20 **Abstract:** We use Optimal Estimation (OE) to quantify methane fluxes based on total column  
21 CH<sub>4</sub> data from the Greenhouse Gases Observing Satellite (GOSAT) and the GEOS-Chem global  
22 chemistry transport model. We then project these fluxes to emissions by sector at 1 degree  
23 resolution and then to each country using a new Bayesian algorithm that accounts for prior and  
24 posterior uncertainties in the methane emissions. These estimates are intended as a pilot dataset  
25 for the Global Stock Take in support of the Paris Agreement. However, differences between the  
26 emissions reported here and widely-used bottom-up inventories should be used as a starting point  
27 for further research because of potential systematic errors of these satellite based emissions  
28 estimates. We find that agricultural and waste emissions are ~263 +/- 24 Tg CH<sub>4</sub>/yr,  
29 anthropogenic fossil emissions are 82 +/- 12 Tg CH<sub>4</sub>/yr, and natural wetland/aquatic emissions  
30 are 180 +/- 10 Tg CH<sub>4</sub>/yr. These estimates are consistent with previous inversions based on  
31 GOSAT data and the GEOS-Chem model. In addition, anthropogenic fossil estimates are

32 consistent with those reported to the United Nations Framework Convention on Climate Change  
33 [80.4 Tg CH<sub>4</sub>/yr for 2019]. Alternative priors can be easily tested with our new Bayesian  
34 approach (also known as prior swapping) to determine their impact on posterior emissions  
35 estimates. We use this approach by swapping to priors that include much larger aquatic emissions  
36 and fossil emissions (based on isotopic evidence) and find little impact on our posterior fluxes.  
37 This indicates that these alternative inventories are inconsistent with our remote-sensing  
38 estimates and also that the posteriors reported here are due to the observing and flux inversion  
39 system and not uncertainties in the prior inventories. We find that total emissions for  
40 approximately 57 countries can be resolved with this observing system based on the degrees-of-  
41 freedom for signal metric (DOFS > 1.0) that can be calculated with our Bayesian flux estimation  
42 approach. Below DOFS of 0.5, estimates for a countries total emissions are more weighted to our  
43 choice of prior inventories. The top five emitting countries (Brazil, China, India, Russia, USA)  
44 emit about half of the global anthropogenic budget, similar to our choice of prior emissions but  
45 with the posterior emissions shifted towards the agricultural sector and less towards fossil  
46 emissions, consistent with our global posterior results. Our results suggest remote sensing based  
47 estimates of methane emissions can be substantially different (although within uncertainty) than  
48 bottom-up inventories, isotopic evidence, or estimates based on sparse in situ data, indicating a  
49 need for further studies reconciling these different approaches for quantifying the methane  
50 budget. Higher resolution fluxes calculated from upcoming satellite or aircraft data such as the  
51 Tropospheric Monitoring Instrument (TROPOMI) and those in formulation such as the  
52 Copernicus CO<sub>2</sub>M, MethaneSat, or Carbon Mapper can be incorporated in our Bayesian  
53 estimation framework for the purpose of reducing uncertainty and improving the spatial  
54 resolution and sectoral attribution of subsequent methane emissions estimates.

57 

## 1.0 Introduction

58 

### 1.1 Atmospheric Methane Background

59

60 Atmospheric methane ( $\text{CH}_4$ ) is the second most important anthropogenic greenhouse gas  
 61 behind carbon dioxide ( $\text{CO}_2$ ) and a contributor to poor surface air quality as it is an ozone  
 62 precursor. Atmospheric methane has increased by nearly a factor 3 over its pre-industrial values  
 63 largely due to anthropogenic emissions (e.g. *Dlugokencky et al.* 2011; *Ciais et al.* 2013, and refs  
 64 therein). Over the last two decades, methane has been increasing but for reasons that are still  
 65 being assessed, although recent studies provide evidence that it is due to a combination of fossil  
 66 and agricultural emissions with some role due to variations in the atmospheric sink of methane  
 67 (e.g. *Schaefer et al.* 2016; *Worden et al.* 2017; *Turner et al.* 2019; *Zhang et al.* 2021). However,  
 68 it is unclear which regions and which sectors are the cause of changes in atmospheric methane  
 69 over the last twenty years because of substantial uncertainties in all components of the methane  
 70 budget (*Kirchke et al.* 2013, *Janssens et al.* 2019; *Sanuois et al.* 2020) from the global (Table 1)  
 71 to local scale (Section 2). Methane has a relatively short lifetime of approximately 9 years  
 72 making it an attractive target for emissions reduction as a decline in emissions will have a rapid  
 73 impact on net radiative forcing and corresponding atmospheric heating (e.g. *Shindell et al.* 2009);

