

How do Cl concentrations matter for simulating CH₄, δ¹³C(CH₄) and estimating CH₄ budget through atmospheric inversions ? - Supplementary Material

Joël Thanwerdas^{1,*}, Marielle Saunois¹, Antoine Berchet¹, Isabelle Pison¹, and Philippe Bousquet¹

¹Laboratoire des Sciences du Climat et de l'Environnement, CEA-CNRS-UVSQ, IPSL, Gif-sur-Yvette, France.

Correspondence: J. Thanwerdas (joel.thanwerdas@lscce.ipsl.fr)

The Supplementary Material provides additional information about fluxes and source isotopic signatures prescribed in the multiple sensitivity simulations (Text S1, Figure S1, Figure S2, Figure S3, Table S1, Table S2 and Table S3). Also, a demonstration of the value used by an inversion system to adjust the globally-averaged source isotopic signature and reduce the mean isotopic signal bias is provided (Text S2). In addition, Tables S5 and S6 provide a list of CH₄ and δ¹³C(CH₄) surface stations used in this study. Table S4 and Figure S4 provide the locations and a list of AirCore profiles. Finally, Text S3 and Figure S5 provide an analysis of the influence of Cl concentrations on XCH₄.

1 Text S1 : Optimized CH₄ fluxes and δ¹³C(CH₄) source isotopic signatures

1.1 Introduction

In this study, the system designed by Thanwerdas et al. (2021) is used to perform an inversion. The posterior CH₄ surface fluxes and δ¹³C(CH₄) source isotopic signatures inferred by the inversion system are then used in the reference simulation (SimREF). This inversion aims to bring the simulated CH₄ and δ¹³C(CH₄) values closer to the available observations and give more credibility to the conclusions of the paper.

The system of Thanwerdas et al. (2021) uses the variational approach that minimizes a cost function (Eq. 1) until a convergence criteria is reached:

$$J(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}^b)^T \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}^b) + \frac{1}{2}(\mathcal{H}(\mathbf{x}) - \mathbf{y}^o)^T \mathbf{R}^{-1}(\mathcal{H}(\mathbf{x}) - \mathbf{y}^o) \quad (1)$$

Here, \mathbf{x} is the control vector including the variables optimized by the system. \mathbf{x}^b is the prior control vector including prior estimates of the control variables (i.e., before the inversion). \mathbf{y}^o is the observation vector that encompasses all observational data. \mathbf{R} and \mathbf{B} are the error covariance matrices associated with the observation errors and the prior errors, respectively. \mathcal{H} is the observation operator that links the observation and control spaces.

Minimization is performed using the M1QN3 minimization algorithm (Gilbert and Lemaréchal, 1989). At each iteration, the gradient of the cost function at point \mathbf{x} is calculated using Eq. 2.

$$\nabla J_{\mathbf{x}} = \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}^b) + \mathcal{H}^*(\mathbf{R}^{-1}(\mathcal{H}(\mathbf{x}) - \mathbf{y}^o)) \quad (2)$$

In practice, an iteration consists of two steps: a direct simulation which allows to calculate the cost function and an adjoint simulation which allows to calculate the gradient of the cost function at a specific point. In this inversion, the control vector \mathbf{x} includes, for five categories presented below, CH₄ surface fluxes and associated $\delta^{13}\text{C}(\text{CH}_4)$ source isotopic signatures at the pixel scale. Initial conditions are also included in \mathbf{x} .

1.2 CH₄ fluxes

CH₄ surface fluxes are divided into five emission categories:

- Biofuels and Biomass burning sources (BB)
- 30 – Agriculture and Waste (AGW)
- Fossil Fuels and Geological sources (FFG)
- Oceanic and termite sources (NAT)
- Wetlands (WET)

We adopt the prior CH₄ emissions compiled for the inversions performed under the Global Methane Budget (Saunois et al., 2020). Anthropogenic emissions (including biofuels) and fire emissions are taken from the EDGARv432 (<http://edgar.jrc.ec.europa.eu/overview.php?v=432&SECURE=123>) and GFED4s (van der Werf et al., 2017) databases, respectively. Statistics from British Petroleum (BP) and the Food and Agriculture Organization of the United Nations (FAO) are used to extend EDGARv432 emissions, which end in 2012, to 2017.

