)), meteorological parameters ([i.e., T, P, and RH](#)), and photolysis  
 159 rate constants ([J\(O<sup>1</sup>D\), J\(NO<sub>2</sub>\), J\(H<sub>2</sub>O<sub>2</sub>\), J\(HONO\), J\(HCHO\), and J\(NO<sub>3</sub>\)](#)), which were mentioned in  
 160 Section 2.1, were input into the OBM-MCM model as constraints. The photolysis rates of other molecules  
 161 were driven by solar zenith angle and were scaled by measured JNO<sub>2</sub> (Saunders et al., 2003). Pre-ran for  
 162 2 days before running the model to constrain the unmeasured compounds reaching a steady-state (Xue et  
 163 al., 2014; [Liu et al., 2022](#)).

165 PAN affects atmospheric photochemistry by acting as a temporary source or sinks of PA radical (Xue  
 166 et al., 2014; Liu et al., 2021), hence the production and sink of PA radical reflecting the PAN formation  
 167 were discussed in our study. Furthermore, relative incremental reactivity (RIR) was used to analyze the  
 168 sensitivity of O<sub>3</sub> (Eq. 1) and PAN (Eq. 2) to their precursors, and was calculated as the ratio of the  
 169 differences in O<sub>3</sub> or PAN net production rate to variety in precursors (Chen et al., 2020; Liu et al., 2021).  
 170 [The production pathways of O<sub>3</sub> include HO<sub>2</sub>+NO and RO<sub>2</sub>+NO reactions, and the destruction pathways](#)  
 171 [of O<sub>3</sub> involve reactions of O<sub>3</sub> photolysis, O<sub>3</sub>+OH, O<sub>3</sub>+HO<sub>2</sub>, O<sub>3</sub>+VOCs, NO<sub>2</sub>+OH, and NO<sub>3</sub>+VOCs. The](#)  
 172 [net O<sub>3</sub> production rate \(P\(O<sub>3</sub>\)\) is calculated by the difference of O<sub>3</sub> production rate and destruction rate,](#)  
 173 [and the detailed net production rate of O<sub>3</sub> \(P\(O<sub>3</sub>\)\) was introduced in our previous study \(Liu et al., 2022\).](#)  
 174 The net production of PAN (P(PAN)) involved the production pathway of PA+NO<sub>2</sub>, and the loss of PAN  
 175 was thermal decomposition and PAN+OH (Zeng et al., 2019).

$$176 \quad RIR(PAN) = \frac{\Delta P(O_3)/P(O_3)}{\Delta X/X} \quad (1)$$

$$177 \quad RIR(O_3) = \frac{\Delta P(PAN)/P(PAN)}{\Delta X/X} \quad (2)$$

178 Here, the  $\Delta X/X$  meaning the reduction in the input mixing ratios of each target O<sub>3</sub> and PAN precursor  
 179 group was 20% (Liu et al., 2021).

180

## 181 **2.3.4 Generalized additive model**

182 The Generalized Additive Model (GAM) is an extension of the additive model proposed. Different  
183 from traditional regression models, GAM is a non-parametric regression model driven by data rather than  
184 statistical distribution models (He et al., 2017). GAM does not need to set the parameter model in advance,  
185 and it can adjust the functional form of the explained variable according to the specific situation. The  
186 Generalized Additive Model (GAM) has been widely used in air pollution research such as O<sub>3</sub> and PM<sub>2.5</sub>,  
187 and can effectively deal with the complex nonlinear relationship between air pollutants and influencing  
188 factors (Ma et al., 2020; Hua et al., 2021; Guan et al., 2019). It is the first time that the GAM is used to  
189 analyze the relationship between PAN and its influencing factors, and the combined effect of multiple  
190 influencing factors on the PAN mixing ratio was discussed in our study. Its form is:

$$191 \quad g(y)=\beta+f_1(x_1)+f_2(x_2)+\dots+f_n(x_n)+\alpha \quad (3)$$

192 Where  $y$  is the response variable;  $g(y)$  is the connection function;  $x_n, x_i, x_j, x_k,$  and  $x_l$  are the  
193 explanatory variables;  $f_n$  is the non-parametric smoothing functions;  $\beta$  is the intercept;  $\alpha$  is the truncation  
194 error.

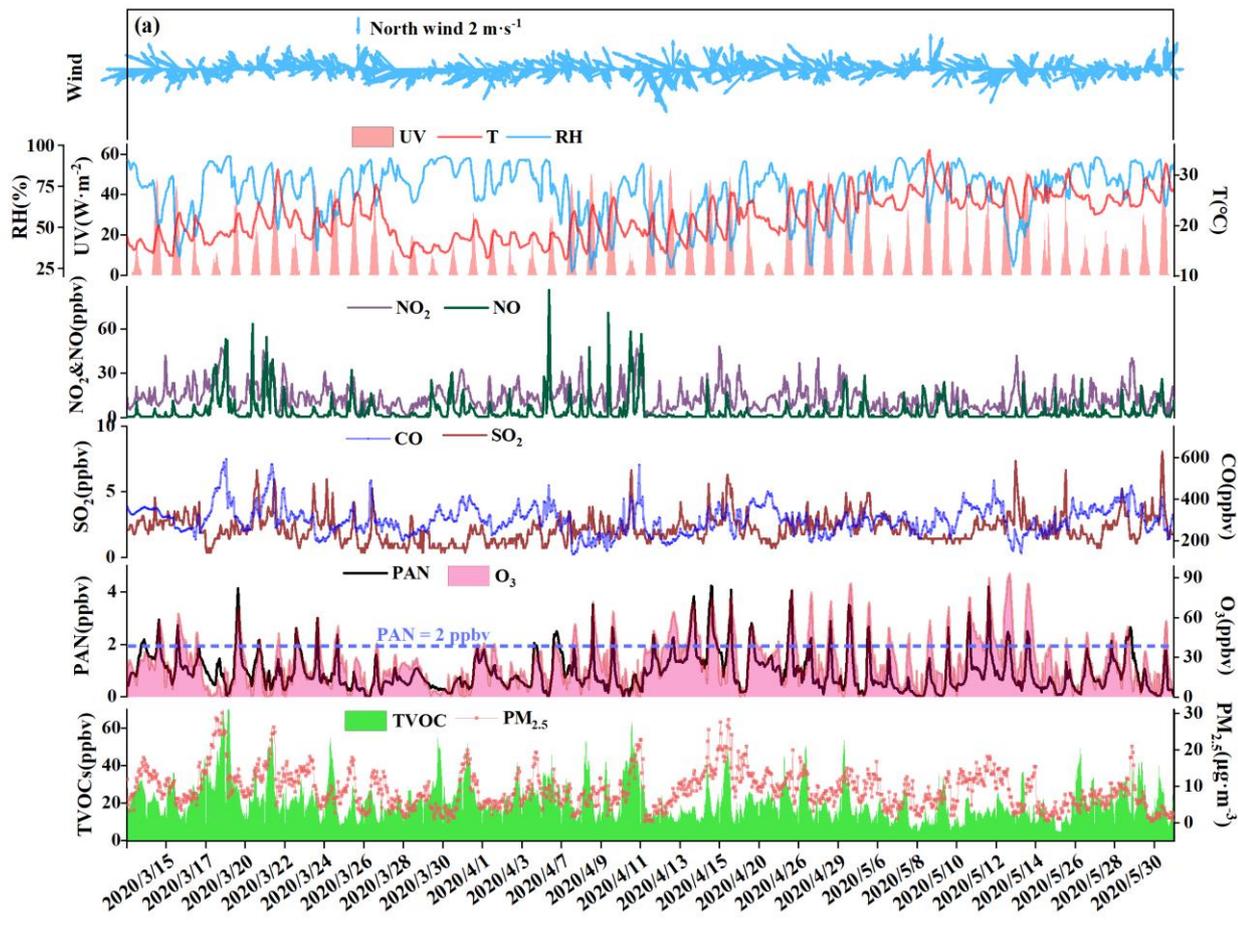

195 The F-value, P-value, adjust R<sup>2</sup>, and deviance explained given by the GAMs model are used to judge  
196 the significance of the influencing factors on PAN and the goodness of the model simulation. Among  
197 them, a high F-value indicates the great importance of the influencing factor; the P-value is used to judge  
198 the significance of the model result; the adjusted R<sup>2</sup> is the value of the regression square ranging from 0  
199 to 1; the deviance explained represents the fitting effect. In addition, when the degree of freedom (edf,  
200 ref.df) of the explanatory variable is 1, it indicates that the explanatory variable and the response variable  
201 are linear. When the degree>1, it is a non-linear relationship.