Sector	Prior (Tg $\text{CH}_4$ /yr)	Posterior (Tg $\text{CH}_4$ /yr)
Wetlands / Aquatic Seeps	199.8+/-52.8 32.0+/-6.2	179.8+/-10.0 22.5+/-3.8
Livestock	87.6+/-17.2	146.1 +/ -10.3
Rice	36.9+/-12.9	67.6 +/ -6.8
Fires	15.1+/-2.5	13.3+/-2.2
Waste	57.7+/-11.9	49.6+/-7.1
Oil	41.6+/-9.7	28.8 +/ -4.7
Gas	24.5+/-4.7	28.0 +/ -3.6
Coal	31.4+/-9.8	25.3 +/ -3.9
Total	526+/-128	561 +/-52

Table 1: Prior emissions and uncertainties are generated from various inventories or models (Section 2.3). Posterior emissions represent projection of satellite based fluxes back to emissions while accounting for the prior emissions distribution and covariances (Section 2.2). We conservatively assume uncertainties are 100% correlated so that the total reported prior and posterior uncertainties are the sum of the individual uncertainties.

74 Ganeson *et al.* 2019; Turner *et al.* 2019). Hence there is significant interest in accurately  
75 quantifying methane emissions for identifying those emissions that can be efficiently reduced.  
76

## 77       **1.2 Global Stock Take**

78       As part of the effort to reduce methane emissions and corresponding risk related to  
79 changes in climate, the Paris Agreement resulted in a framework by which countries provide an  
80 accounting of their emissions. A “Global Stock Take” (GST) to track progress in emission  
81 reductions is conducted at five-year intervals, beginning 2023. To support the first GST, Parties  
82 to the Paris Agreement are compiling inventories of GHG emissions and removals to inform  
83 their progress. Inventories are generally estimated using “bottom-up” approaches, in which  
84 emission estimates are generally based on activity data and emission factors. These bottom-up  
85 methods can provide precise and accurate emission estimates when the activity data are well  
86 quantified and emission factors are well understood. However, substantial uncertainties exist for  
87 emissions in many parts of the globe where these measurements are not rigorously made or  
88 tested across multiple sites. Even regions and emissions that are thought to be well measured can  
89 have significant differences between independent assessments and official reports; for example,  
90 Alvarez *et al.* (2018) demonstrates that 2015 oil and gas emissions are under estimated by the  
91 United States Environmental Protection Agency by about 60%. These differences, if they are  
92 representative for emissions across the globe indicate a need for an independent assessment of  
93 emissions and their uncertainties to better evaluate if reported changes in emissions are in fact  
94 occurring or if changes in the natural carbon cycle through wetlands and the methane sink are  
95 substantively affecting atmospheric methane burden. Top down estimates of methane emissions  
96 using atmospheric measurements provide an independent way of testing these inventories as  
97 observed methane concentrations are compared against expected concentrations that result from  
98 reported inventories. The objective of this paper is to demonstrate the use of satellite  
99 observations for testing and updating emissions by sector for use with the Global Stock Take.  
100 While these top-down atmospheric methane budgets cannot replace the detailed activity reports  
101 used to generate bottom-up inventories, they can be combined with those bottom-up products to  
102 produce a more complete and transparent assessment of progress toward greenhouse gas  
103 emission reduction targets. They can also help determine if the natural part of the methane  
104 budget is becoming a strong component of atmospheric methane increases. As discussed next, an

106 important component of this assessment is the evaluation of uncertainties from both bottom-up  
107 inventories and in top-down approaches.

108  
109

### 110        ***1.3 Overview of Bottom-Up Emissions And Uncertainties***

111        Bottom-up uncertainties are calculated for the methane budget by comparison between  
112 independent methods or sources, evaluating multiple estimates from a single source, comparison  
113 between models and remote sensing data, and expert opinion. For example, Saunois *et al.*  
114 (2020) uses a range of results from different studies to quantify uncertainty in the different  
115 sectors of the methane budget. However, these uncertainties are likely underestimated as they  
116 suggest that total anthropogenic agricultural emissions, for example, are known to 10% or  
117 better, whereas comparisons between different global inventories (e.g., Janssens-Maenhout *et al.*  
118 2019) suggest a much larger range of estimates for the global totals (e.g., 129 to 219 Tg CH<sub>4</sub>/yr  
119 for agriculture, and 129 to 164 Tg CH<sub>4</sub>/yr for fossil emissions). Uncertainties in national or  
120 regional total emissions are even more challenging to estimate such that expert opinion is used:  
121 Janssens-Maenhout *et al.* (2019) suggests that Annex 1 (developed) countries have  
122 approximately 15% uncertainty in reported fossil emissions whereas Annex 2 countries have  
123 ~30% uncertainties, essentially asserting that less informed inventories have double the  
124 uncertainty of better informed emissions. Wetland emissions, which comprise ~30-45 % of the  
125 methane budget also show significant differences of up to 40% across wetland models (e.g.  
126 Melton *et al.* 2013; Poulter *et al.* 2017, Ma *et al.* 2021), depending on region. An example of  
127 how these uncertainties are projected to the total methane budget for each of the main sectors is  
128 presented in Table 1 using the prior emissions and their uncertainties for the analysis discussed  
129 in this paper (Section 2.3).