Estimates from natural sources are based on average values in the literature: Poulter et al. (2017) for wetlands, Kirschke et al. (2013) for termites, Lambert and Schmidt (1993) for oceanic sources and Etiope (2015) for geological sources. The soil sink is based on Ridgwell et al. (1999). CH₄ emissions are compiled in Table S1.

1.3 Source isotopic signatures

Each emission category is associated with a source isotopic signatures map in order to extract ¹²CH₄ and ¹³CH₄ emissions from CH₄ emissions. References and globally-averaged source signatures are compiled in Table S2. Signatures maps are shown in Figure S2.

1.4 Sinks

Concentrations of species that remove CH₄ from the atmosphere (OH, O(¹D), Cl) are not included in the control vector \mathbf{x} and therefore sink intensities are not optimized.

Three-dimensional and time-dependent oxidant concentration fields (OH, O(¹D) and Cl) were simulated by the General Circulation Model LMDz coupled to the INCA [INteraction with Chemistry and Aerosols] chemistry model (Hauglustaine et al., 2021; Folberth et al., 2006; Hauglustaine et al., 2004). Seventeen ozone-depleting substances consisted of CFCs (CFC-12,

CFC-11, CFC-113), three HCFCs (HCFC-22, HCFC-141b, HCFC-142b), two halons (Halon-1211, Halon-1301), CH_3CCl_3 , CCl_4 , CH_3Cl , methylene chloride (CH_2Cl_2), chloroform (CHCl_3), methyl bromide (CH_3Br) and HFC-134a, and their associated photochemical reactions, were included in the INCA chemical scheme to produce Cl radicals (Terrenoire et al., 2020). In
55 the LMDz-INCA simulations, surface concentrations of these long-lived Cl source species were prescribed based on historical data sets prepared by Meinshausen et al. (2017). The model was run for the period 1850-2018 (Hauglustaine et al., 2021).

This simulation was originally dedicated to the study of Cl in the stratosphere. To be consistent with our reference scenario, the tropospheric mean Cl concentration ($330 \text{ molec.cm}^{-3}$) was scaled to that of Wang et al. (2019) ($620 \text{ molec.cm}^{-3}$), very similar to that of Wang et al. (2021) ($630 \text{ molec.cm}^{-3}$)

60 Sink intensities over the period 1998-2018 and the associated fractionation coefficients are compiled in Table S3.

1.5 Assimilated observations

CH_4 observations between 1998 and 2018 provided by 79 surface stations of the Global Greenhouse Gas Reference Network (GGGRN), part of the NOAA-ESRL Global Monitoring Division (NOAA-ESRL GMD), are assimilated by the system (Table S5). In addition, flask samples retrieved at 22 NOAA-ESRL stations and analyzed by the Institute of Arctic and Alpine
65 Research (INSTAAR) to provide $\delta^{13}\text{C}(\text{CH}_4)$ observations, are also assimilated (Table S6).

1.6 Model-observation agreement

As each iteration took 3 days to run, the inversion was stopped when a model-observation agreement sufficient to perform the analysis of the paper was obtained. The Root-Mean-Square Error (RMSE) on the global averages reach 3.6 ppb for CH_4 and 0.04 ‰ for $\delta^{13}\text{C}(\text{CH}_4)$ for SimREF (Figure S1).

70 2 Text S2 : Demonstration of the value of global source isotopic signature adjustment

Here, we demonstrate the result used in Sect. 3.3 of the main paper. That is, the bias of $\delta^{13}\text{C}(\text{CH}_4)$ between a sensitivity simulation and the SimREF simulation tends to a stabilized value (steady-state) that is equal to the adjustment value of the globally-averaged source isotopic signature applied by the inversion system. For ease of demonstration, this relationship is shown by approximating that the tropospheric mixing ratios of $^{12}\text{CH}_4$ are equal to those of CH_4 and we simplify the problem

75 by reducing it to a one-box model problem.