202

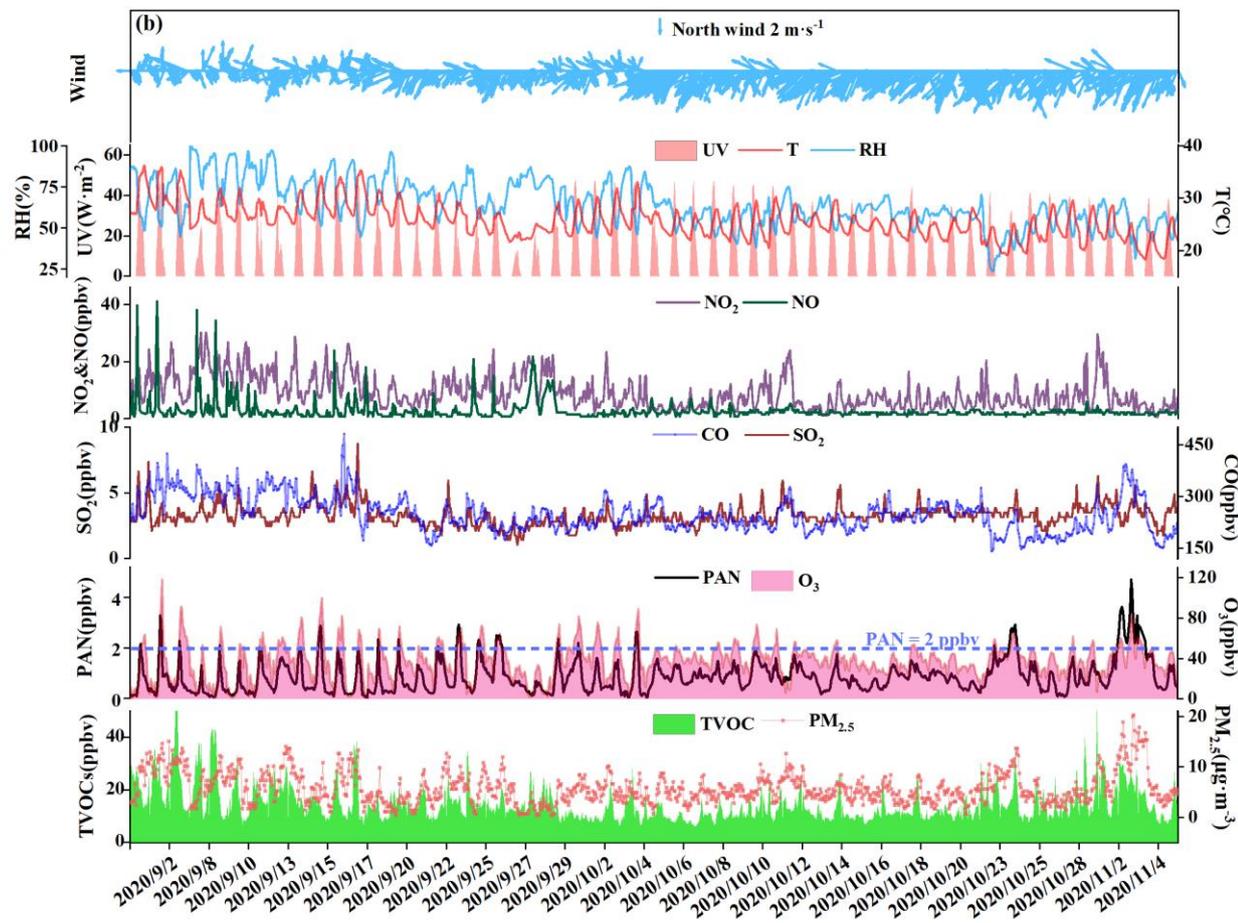

### 203 **3 Results and discussion**

#### 204 **3.1. Overview of observation**

205

206

207

Fig. 2. Time series of PAN, O<sub>3</sub>, NO<sub>x</sub>, CO, SO<sub>2</sub>, TVOCs, PM<sub>2.5</sub>, and meteorological parameters in (a) spring and

208 **(b) autumn.**

209  
210  
211 The time series of air pollutants and meteorological parameters are shown in Fig. 2. The average  
212 levels of PAN in autumn ( $0.87\pm 0.66$  ppbv) were comparable to that in spring ( $0.96\pm 0.73$  ppbv), while  $O_3$   
213 mixing ratios in autumn ( $37.22\pm 16.89$  ppbv) were 1.39 times higher than that in spring ( $26.73\pm 18.63$   
214 ppbv). PAN and  $O_3$  are produced by the photochemical reactions of VOCs and  $NO_x$ , thus they usually  
215 show a relatively close relationship ( $R^2\geq 0.49$ , Fig. S1). The PAN level ( $0.92\pm 0.69$  ppbv) in Xiamen was  
216 lower than that of megacities such as Beijing ( $3.79\pm 3.26$  ppbv) (Xu et al., 2021), Jinan (2.54 ppbv) (Liu  
217 et al. 2018), Santiago (6.4 ppbv) (Rubio et al., 2005) and Chongqing (2.05 ppbv) (Sun et al., 2020), and  
218 was comparable to the coastal cities with relatively clean air, including Shenzhen ( $1.01\pm 0.94$  ppbv) (Xia  
219 et al., 2021), and Qingdao (0.81 ppbv) (Liu et al., 2021).

220 The averaged values of PAN and  $NO$ ,  $NO_2$ ,  $CO$ , TVOCs in spring were 1.70, 1.32, 1.21, and 1.46  
221 times higher than those in autumn, respectively. The details of measured VOCs were provided in Table  
222 S2. Alkanes, OVOCs, aromatics, and halocarbons accounted for about 90% of total VOCs, suggesting the  
223 impacts of atmospheric oxidation capacity and marine emissions in coastal regions (Liu et al., 2020a; Liu  
224 et al., 2020b). During the transition from spring to summer the wind direction fluctuated between  
225 northwest and southeast while during the transition from summer to autumn the wind direction fluctuated  
226 from southeast to northeast. The wind rose charts showed that the wind direction frequencies with  
227 relatively high wind speed ( $>3\text{ m}\cdot\text{s}^{-1}$ ) in spring and autumn were southeast wind and northeast wind (Fig.  
228 S2), respectively. Although the frequency of northwest wind (NNW) also accounted for a certain  
229 proportion, the NNW speeds were generally slow, and the direction of the NNW was mainly rural  
230 residential and mountainous areas with less anthropogenic emissions, so that it was not the focus of this  
231 research. The ultraviolet radiation (UV), WS and T in spring ( $15.32\text{ W}\cdot\text{m}^{-2}$ ;  $1.96\text{ m}\cdot\text{s}^{-1}$ ;  $21.51\text{ }^\circ\text{C}$ ) were  
232 weaker than those in autumn ( $18.43\text{ W}\cdot\text{m}^{-2}$ ;  $3.01\text{ m}\cdot\text{s}^{-1}$ ;  $25.85\text{ }^\circ\text{C}$ ), and RH and P in spring (73.25 %;  
233  $1010.71\text{ hPa}$ ) were higher than that in autumn (65.21 %;  $1008.71\text{ hPa}$ ). These meteorological conditions  
234 carried by the WPSH (high T, low RH, and stagnant weather conditions) were conducive to the  
235 photochemical reaction and accumulation of air pollutants in autumn (Wu et al., 2019; Xia et al., 2021).  
236 High precursor levels of PAN in spring were conducive to the continuous and stable production of PAN,  
237 and the high air temperature in autumn accelerated the thermal decomposition of PAN. However, the  $O_3$   
238 levels in autumn were higher than that in spring, attributing to the influence of strong photochemical  
239 reaction conditions, regional transport from the Yangtze River Delta region or increased atmospheric

240 background levels (Monks, 2000). High O<sub>3</sub> values in both seasons were concentrated on the wind  
241 direction of southeast and northeast (Fig. S3). High PAN values in spring easily happened in the wind  
242 direction of the southeast with low wind speed (<3 m·s<sup>-1</sup>), showing the influence of urban plumes from  
243 the downtown of Xiamen island. High PAN values in autumn also appeared in the wind direction of the  
244 southeast, as well as the northeast with a relatively high wind speed (from Quanzhou city, an industrial  
245 city adjacent to Xiamen). Anymore, PAN lifetimes in our observation site were relatively short due to the  
246 high ambient temperature, and the PAN lifetimes in autumn (2.02 hours) were significantly lower than  
247 that in spring (6.39 hours), which was not conducive to regional transport (Hu et al., 2020; Liu et al.,  
248 2018). Accordingly, O<sub>3</sub> showed obvious characteristics of long-range transport, and PAN pollution was  
249 mainly from local production/accumulation in spring and autumn, but short-range transport from adjacent  
250 cities might contribute to the high PAN concentrations in autumn to a certain extent.