131        However, recent studies challenge even these estimates of emission uncertainties;  
132 emissions for lakes and rivers could be as large or larger than wetlands, with correspondingly  
133 larger uncertainties of 50% or more (Saunois *et al.* 2020; Rosentreter *et al.* 2021). Primarily  
134 because of this extra term from lakes and rivers, the total budget from bottom-up inventories  
135 discussed in Saunois *et al.* (2020) ranges from 583 – 861 Tg CH<sub>4</sub>/yr. Contrasting with this much  
136 larger than expected biogenic source is isotopic evidence that suggests fossil emissions are also  
137 much larger than expected, 160 +/- 40 Tg CH<sub>4</sub>/yr (Schweitzke *et al.* 2017). These larger than

138 expected values from aquatic and fossil sources are challenging to reconcile with existing bottom  
139 up estimates and with global estimates from the top down which are primarily constrained by the  
140 methane sink. For example, the methane sink must approximately balance total methane  
141 emissions, leading to total emissions of  $560 \pm 60$  Tg CH<sub>4</sub>/yr (e.g., Prather *et al.* 2012).  
142 Consequently much larger values in either aquatic emissions or fossil emissions must be  
143 balanced by much lower emissions in other sectors indicating that either our knowledge of the  
144 processes controlling different components of the methane sink are fundamentally wrong or one  
145 or both of these inflated emissions is incorrect, that is, well outside calculated uncertainties.  
146

#### 147       **1.4 Use of Remote Sensing For Quantifying Emissions and Uncertainties**

149       Top-down approaches using in situ or remote sensing measurements of atmospheric  
150 methane can be used to evaluate and update bottom-up emissions (or inventories) by first  
151 projecting bottom up emissions through a chemical transport model to atmospheric  
152 concentrations and then comparing these modeled concentrations to observations (e.g.