If we start from a mass-conservation balance equation in a one-box problem, we have :

$$\begin{cases} \frac{dB}{dt} = S - k \cdot B \\ \frac{dB_{13}}{dt} = S_{13} - k_{13} \cdot B_{13} \end{cases} \quad (3)$$

where B et B_{13} are the total masses of $^{12}\text{CH}_4$ et $^{13}\text{CH}_4$ in the atmosphere, respectively. k and k_{13} are the reaction rate constants of $^{12}\text{CH}_4$ and $^{13}\text{CH}_4$ chemical sinks, respectively. S and S_{13} are the total sources of $^{12}\text{CH}_4$ and $^{13}\text{CH}_4$ (including soil sink as a

80 negative source), respectively.

Let R_{atm} , R_s and $\varepsilon = \alpha - 1 = \frac{k_{13}}{k} - 1$ be the atmospheric isotopic ratio, the source isotopic ratio and the isotopic fractionation coefficient of the total chemical CH_4 sink. We can infer an equation linking these three terms :

$$\frac{dB_{13}}{dt} = S_{13} - k_{13} \cdot B_{13} \quad (4)$$

$$\implies \frac{d(R_{\text{atm}} \cdot B)}{dt} = R_s \cdot S - (k \cdot \alpha) \cdot (R_{\text{atm}} \cdot B) \quad (5)$$

$$85 \implies \frac{d(R_{\text{atm}} \cdot B)}{dt} = R_s \cdot S - (1 + \varepsilon) \cdot R_{\text{atm}} \cdot P \quad (6)$$

At steady state, with time derivatives equal to zero, we have :

$$\begin{cases} S - P = 0 \\ R_s \cdot S - (1 + \varepsilon) \cdot R_{\text{atm}} \cdot P = 0 \end{cases} \quad (7)$$

Subsequently, these equations can be reshaped to obtain a relationship between δ_a , which is the mean atmospheric isotopic signal at steady state, and δ_s , which is the globally-averaged source isotopic signature.

$$90 \quad R_s \cdot S - (1 + \varepsilon) \cdot R_{\text{atm}} \cdot P = 0 \quad (8)$$

$$\implies R_s - (1 + \varepsilon) \cdot R_{\text{atm}} = 0 \quad (9)$$

$$\implies (1 + \delta_s) \cdot R_{\text{std}} = (1 + \varepsilon) \cdot (1 + \delta_a) \cdot R_{\text{std}} \quad (10)$$

$$\implies \delta_a = \frac{1 + \delta_s}{1 + \varepsilon} - 1 \quad (11)$$

With the isotopic signal being $\delta^{13}\text{C}(\text{CH}_4)$, we have $1 + \varepsilon \approx 1$. To understand the effect of isotopic fractionation on the atmospheric isotopic signal, we choose to simplify the equation :

95

$$\delta_a \approx \delta_s - \varepsilon - \delta_s \cdot \varepsilon \approx \delta_s - \varepsilon \quad (12)$$

For CH₄, ϵ is negative, hence the isotopic fractionation of CH₄ sinks enriches the atmospheric isotopic signal in ¹³C compared to the globally-averaged source isotopic signature.

We want to predict the adjustment value that an inversion system would apply to the source isotopic signature in order to increase the agreement between the simulated and observed mean atmospheric isotopic signal $\delta^{13}\text{C}(\text{CH}_4)$. To do so, we consider two simulations of CH₄ mole fractions and isotopic signal $\delta^{13}\text{C}(\text{CH}_4)$, denoted simulation n°1 and simulation n°2. We prescribe equal CH₄ sources with the same isotopic signature $\delta_{s,1} = \delta_{s,2}$. Also, we prescribe sinks with distinct fractionation coefficients ϵ_1 et ϵ_2 . Equal initial conditions are adopted in the two simulations.