251 Based on the above analysis, we found that the photochemical reactions were still intense and even  
252 stronger under the low precursor levels. Although the precursor abundances of PAN and O<sub>3</sub> in spring were  
253 significantly higher than those in autumn (P<0.01), PAN values were comparable to and O<sub>3</sub> values were  
254 much higher in autumn than those in spring, respectively. Therefore, it is very necessary to furtherly  
255 explore the key influencing factors and their formation mechanisms.

### 256

### 257 3.2 The influencing factors of PAN using the GAM

258 PAN levels are not only related to chemical reactions in the boundary layer, but also affected by  
259 meteorological conditions (Hu et al., 2020). According to the collinearity analysis (He and Lin, 2017), the  
260 meteorological parameters (UV, T, RH, and WS) and other air pollutants (NO, TVOCs, PM<sub>2.5</sub> and O<sub>x</sub>)  
261 were considered into the multiple-factor GAM model (Table S3). As shown in Table 1, the adjusted R<sup>2</sup>  
262 and deviance explained for the smoothed variables of the multiple-factor GAM model were 0.70 and 72%  
263 in spring, 0.60 and 63% in autumn. According to the F-values, the orders of the explanatory variables in  
264 spring and autumn were UV (60.64) > O<sub>x</sub> (57.65) > T (17.55) > PM<sub>2.5</sub> (9.94) > TVOCs (9.52) > NO  
265 (8.73) > WS (7.42) > RH (3.4) and O<sub>x</sub> (58.45) > TVOCs (21.63) > T (20.46) > PM<sub>2.5</sub> (14.53) > RH (10.99) >  
266 UV (7.13) > NO (4.16) > WS (2.55), respectively.

267 Response curves of the PAN to explanatory factors in the multiple-factor model were presented (Fig.  
268 3 and Fig. S4). Except for UV and T in spring, the degrees of freedom (df) of the explanatory variables  
269 were greater than 1, indicating the non-linear relationships between explanatory variables and PAN. The  
270 PAN in both seasons showed a downward trend with the increase of NO. PAN in spring was

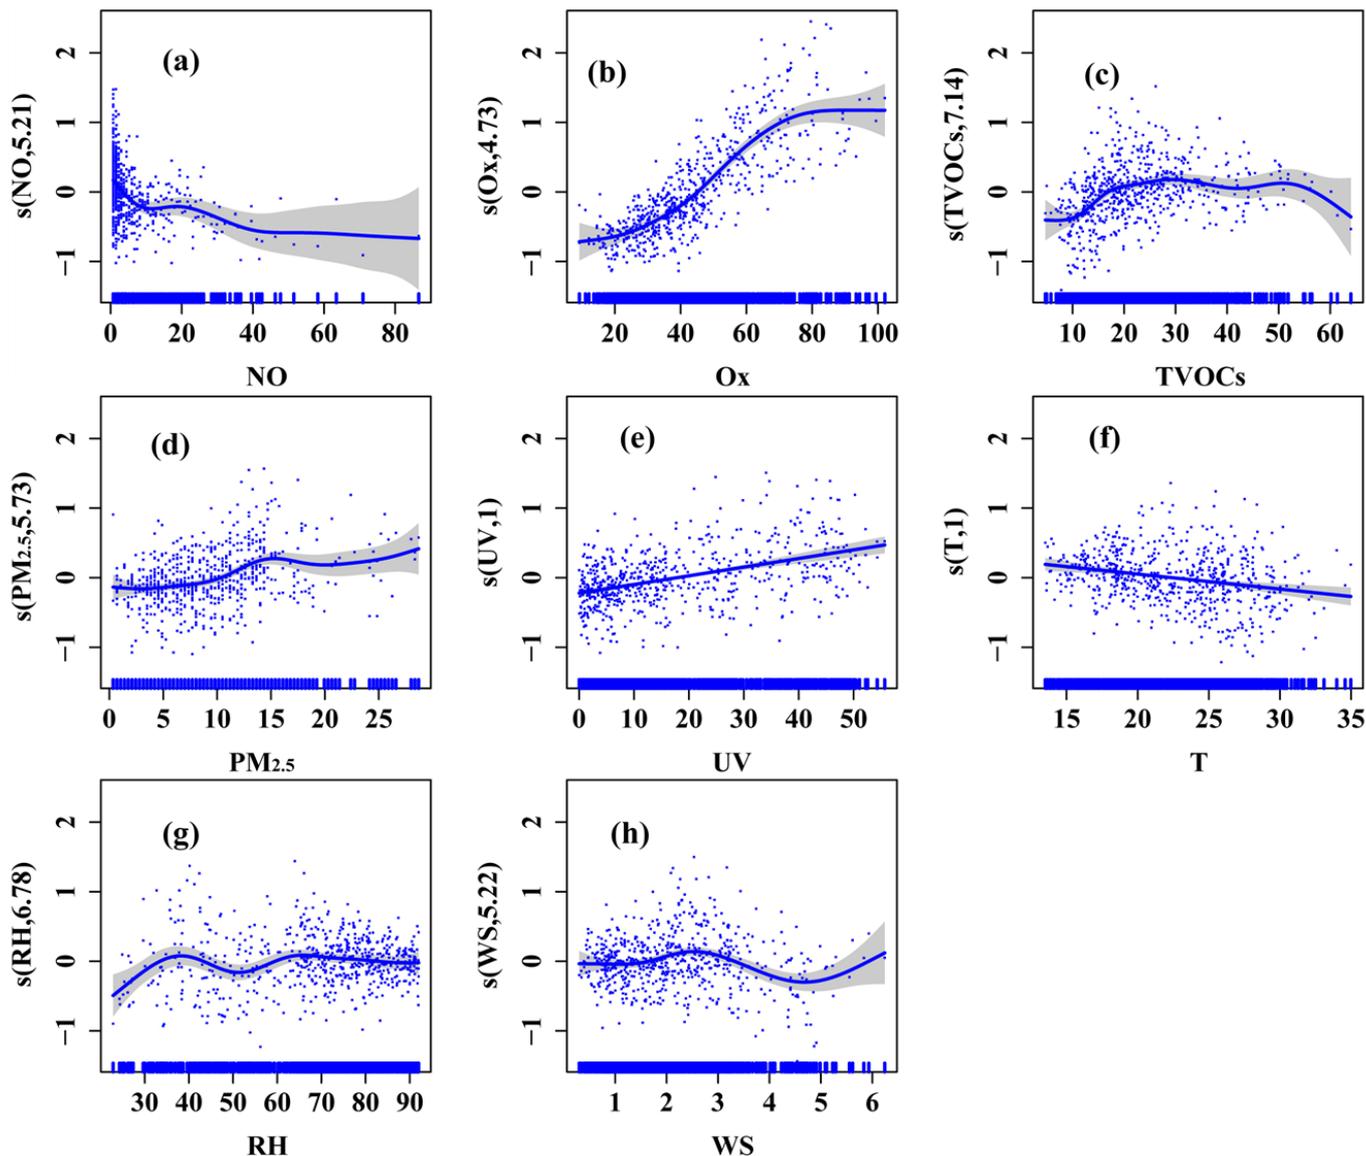

constant unchanged with NO fluctuation between 10 and 23 ppbv, and the confidence interval (CI) of NO concentration was relatively narrow. As we all know, the reaction of PA+NO is one of the most important loss pathways of PA, and the NO<sub>2</sub> production by NO oxidation in the O<sub>3</sub> formation cycle can react with PA radical to produce PAN, suggesting the fact that NO can consumed and produce PAN indirectly (Liu et al., 2021). The consumption of NO to PAN was basically equal to the production when the NO levels were relatively high (>10 ppbv), and the consumption of NO to PAN is greater than the production when the NO levels were low in spring. High values of NO mainly happened during rush hour traffic, thus controlling vehicle emissions can effectively alleviate PAN pollution. Ox had a positive correlation with PAN, representing the promotion effects of atmospheric oxidation capacity on PAN formation. The Ox levels <70 ppbv (with narrow CI) played a significant promotion role in PAN formation (Fig. 3(b) and Fig. S4(b)). High Ox >70 ppbv showed little influence on PAN, which could be explained as high Ox with relatively high air temperature leading to intense PAN thermal decomposition. When TVOCs were between 10 and 30 ppbv and PM<sub>2.5</sub> levels were <17 μg·m<sup>-3</sup>, PAN showed an upward trend with narrow CI. According to our previous study (Liu et al., 2022; Hu et al., 2020), the results of sensitivity analysis in Xiamen was VOCs-sensitive; the relatively low PM<sub>2.5</sub> concentrations in Xiamen showed limited influence on solar radiation through scattering and absorption, but promoted heterogeneous reactions producing radicals to a certain extent. UV and T had significant positive and negative nonlinear correlations with PAN, respectively. When UV changed between 0 and 50 W·m<sup>-2</sup> and T changed between 15 and 35 W·m<sup>-2</sup>, the CIs barely increased. In addition, when RH was more than 40%, the increase of RH was unfavorable for PAN production in both seasons. Some studies also found that high water vapor content could remove PAN and its precursors (Yan et al., 2018; Ma et al., 2020). Overall, the multiple-factor GAM analysis could better simulate the variations of PAN under real atmospheric conditions and evaluate the contributions of the influence factors to PAN formation.

**Table 1** Estimated degree of freedom (Edf), degree of reference freedom (Ref. df), P-value, F-value, deviance explained (%), adjusted R<sup>2</sup>, deviance contribution (%) for the smoothed variables in the multiple-factor GAM model.

Smoothed variables	Spring				Autumn			
	Edf	Ref.df	F-value	P-value	Edf	Ref.df	F-value	P-value

**Fig. 3.** Response curves (spring) in the multiple-factor model of PAN to changes in (a) NO, (b) Ox (Ox=O<sub>3</sub>+NO<sub>2</sub>), (c) TVOCs, (d) PM<sub>2.5</sub>, (e) ultraviolet radiation (UV), (f) air temperature (T), (g) relative humidity (RH), and (h) wind speed (WS). The y-axis is the smoothing function values. For example, s(NO, df) shows the trend in PAN when NO changes, and the number of df is the degree of freedom. The x-axis is the influencing factor, and the shaded area around the solid red line indicates the 95% confidence interval of PAN. The blue vertical short lines represent the concentration distribution characteristics of the explanatory variables (units: NO (ppbv), Ox (O<sub>3</sub>+NO<sub>2</sub>) (ppbv), TVOCs (ppbv), PM<sub>2.5</sub> (µg·m<sup>-3</sup>), UV (W·m<sup>-2</sup>), T (°C), RH (%), WS (m·s<sup>-1</sup>)).

### 3.3. Formation mechanism of PAN

#### 3.3.1 Diurnal variation during episodes and non-episodes

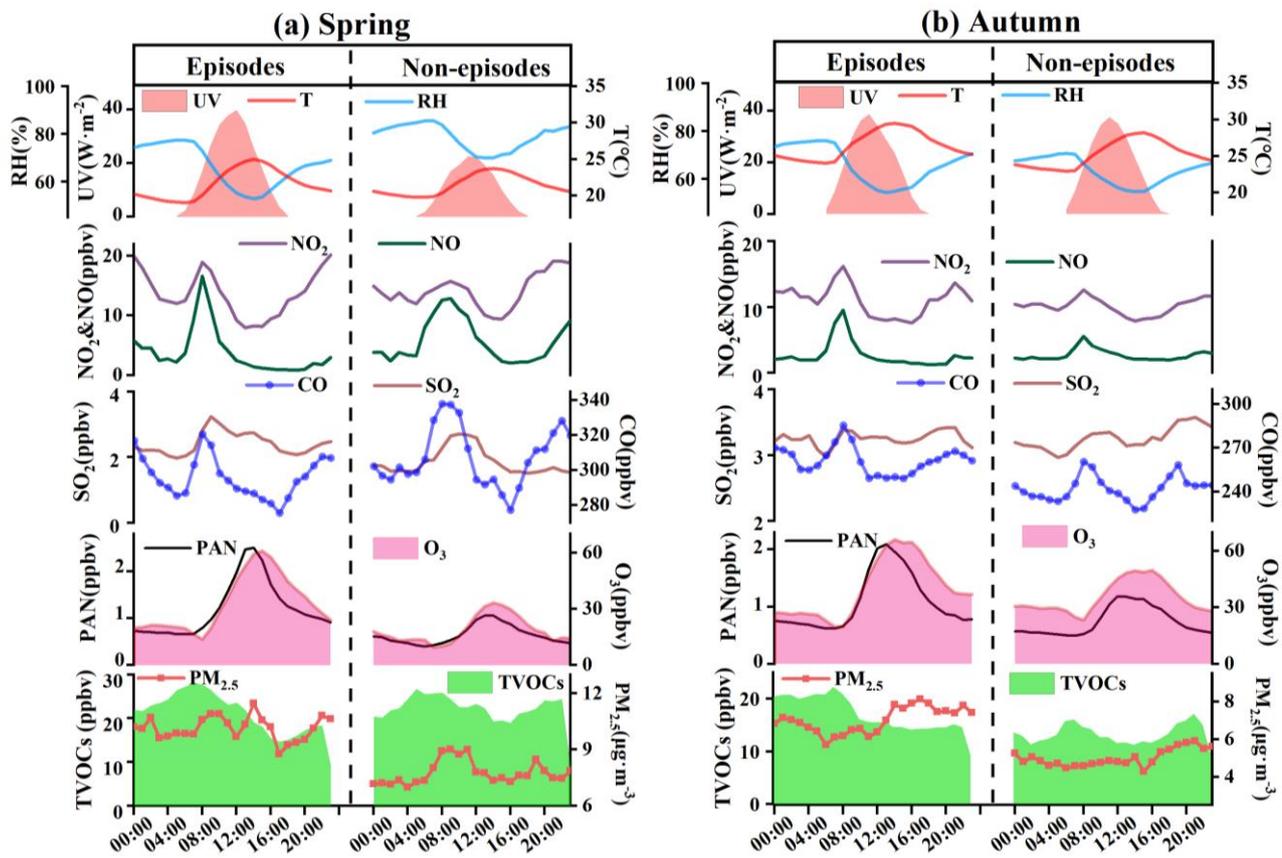

Fig. 4. Diurnal trends of PAN, O<sub>3</sub>, TVOCs, PM<sub>2.5</sub>, other trace gases and meteorological parameters during episodes and non-episodes in (a) spring and (b) autumn, respectively.

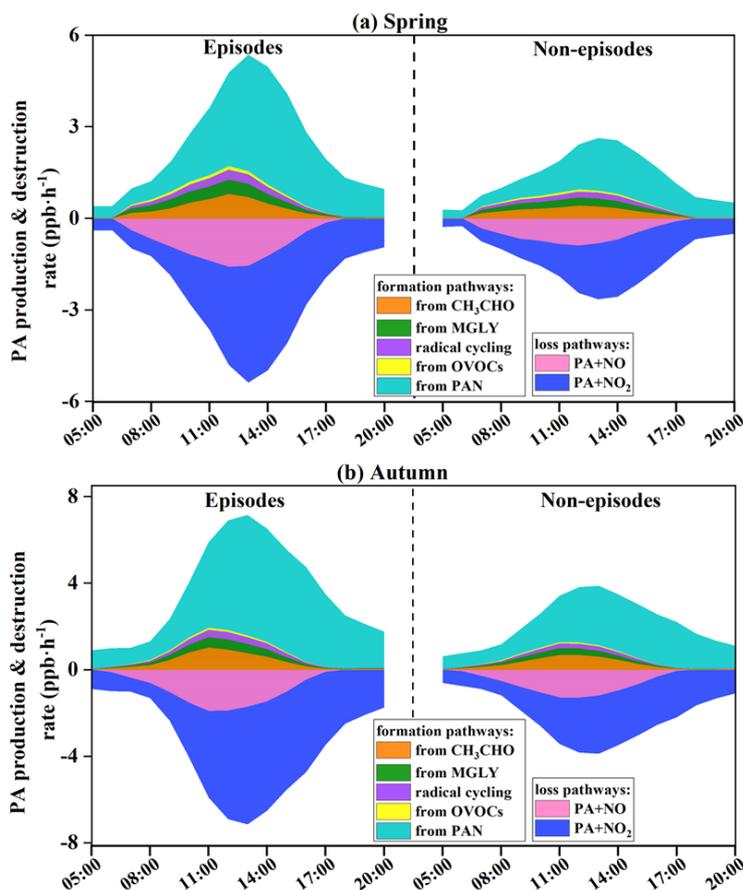

Throughout the 53-days campaign, 30 and 21 days (i.e., 57% and 40%) with the peak values of PAN exceeding 2 ppbv were observed in spring and autumn, respectively. The scenarios of episodes and non-episodes were classified, according to the previous method (Xue et al., 2014). Diurnal variations of air pollutants and meteorological parameters during episodes and non-episodes are shown in Fig. 4, which could be explained by the evolution of the planetary boundary layer, local emissions, and atmospheric photochemistry. PAN reached a maximum value at 12:00-14:00, then decreased with weak solar radiation and reached the lowest in the early morning. Similar diurnal patterns of PAN and O<sub>3</sub> were observed, indicating the dominance of local photochemistry during the observation period (Zeng et al., 2019). CO, NO<sub>x</sub> and TVOCs showed highest values in the morning and the lowest values in the afternoon.