Little by little, a bias between the isotopic signals simulated by these two simulations will increase and stabilize after some decades :

$$\begin{cases} \delta_{a,1} \approx \delta_{s,1} - \epsilon_1 - \delta_{s,1} \cdot \epsilon_1 \\ \delta_{a,2} \approx \delta_{s,2} - \epsilon_2 - \delta_{s,2} \cdot \epsilon_2 \end{cases} \quad (13)$$

$$\implies \Delta\delta_a \approx -\Delta\epsilon \cdot (1 + \delta_{s,1}) \quad (14)$$

$$\implies \Delta\epsilon \approx -\frac{\Delta\delta_a}{1 + \delta_{s,1}} \quad (15)$$

We consider that $\delta_{a,1}$ represents the observed value and we decide to integrate the simulation n°2 into an inversion system to reduce the bias between $\delta_{a,2}$ and the observed value (here $\delta_{a,1}$). The inversion system will shift the source isotopic signature in order to remove this bias caused by the fractionation difference $\Delta\epsilon$. The $\delta_{s,2}$ posterior value is denoted $\delta_{s,post}$. Using the Eq. 11, we can obtain the fractionation difference $\Delta\epsilon$ between the two simulations from the bias $\Delta\delta_a$:

$$\begin{cases} \delta_{a,1} = \frac{1 + \delta_{s,1}}{1 + \epsilon_1} - 1 \\ \delta_{a,2} = \delta_{a,1} = \frac{1 + \delta_{s,post}}{1 + \epsilon_2} - 1 \end{cases} \quad (16)$$

115

$$\implies \delta_{s,post} - \delta_{s,1} \approx -\Delta\epsilon \cdot (1 + \delta_a) \quad (17)$$

Finally, we obtain the following relationship by combining the different equations :

$$\delta_{s,post} - \delta_{s,1} \approx -\Delta\delta_a \cdot \frac{1 + \delta_{a,1}}{1 + \delta_{s,1}} \approx -\Delta\delta_a \quad (18)$$

2.1 Text S3 : XCH₄ columns

120 We investigate the influence of Cl concentrations on column-averaged CH₄ dry-air mole fractions (hereafter referred to as simply XCH₄) using version 9.0 of the GOSAT Proxy XCH₄ dataset provided by the University of Leicester (Parker et al., 2020). The Greenhouse Gases Observing Satellite (GOSAT) carrying the Thermal And Near-infrared Sensor for carbon Observation Fourier Transport Spectrometer (TANSO-FTS) (Kuze et al., 2009) provides radiance measurements in a spectral band centered on a value close to 1.6 μm , in which CH₄ has a high absorption capacity. The University of Leicester’s retrieval algorithm
125 is able to produce XCH₄ from these radiances. The dataset shows an accuracy of 13.72 ppb associated with a correlation coefficient of 0.92 when compared to the Total Carbon Column Observing Network (TCCON) data (Parker et al., 2020).

XCH₄ obtained by remote sensing techniques are now massively assimilated in inversions because satellite observations offer a much larger spatial coverage than in situ measurements. Ostler et al. (2016) showed that model errors in simulating stratospheric CH₄ contribute to model biases when compared to observed XCH₄ from TCCON. From our analysis of the CH₄
130 vertical profiles, we know that the biases generated by a modification of the Cl sink will likely affect the simulated XCH₄. To quantify the influence of the Cl field on XCH₄, vertical profiles simulated by LMDz-SACS are sampled at the observations locations and times in 2018 and convolved with the retrieval of a priori vertical profile and column averaging kernels provided by the University of Leicester. The individual XCH₄ retrievals and model simulations are aggregated in model-resolution grid boxes. We define the bias $b_{p,i}$ for a specific pixel p and a specific simulation i as :

$$135 \quad b_{p,i} = \overline{X_{p,i} - X_{p,\text{SimREF}}}^p \quad (19)$$

where $X_{p,i}$ is a XCH₄ simulated value from the simulation i whose location is inside the pixel p . The mean bias is then an average over the whole year.

The mean biases exhibit a very small spatial variability (less than 1 ppb) for SimINCA, SimSherwen, SimNoTropo and SimTaki and are very close to the biases at the surface (difference of 6 ppb for SimTaki and 1-3 ppb for the others). For
140 SimNoCl (see Fig. S5), those values are larger because the change in contribution from the stratospheric Cl sink between SimNoCl and SimREF (-1.1%) is larger than between other simulations and SimREF ($+0.5\%$ for SimTaki and $\pm 0.1\%$ for others). While the bias at the stations is about 20 ppb in 2018 for SimNoCl, those on the columns range from 20 ppb in the Tropics to 30 ppb in the higher latitudes. To summarize, if the Cl sink is removed, i) the bias becomes larger on the total column than at the surface and ii) the bias becomes latitude-dependent.