In autumn, averaged PAN and O<sub>3</sub> during episodes (PAN:  $1.08 \pm 0.87$  ppbv, and O<sub>3</sub>:  $40.06 \pm 20.27$  ppbv) were higher than those during non-episodes (PAN:  $0.74 \pm 0.41$  ppbv, and O<sub>3</sub>:  $35.36 \pm 13.95$  ppbv). Meanwhile, some air pollutants and meteorological parameters during episodes were 1.03-1.40 times higher than those during non-episodes. The rainfall in Xiamen is more frequent in spring (Hu et al., 2020), leading to the obvious differences in UV and RH levels between episodes and non-episodes. In spring, the precursors (CO, NO<sub>x</sub>, TVOCs) of PAN during episodes were 1.04-1.49 times lower than those during

331 non-episodes. Moreover, the PAN and O<sub>3</sub> mixing ratios during episodes (PAN: 1.20±0.81 ppbv, and O<sub>3</sub>:  
 332 32.92±19.81 ppbv) were still significantly higher than those during non-episodes (PAN: 0.64±0.43 ppbv,  
 333 and O<sub>3</sub>: 18.65±13.16 ppbv), attributing to the favorable meteorological conditions of photochemical  
 334 reactions (strong UV, high T, and low RH). These results further explained that UV, Ox, and T in spring  
 335 and Ox, TVOCs, T, and PM<sub>2.5</sub> in autumn played important roles in the formation of PAN based on the  
 336 GAM analysis.

337

### 338 3.3.2. Formation and loss of PA radical

339

340 **Fig. 5. Formation and destruction rates of PA radical (hence PAN) during episodes and non-episodes in (a) spring**  
 341 **and (b) autumn, respectively.**

342

343 The formation and sink pathways of PA radical were further explored under different pollution  
 344 scenarios (Fig. 5). Both the PA (hence PAN) production and destruction rates during episodes were 1.80  
 345 times higher than those during non-episodes. Combined with the analysis of Section 3.3.1, PA production  
 346 rates during the daytime (06:00-17:00 LT) in autumn were 1.58 times higher than that in spring, even  
 347 though the precursor levels in autumn were much low compared to those in spring. These results indicated  
 348 favorable meteorological condition was the dominant factor to produce PAN through accelerating its  
 349 production rate and accumulation. The thermal decomposition of PAN to PA radical in autumn accounted

350 for  $77\pm 12\%$  (episodes) and  $73\pm 16\%$  (non-episodes) of total PA production, as well as  $70\pm 12\%$  (episodes)  
351 and  $64\pm 15\%$  (non-episodes) in spring, attributing to the relatively high air temperature and UV intensity.  
352 The thermal decomposition of PAN peaked at around 13:00~14:00 LT, when the air temperature was the  
353 highest in the day, and the pathways without considering the transform between PA and PAN peaked at  
354 noontime around 12:00 LT, when the solar radiation was the highest and photochemical reactions became  
355 the most intensive.

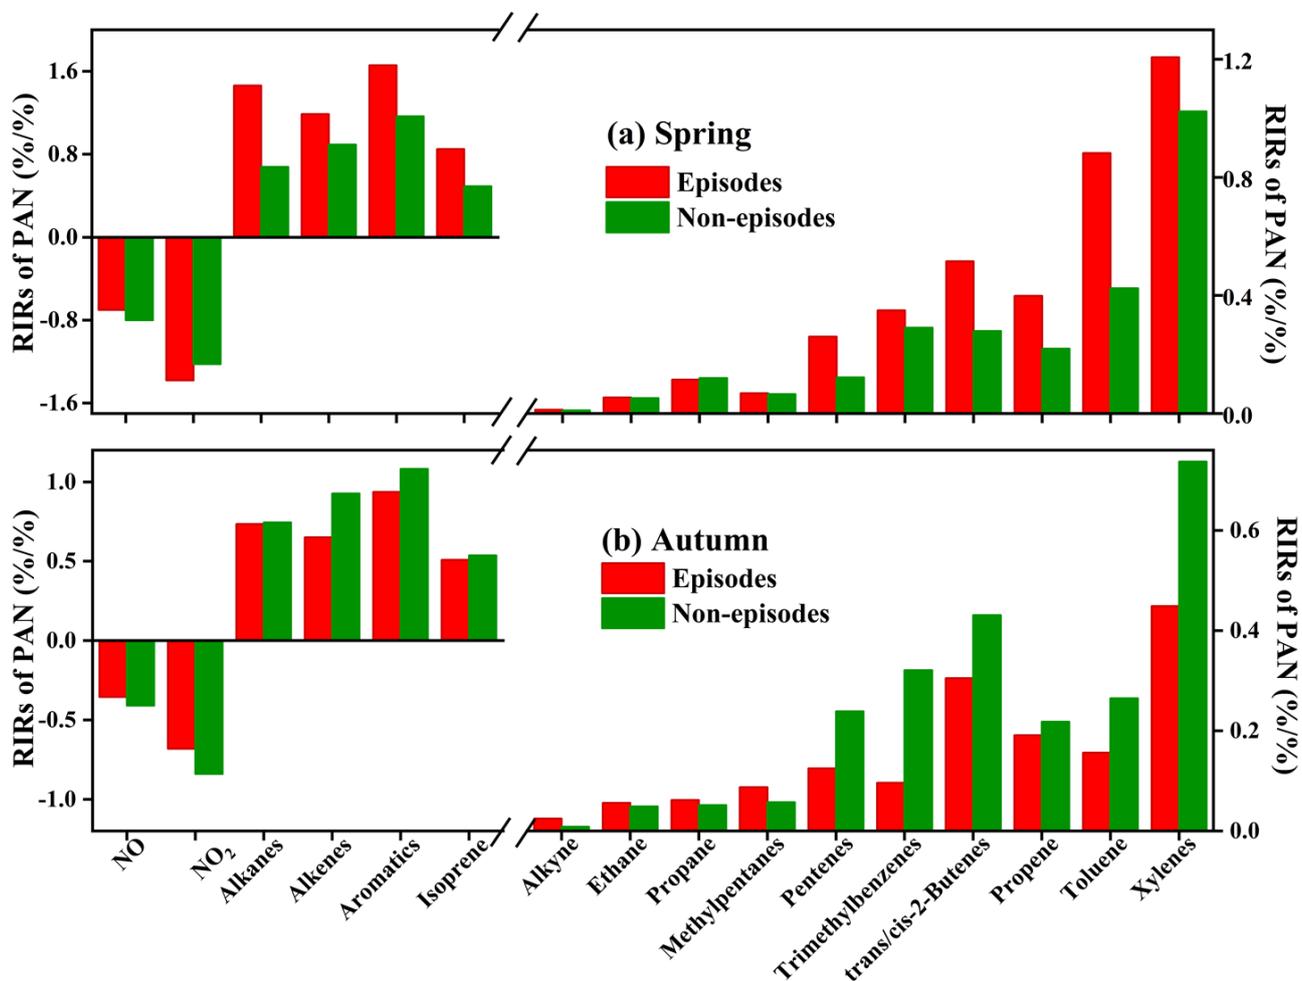

356 The average daytime PAN production rate from  $\text{CH}_3\text{CHO}$  by reacting with OH and  $\text{NO}_3$  contributed  
357  $0.36\pm 0.25$  ppb  $\text{h}^{-1}$  and  $0.24\pm 0.13$  ppb  $\text{h}^{-1}$  during episodes and non-episodes in spring. While the rate of  
358  $0.46\pm 0.35$  ppb  $\text{h}^{-1}$  and  $0.34\pm 0.24$  ppb  $\text{h}^{-1}$  during episodes and non-episodes were observed in autumn.  
359 The second production reaction was photolysis and oxidation by OH and  $\text{NO}_3$  of MGLY (episode:  
360  $0.25\pm 0.15$  ppb  $\text{h}^{-1}$  and non-episodes:  $0.17\pm 0.08$  ppb  $\text{h}^{-1}$  in spring; episode:  $0.24\pm 0.17$  ppb  $\text{h}^{-1}$  and non-  
361 episodes:  $0.16\pm 0.11$  ppb  $\text{h}^{-1}$  in autumn). Then, the processes of radical cycling including RO radical  
362 decomposition and reactions of acyl peroxy radicals with NO were also the important sources to produce  
363 PA, with the contributions of  $20\pm 3\%$  and  $18\pm 3\%$  in spring and autumn. PA from the other OVOCs (not  
364 including  $\text{CH}_3\text{CHO}$ , MGLY, MVK, MACR, and acetone) through reactions of photolysis and oxidation  
365 by OH,  $\text{NO}_3$ , and  $\text{O}_3$ , accounted for  $7\pm 2\%$  and  $6\pm 1\%$  in spring and autumn, respectively. Other reactions  
366 of acetone, MVK, MACR, MPAN, and isoprene had a minor contribution (around 1% in total) to PA  
367 formation. In contrast, the major contributor of PAN destruction rate was  $\text{PA}+\text{NO}_2$  ( $69\pm 16\%$  in spring and  
368  $73\pm 14\%$  in autumn), followed by  $\text{PA}+\text{NO}$  ( $31\pm 17\%$  and  $27\pm 13\%$ ), while the other reactions with  $\text{NO}_3$ ,  
369  $\text{HO}_2$ , and  $\text{RO}_2$  contributed limitedly (around 0.1% of the total).

370 The second-generation precursors of PAN of  $\text{CH}_3\text{CHO}$  and MGLY have both primary and secondary  
371 sources, and the other OVOCs are mainly oxidation products of hydrocarbons (Sinha et al., 2019; Sarkar  
372 et al., 2017). Consequently, the contribution and importance of first-generation precursors of PAN are  
373 necessary to identify to better control photochemical pollution, which will be discussed in the next section.

374

### 375 3.3.3. Sensitivity of PAN precursors

376

377  
 378 **Fig. 6.** The OBM-MCM calculated relative incremental reactivity (RIR) for major PAN precursor groups and top  
 379 **10 specific species in (a) spring and (b) autumn during the daytime (06:00-17:00 LT).**  
 380

381 The OBM-MCM model analysis could be used to examine the relationship between PAN and its  
 382 precursors, and quantify the contribution of first-generation precursors (Liu et al., 2021; Cardelino and  
 383 Chameides, 1995). During these simulations (except for NO and NO<sub>2</sub>), the model was not constrained by  
 384 the OVOC measurements considering that these first-generation precursors contribute to PAN production  
 385 through formation of OVOCs. The relative incremental reactivities (RIRs) for O<sub>3</sub> and PAN are shown in  
 386 Fig. 6 and Fig. S5. The PAN production was highly VOCs-sensitive, while the RIRs of NO and NO<sub>2</sub> were  
 387 negative ranging from -0.17 to -1.94%/ during the daytime (06:00-17:00 LT). This consisted of the  
 388 fact that high dense mobiles resulted in the large emissions of vehicle exhausts in Xiamen city. The ratio  
 389 of VOCs/NO<sub>x</sub> (1.11±0.32) also convinced NO<sub>x</sub> was not the limiting factor on the photochemical reaction  
 390 (Tan et al., 2019). In suburban or rural areas, the transition regime and NO<sub>x</sub>-sensitive for PAN and O<sub>3</sub>  
 391 production were usually found (Xue et al., 2014; Liu et al., 2021). Zeng et al. (2019) found NO<sub>2</sub>-positive  
 392 and NO-negative to PAN formation in a suburban of Hong Kong, consisting with the fact that NO<sub>2</sub> directly  
 393 produced PAN and NO consumed PA radical inhibiting PAN formation.

394 As shown in Fig.6, aromatics showed the largest RIRs for PAN in spring (1.41%/%) and autumn  
395 (1.03%/%), followed by alkanes (1.04%/% in spring and 0.78%/% in autumn), Alkenes (1.04%/% and  
396 0.74%/%), and isoprene (0.67%/% and 0.52%/%). The sensitivities of PAN precursors in spring were  
397 1.37-2.07 times higher than those in autumn, due to the large percentages of PAN decomposition at high  
398 air temperatures in autumn. In spring, the weak solar radiation led to poor photochemical reactions, so  
399 the RIRs of PAN during non-episodes were lower than that during episodes. However, the PAN  
400 sensitivities during episodes were lower than those during non-episodes, attributed to the rapid PAN  
401 decomposition in autumn (Liu et al., 2021). In addition, RIRs of VOCs and NO<sub>x</sub> for PAN were  
402 significantly higher than that of O<sub>3</sub> (Fig. S5). For RIRs of VOCs, except for air temperature, the different  
403 formation mechanisms of PAN and O<sub>3</sub> should be considered. Only a small part of the VOCs could produce  
404 PA to form PAN, thereby, the VOCs were insufficient to produce PAN (Fischer et al., 2014). For RIRs of  
405 NO<sub>x</sub>, O<sub>3</sub> was produced from the NO<sub>2</sub> conversion process, and was also rapidly consumed by NO titration.  
406 High levels of VOCs and NO<sub>x</sub> enhanced the PAN formation, even though a pathway of NO destructed  
407 PAN, which was negligible compared to thermal decomposition. For this reason, the RIRs of NO<sub>x</sub> for  
408 PAN were higher than those for O<sub>3</sub>.

409 In addition, the top 10 VOCs species (including xylenes, toluene trans/cis-2-butenes,  
410 trimethylbenzenes, propene, pentenes, and methypentanes) governing PAN production were further  
411 identified (Fig. 6). The results suggested that the reduction of aromatics, alkenes, and alkanes with ≤5  
412 carbons could effectively decrease PAN pollution.