145 As in a surface-based inversion, a satellite-based inversion system would compensate for this bias by adjusting the surface fluxes. We cannot rigorously apply here the same methods as in Sect 3.2 of the main paper to calculate this adjustment because a box model representation is too simple to model the bias on XCH₄. Due to differences between XCH₄ and CH₄ biases, CH₄ global source adjustments inferred by a satellite-based inversion or by a surface-based inversion could be different. However, these biases differences are very small when the Cl stratospheric sink is modified within the realistic ranges given here and
150 becomes noticeable only when the stratospheric Cl sink is neglected. We conclude that the results from the two types of inversions should be very similar when changing the Cl field.

Table S1. Prior and posterior estimates of global CH₄ emissions and associated flux-weighted isotopic signatures by source category. Given values are averages over 1998-2018. Numbers in brackets are minimum and maximum over this period of time [min/max].

Table S6. List of $\delta^{13}\text{C}(\text{CH}_4)$ surface in-situ observation sites that provided measurements assimilated in the inversion between 1998 and 2018. WPC is a mobile station. Its characteristics are compiled into a single line, providing latitude and longitude ranges of the measurements. Stations that retrieved samples consisting mainly of well-mixed MBL air are indicated in bold red.

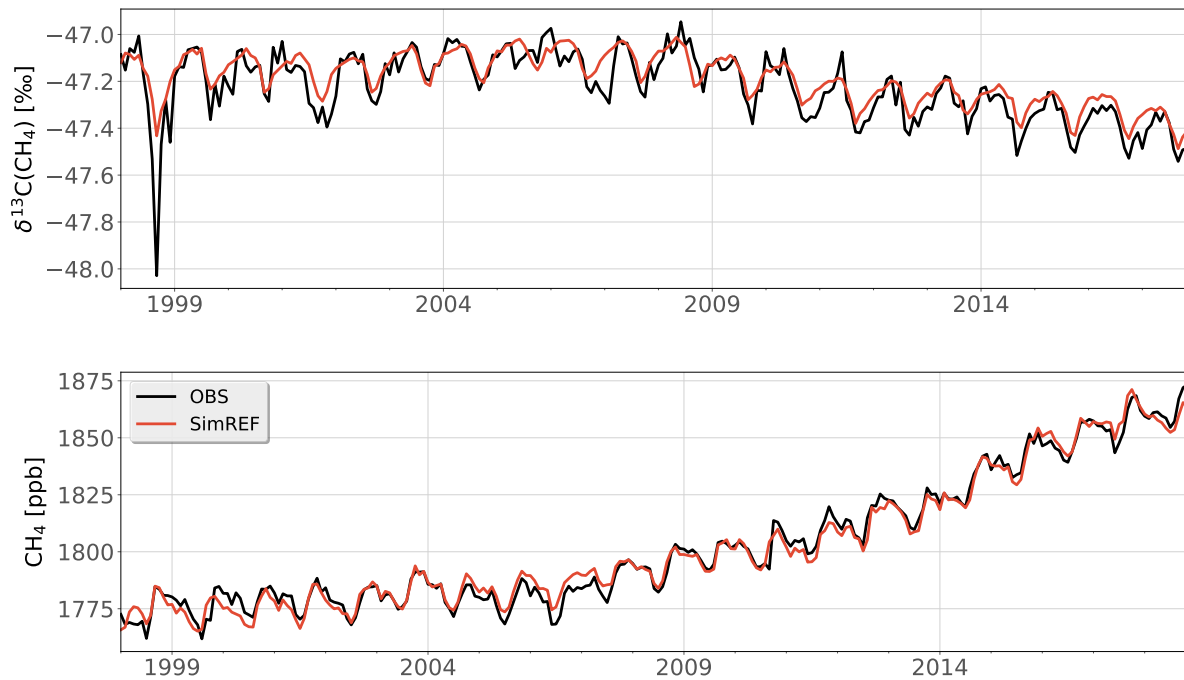

Figure S1. Time-series of observed and simulated CH_4 and $\delta^{13}\text{C}(\text{CH}_4)$ monthly values averaged over the globe using latitudinal band average. Simulated values are outputs from SimREF.