413

### 414 **3.4. Impacts of PAN on O<sub>3</sub> formation**

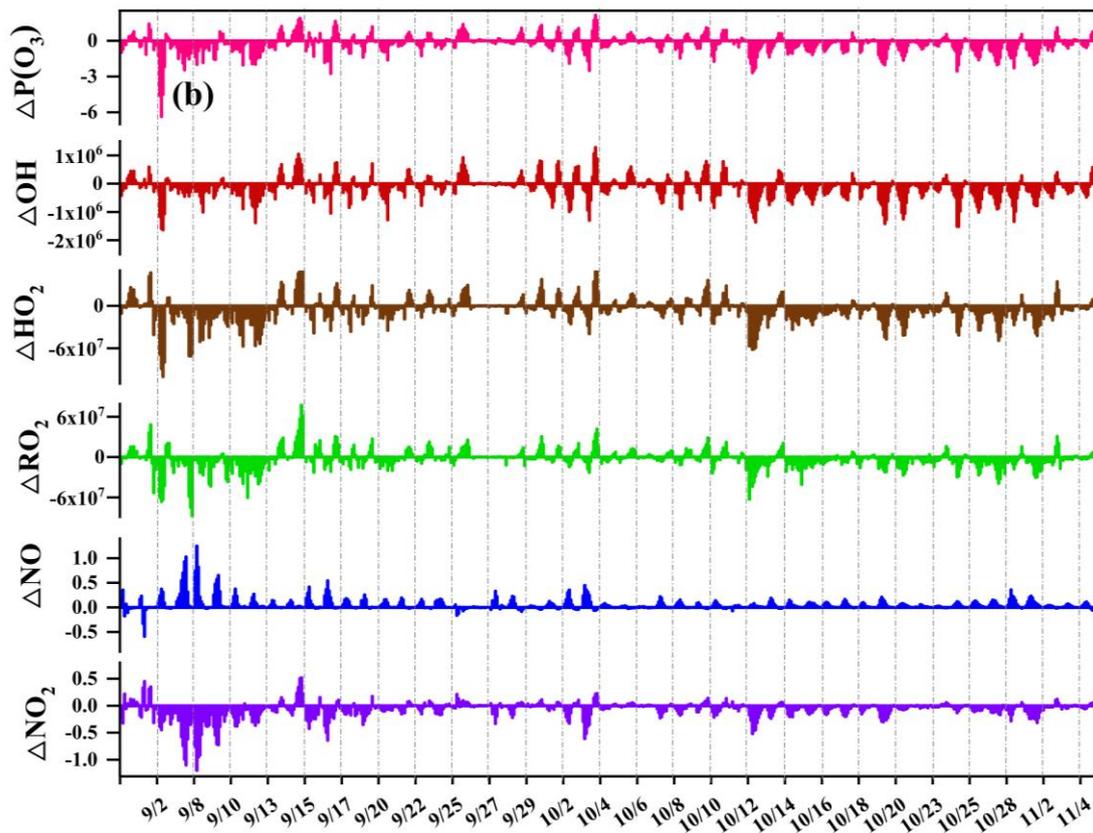

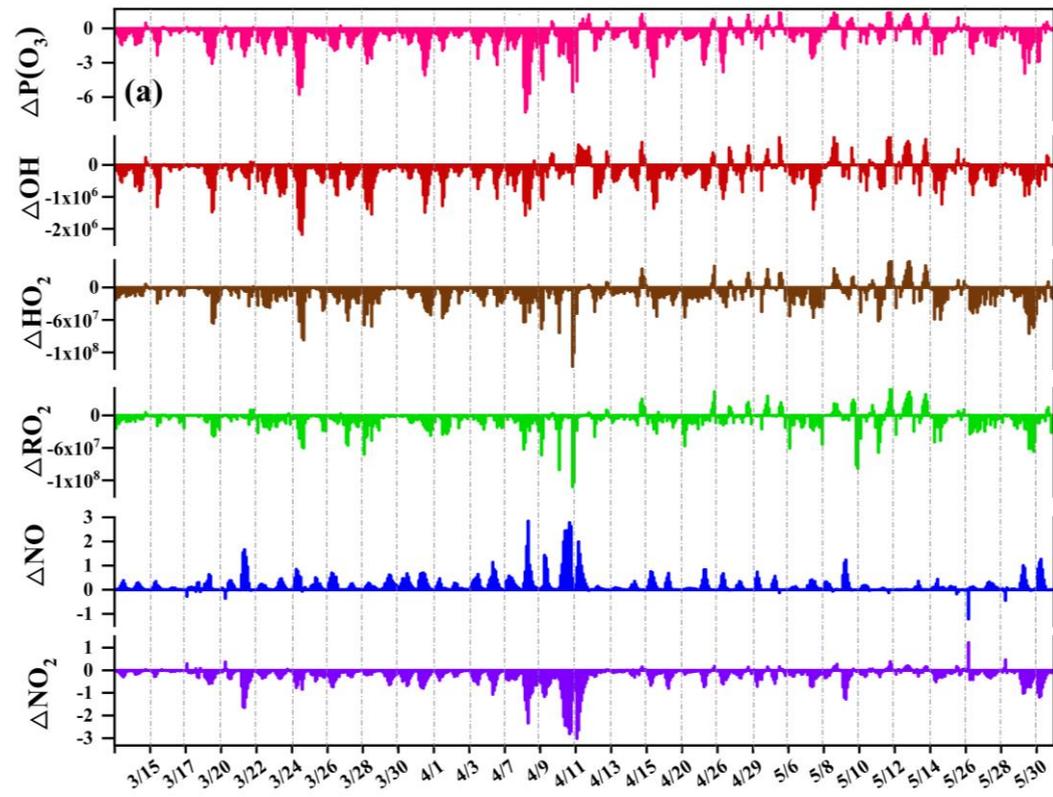

#### 415 **3.4.1 Inhibition and promotion effect of PAN on O<sub>3</sub> formation**

416

417

418

419

420

421 Fig. 7. The differences of O<sub>3</sub> net production  $\Delta P(O_3)$ ,  $\Delta OH$ ,  $\Delta HO_2$ ,  $\Delta RO_2$ ,  $\Delta NO$  and  $\Delta NO_2$  between the SC1  
 422 and the SC2 during the daytime (06:00-17:00) in (a) spring and (b) autumn (Unit: ppbv·h<sup>-1</sup> for  $\Delta P(O_3)$ ; ppbv for  
 423  $\Delta NO$  and  $\Delta NO_2$ ; molecules·cm<sup>-3</sup> for  $\Delta OH$ ,  $\Delta HO_2$  and  $\Delta RO_2$ ). The SC1 scenario was the base scenario putting  
 424 all detected data (i.e. VOCs, trace gases, and meteorological parameters) into the model with all reaction pathways  
 425 of the MCM mechanism, and the SC2 disabled the PAN chemistry, which is the only difference between SC1 and  
 426 SC2.

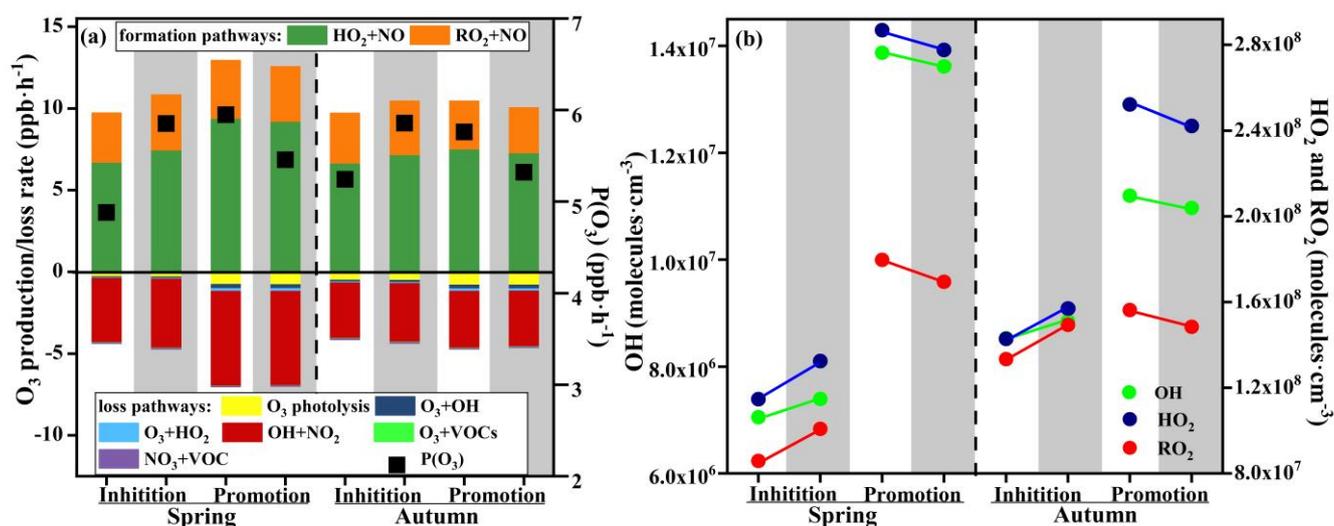

428 PAN could affect O<sub>3</sub> production by acting as a temporary source of NO<sub>x</sub> or sink of PA radical to  
 429 affect precursors and radical chemistry in the troposphere (Xia et al., 2021). To quantify the changes of  
 430 O<sub>3</sub> in response to PAN chemistry in the coastal city, two parallel scenarios (SC1 and SC2) were conducted  
 431 based on the OBM model. The SC1 was the base scenario putting all detected data (i.e. VOCs, trace gases,  
 432 and meteorological parameters) into the model with all reaction pathways (as the description in Section  
 433 2.2), and the SC2 disabled the PAN chemistry, which is the only difference between SC2 and SC1. Figure  
 434 7 shows the differences of O<sub>3</sub> net production rates  $\Delta P(O_3)$ ,  $\Delta OH$ ,  $\Delta HO_2$ ,  $\Delta RO_2$ ,  $\Delta NO$  and  $\Delta NO_2$   
 435 between the SC1 and the SC2. Negative and positive values represented the inhibition and promotion  
 436 effects of PAN photochemistry on O<sub>3</sub> formation, respectively. Overall, PAN mostly inhibited the O<sub>3</sub>  
 437 formation during the observation days.  $\Delta P(O_3)$  had significantly positive correlations with  $\Delta OH$   
 438 ( $R^2=0.96$  in spring and  $0.95$  in autumn),  $\Delta HO_2$  ( $R^2=0.91$  and  $0.96$ ),  $\Delta RO_2$  ( $R^2=0.86$  and  $0.86$ ) and  $\Delta NO_2$   
 439 ( $R^2=0.72$  and  $0.85$ ), and negative correlation with  $\Delta NO$  ( $R^2=-0.63$  and  $-0.65$ ). As shown in Fig. S6, the  
 440 promotion effects of PAN on O<sub>3</sub> mainly happened during the periods of 11:00-16:00 LT, and most of them  
 441 concentrated on PAN pollution episodes. The percentage of negative  $\Delta P(O_3)$  values were 83% and 69%  
 442 in spring and autumn, defined as “inhibition effect stages”. While the positive  $\Delta P(O_3)$  values accounted  
 443 for 17% and 31% in spring and autumn, defined as “promotion effect stages”.