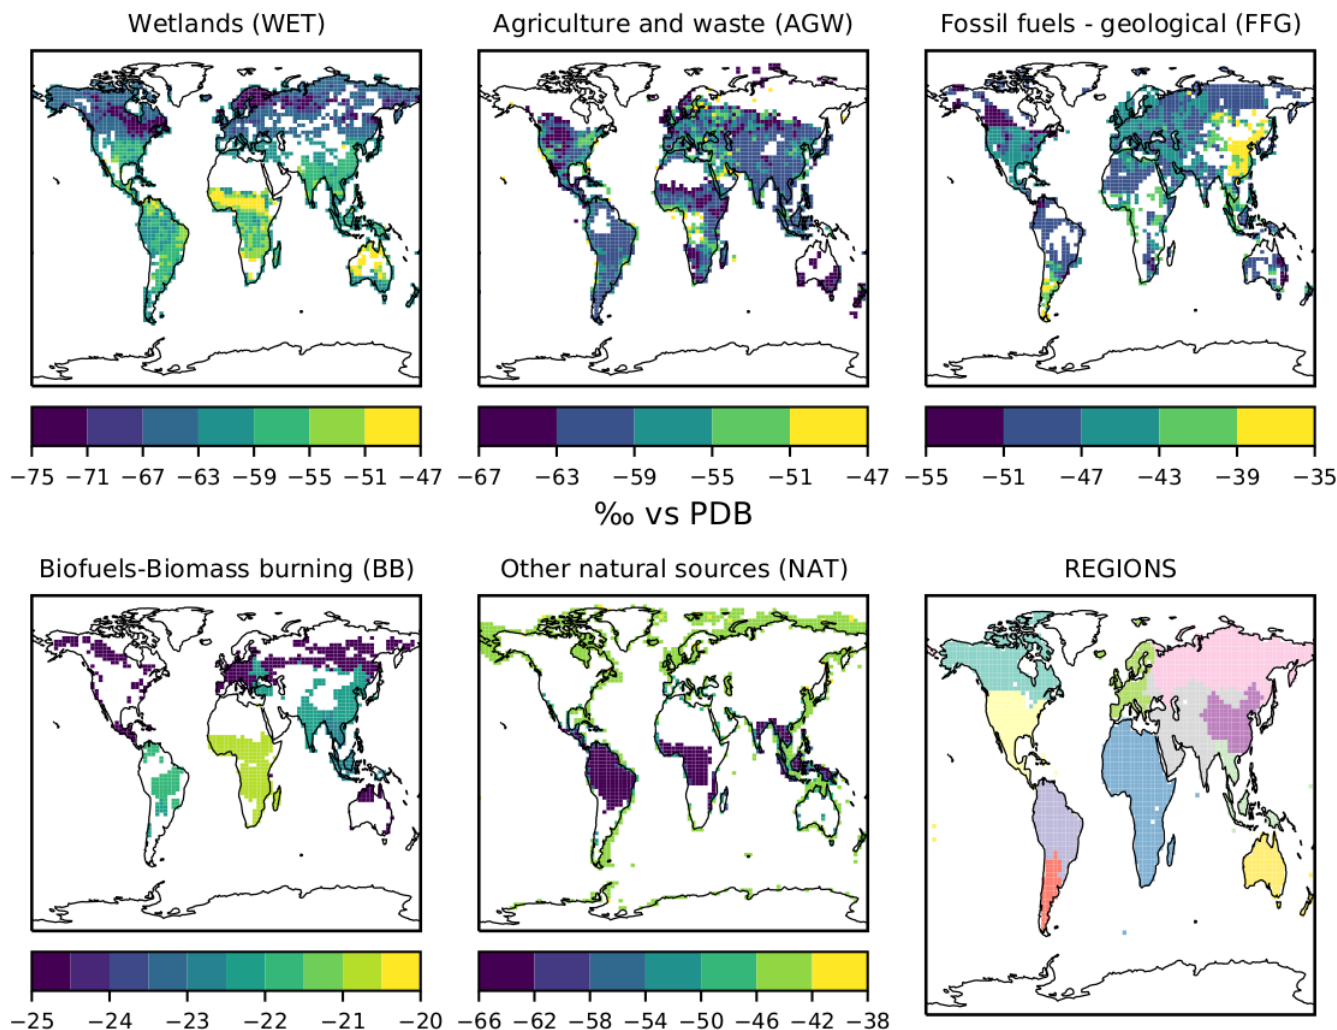

Figure S2. Prior estimates of $\delta^{13}\text{C}(\text{CH}_4)_{\text{source}}$ isotopic signatures for each of the five emission categories averaged over the 1998-2018 period. The regions over which the values are optimized are shown in the lower-right panel. WET source signatures are dependent on the latitude, with more depleted values in boreal regions than in tropical regions. BB source signatures are dependent on the vegetation (C3/C4). Burning C4 vegetation tropical regions releases CH_4 that is more ^{13}C -enriched than CH_4 released when burning C3 vegetation. AGW source signatures is dependent