444 Figure 8 shows the variations of modeled  $P(O_3)$ , O<sub>3</sub> budgets, and RO<sub>x</sub> on the inhibition and  
 445 promotion effect stages in spring and autumn. The abundance of RO<sub>x</sub> in autumn ( $2.85 \times 10^8$  molecules  
 446  $cm^{-3}$ ) was higher than that in spring ( $2.08 \times 10^8$  molecules  $cm^{-3}$ ) during inhibition effect stages, while the  
 447  $P(O_3)$  value in autumn ( $5.24$  ppbv  $h^{-1}$ ) was higher than that in spring ( $4.88$  ppbv  $h^{-1}$ ). On the contrary, the  
 448 level of RO<sub>x</sub> in spring ( $4.81 \times 10^8$  molecules  $cm^{-3}$ ) was higher than that in autumn ( $4.20 \times 10^8$  molecules  
 449  $cm^{-3}$ ) during promotion effect stages, and the  $P(O_3)$  value ( $5.95$  ppbv  $h^{-1}$ ) in spring was higher than that  
 450 in autumn ( $5.76$  ppbv  $h^{-1}$ ). The results indicated that high RO<sub>x</sub> concentration was an important factor for  
 451 the formation of O<sub>3</sub>. In the case of closing PAN photochemistry, the  $P(O_3)$  increased 1.20 and 1.12 times  
 452 during inhibition effect stages and decreased 1.09 and 1.08 times during promotion effect stages in spring  
 453 and autumn, respectively (Fig. 8a). This was consistent with the corresponding changes of RO<sub>x</sub> radical  
 454 (Fig. 8b). During the inhibition effect stages, the averaged concentrations of OH, HO<sub>2</sub>, and RO<sub>2</sub> increased  
 455 1.05, 1.16, and 1.17 times in spring, and increased 1.04, 1.10, and 1.12 times in autumn. During the  
 456 promotion effect stages, the averaged concentrations of OH, HO<sub>2</sub> and RO<sub>2</sub> decreased 1.02, 1.03, and 1.06  
 457 times in spring, and decreased 1.02, 1.04, and 1.05 times in autumn. These results indicated that the  
 458 changes in RO<sub>x</sub> dominated the  $P(O_3)$  trend without PAN photochemistry. Furthermore, the  $P(O_3)$  level

459 during promotion effect stages ( $5.95 \text{ ppbv h}^{-1}$  in spring,  $5.76 \text{ ppbv h}^{-1}$  in autumn) was higher than that  
 460 during inhibition effect stages ( $4.88 \text{ ppbv h}^{-1}$  in spring,  $5.24 \text{ ppbv h}^{-1}$  in autumn). For model-simulated  
 461  $\text{P}(\text{O}_3)$  and  $\text{O}_3$  budgets (Fig. 8a),  $\text{HO}_2+\text{NO}$  (account for  $70\pm 4\%$ ) and  $\text{RO}_2+\text{NO}$  ( $30\pm 6\%$ ) were the main  
 462 pathways of  $\text{O}_3$  formation, and the main loss reactions were  $\text{OH}+\text{NO}_2$  ( $83\pm 12\%$ ).

463 PAN competed with  $\text{O}_3$  precursors and terminated the radical chain to suppress  $\text{O}_3$  formation by  
 464 decreasing the  $\text{RO}_x$  production during the inhibition effect stages. During the promotion effect stages, the  
 465 intensive atmospheric oxidation capacity and photochemical reaction enhance the  $\text{RO}_x$  formation rates  
 466 from PAN to promote  $\text{O}_3$  formation (Fig. 8b).

467

468

469 **Fig. 8. Model-simulated (a) net  $\text{O}_3$  production rate and  $\text{O}_3$  budgets, (b)  $\text{OH}$ ,  $\text{HO}_2$ , and  $\text{RO}_2$  on the inhibition effect stages and promotion effect stages. Note: the white background parts represent the SC1 scenarios using the MCM mechanism, and the gray background parts represent the SC2 scenarios using the MCM mechanism with PAN chemistry disabled.**

### 3.4.2 The influencing factors during inhibition and promotion stages

475

476

477

478

479

480

481

482

483

484

Table S4 showed the air pollutants and meteorological parameters during the inhibition effect stages and promotion effect stages. In detail, the levels of CO and the precursors of  $\text{O}_3$  and PAN during the inhibition effect stages were significantly higher than those during the promotion effect stages. However, the  $\text{PM}_{2.5}$  level during the inhibition effect stages was relatively lower than that during the promotion effect stages, reflecting the influence of heterogeneous reactions on  $\text{PM}_{2.5}$  by supplying key photochemical oxidants to enhance PAN production (Xu et al., 2021). In addition,  $\text{SO}_2$  and wind speed were comparable during the two scenarios. During the promotion effect stages, UV and T were significantly high, while P and RH were significantly low ( $P < 0.01$ ). Meanwhile, the PAN ( $1.89$  in spring,  $1.58$  ppbv in autumn) and  $\text{O}_3$  ( $50.26$  ppbv in spring and  $53.51$  in autumn) under the promotion effects were higher than those under the inhibition effects (PAN:  $1.04$  and  $0.84$  ppbv;  $\text{O}_3$ :  $27.32$  and  $36.42$  ppbv in spring and autumn,

485 respectively).

486 In general, ROx radicals dominated the atmospheric oxidative capacity and were the indicators of  
487 atmospheric photochemical reaction (Li et al., 2018). According to Section 3.2 of GAM analysis, we  
488 chose the factors of NO, TVOCs, PM<sub>2.5</sub>, UV, T, RH, WS, and  $\Delta$ ROx ( $\Delta$ ROx= $\Delta$ OH+ $\Delta$ HO<sub>2</sub>+ $\Delta$ RO<sub>2</sub>), to  
489 discuss the key influencing factor under promotion effect stages. Here, the  $\Delta$ P(O<sub>3</sub>) rate and the relevant  
490 influencing factors were set as the response and explanatory variables, respectively. Table 2 showed the  
491 influencing factors on  $\Delta$ P(O<sub>3</sub>) under promotion effects in spring and autumn. The factors that did not pass  
492 the significance test were deleted. As the adjusted model showed, the adjusted R<sup>2</sup> and deviance explained  
493 for the smoothed variables in four GAM models ranged from 0.67~0.78 and 70%~80%, verifying the  
494 good fitting effect of the multiple-factor GAM model. According to the F-values, the effects of  $\Delta$ ROx  
495 (21.56 in spring; 45.45 in autumn) and UV (9.66 in spring; 30.55 in autumn) were the main factors leading  
496 to the promotion effect in both seasons. Both  $\Delta$ ROx and UV had significant positive non-linear  
497 relationships with  $\Delta$ P(O<sub>3</sub>) during promotion effect stages in both seasons (Fig. S7 and S8). The minor  
498 influences of WS and T were observed in autumn. The promotion effects easily happened during periods  
499 of favorable meteorological conditions for photochemical reactions.

500 Liu et al. (2021) found that PAN photochemistry inhibited O<sub>3</sub> production under low-NOx and low-  
501 ROx conditions, and promoted O<sub>3</sub> formation under high-NOx. However, in this study, surplus NOx  
502 prevented NOx from being the limiting factor photochemical formation of secondary pollution and the  
503 change of NOx could be ignored. Whether PAN photochemistry suppressed or enhanced O<sub>3</sub> production  
504 mainly depended on the meteorological conditions of photochemical reaction and the ROx levels.

505

#### 510 4. Conclusions

511 Field observation was continuously conducted in spring and autumn in a coastal city of Southeast  
512 China. We clarified the seasonal variations of PAN pollution, formation mechanisms, influencing factors,  
513 and impacts on O<sub>3</sub> production. The average levels of PAN in autumn were lower than that in spring, while  
514 the O<sub>3</sub> showed the opposite characteristics. The multiple-factor GAM model showed that the key factors  
515 on PAN mixing ratio were UV, Ox, and T in spring, while Ox, TVOCs, T, and PM<sub>2.5</sub> played important  
516 roles in PAN formation in autumn. The MCM model is an ideal tool to explore PAN photochemical  
517 formation and its key precursors at the species level and provides more relevant suggestions for reducing  
518 photochemical pollution. The controlling emissions of aromatics and alkenes with ≤5 carbons were  
519 benefit for PAN pollution mitigation, and carbonyl compounds especially acetaldehyde were dominant in  
520 the PAN production mechanism. PAN presented the inhibition or promotion effects on O<sub>3</sub> under different  
521 environmental conditions. The promotion effects of PAN on O<sub>3</sub> mainly happened during the periods of  
522 11:00-16:00 LT, most of which concentrated on PAN pollution episodes. According to the GAM analysis,  
523 the levels of RO<sub>x</sub> and UV were the main factors leading to the promotion effects in both seasons. Overall,  
524 PAN stimulated O<sub>3</sub> formation under high levels of UV, T, and RO<sub>x</sub> in the coastal city. These results  
525 indicate that the monitoring of PAN and its precursors and the quantification of its impacts on O<sub>3</sub>  
526 formation have significant guidance on photochemical pollution control. The scientific analysis methods  
527 used in this study provide a reference for the research on the formation mechanism of PAN and O<sub>3</sub> in  
528 other regions.

#### 529 Authorship Contribution Statement

530 Taotao Liu performed chemical modeling analyses of OBM-MCM and wrote the paper. Taotao Liu  
531 collected the data, contributed to the data analysis. Jinsheng Chen and Youwei Hong designed and revised  
532 the manuscript. Jinsheng Chen supported funding of observation and research. Gaojie Chen, Lingling Xu,  
533 Mengren Li, Yanting Chen, Xiaoting Ji, Chen Yang, and Yuping Chen contributed to discussions of results.  
534 Weiguo Huang, Quanjia Huang and Hong Wang provided part of the data in Xiamen.