on the country/region and the C3 versus C4 livestock diet. FFG source signatures mainly depend both on the location and the contributions from coal, oil&gas and geological sources to the total FFG emissions of a specific country/region. For example, China ^{13}C -enriched large coal emissions highly contributes to the FFG source signature in this region which is notably ^{13}C -enriched compared to other regions.

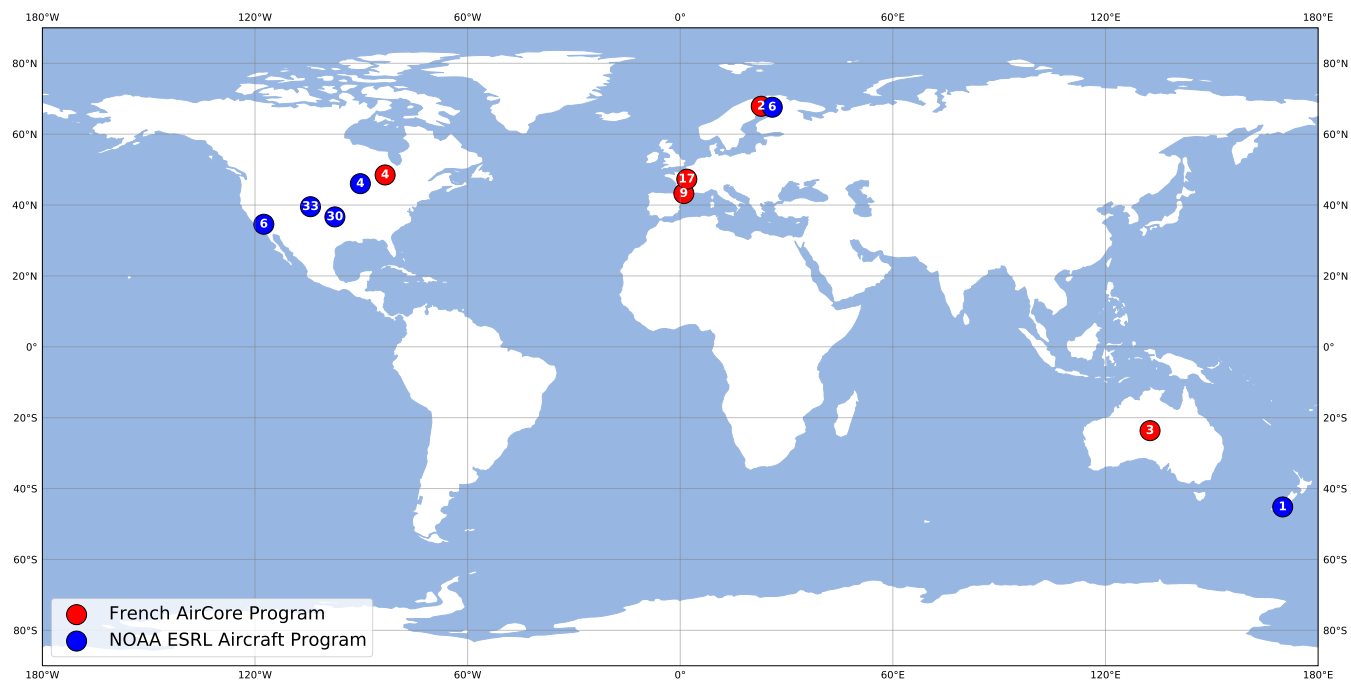

Figure S4. Locations and numbers of CH₄ vertical profiles retrieved using the AirCore technique. A comprehensive list of the locations and the associated providers can be found in Table S4.

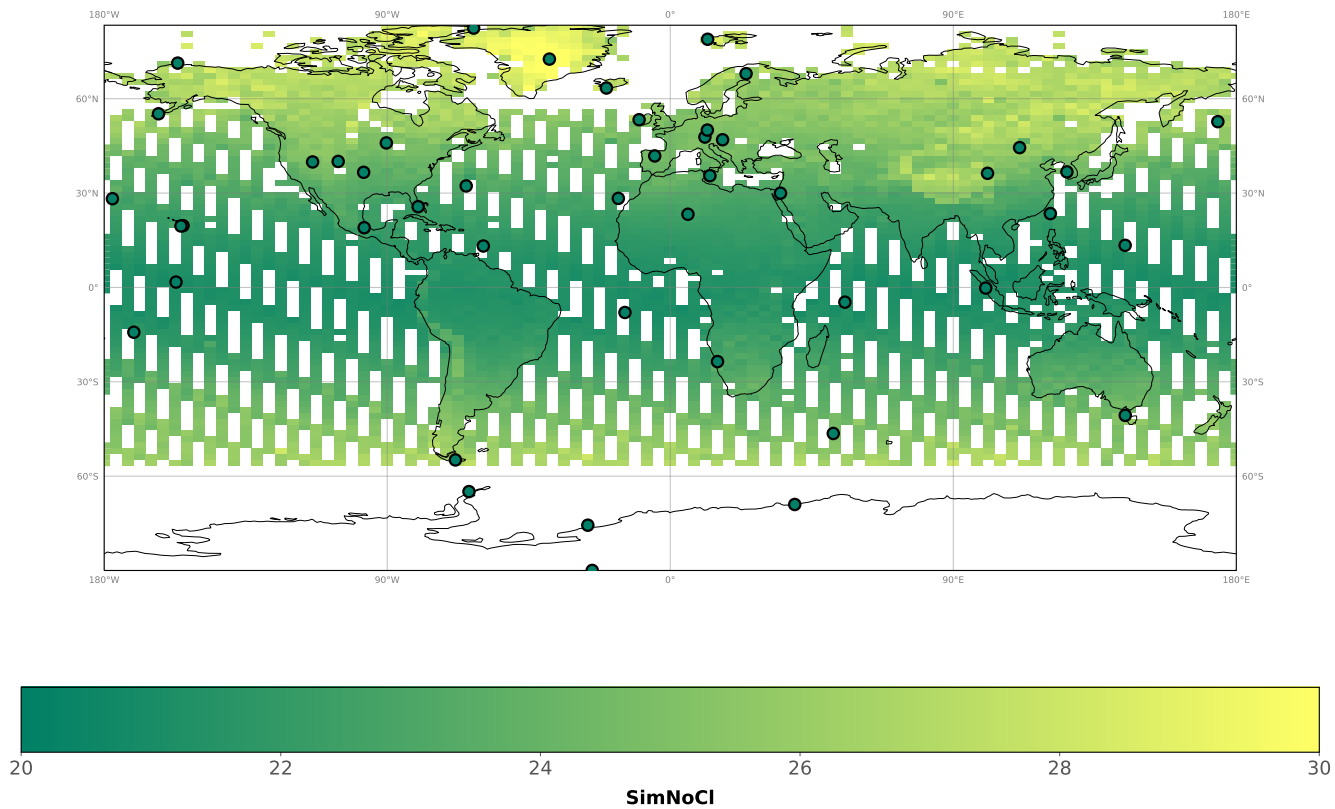

Figure S5. XCH₄ annual bias in 2018 between SimNoCl and SimREF. Colored dots show the bias at NOAA GML surface stations.