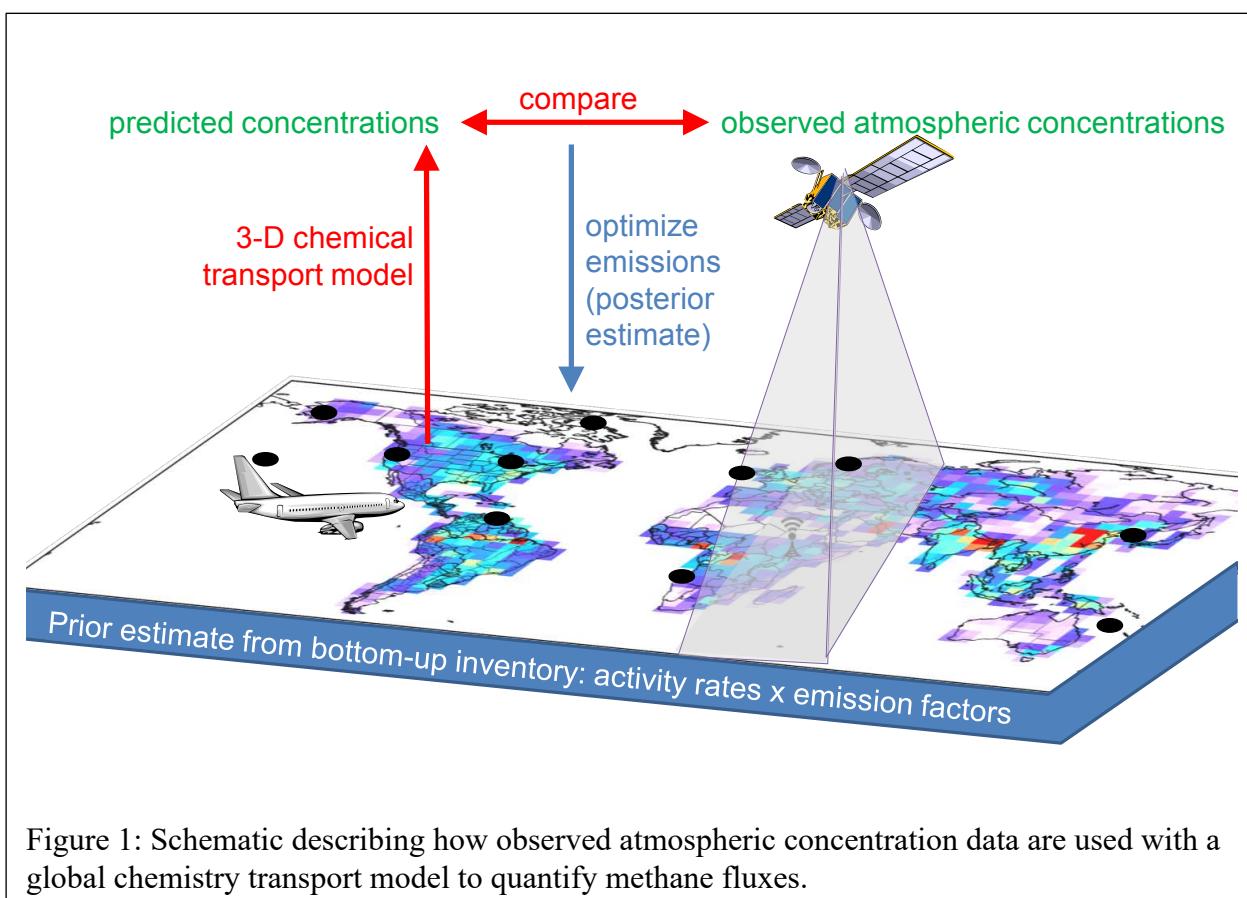

Figure 1: Schematic describing how observed atmospheric concentration data are used with a global chemistry transport model to quantify methane fluxes.

153 Frankenberg *et al.* 2005; Bergamaschi *et al.* 2013, Qu *et al.* 2021 and refs therein). An inverse  
154 method is utilized to update the net flux (or total emissions and surface sinks) within a chosen  
155 grid scale based on the mismatch between modeled and observed concentrations (Figure 1).  
156 When the top-down quantified flux can be uniquely associated with a single source, these tests of  
157 bottom-up inventories provide information about biases in the reported emission (e.g., Duren *et*  
158 *al.* 2019, Varon *et al.* 2019, Pandey *et al.* 2019) which can be used to either update the emissions  
159 or provide evidence that additional research is needed to improve the process knowledge used to  
160 construct the emissions. However, top-down fluxes have other uncertainties that must be  
161 accounted for when comparing to bottom-up inventories, these include 1) systematic and random  
162 uncertainties in the data, 2) systematic errors in the model that relates observed methane  
163 concentrations to fluxes, and 3) smoothing error related to uncertainty in the prior emissions  
164 combined with the spatial resolution of the top-down estimate.

165 Top-down approaches can typically quantify the precision of the fluxes as it is directly  
166 related to the uncertainties of the observations and the prior knowledge of the flux distribution.  
167 However, the accuracy of the top-down fluxes related to data and model is more challenging to  
168 quantify and recent results suggest that these errors can be substantive. For example, Qu *et al.*  
169 (2021) demonstrates that systematic differences between total column CH<sub>4</sub> concentrations from  
170 TROPOMI and GOSAT satellite data, likely related to poorly characterized surface albedo, can  
171 lead to substantial differences when used to constrain top-down fluxes. For example, there is  
172 almost a 100% difference between estimated livestock emissions in Brazil when comparing  
173 TROPOMI versus GOSAT based fluxes, which Qu *et al.* (2021) attributes to biases in the  
174 TROPOMI total column data due to surface albedo variations over Brazil.

175 Errors in model transport and chemistry are another significant uncertainty when  
176 inverting concentration data to fluxes. For example, Mcnorton *et al.* (2020) finds that model  
177 errors in atmospheric concentrations that result from atmospheric transport can be as large or  
178 larger as uncertainties in the data, leading to almost a doubling of the uncertainty in top-down  
179 fluxes. Schuh *et al.* (2019) demonstrates that transport errors can result in biases of up to 1.7  
180 Petagrams of carbon in top-down CO<sub>2</sub> fluxes, about the same as the global net yearly carbon  
181 sink. Jiang *et al.* (2013) also demonstrates that errors in convection can affect surface emissions  
182 estimates of CO by up to 40% in regions of strong convection such as S.E. Asia. Unfortunately,  
183 challenges remain in quantifying how model uncertainties project to flux uncertainty. One

184 approach is to use an ensemble of models for the inversion in which the same data and  
185 constraints are used for the inverse model; a challenge here is to ensure that the inversion  
186 approach used with each model is consistent. For example, the Global Carbon Project (Saunois *et*  
187 *al.* 2020) uses an ensemble of model inversions using different data sets to evaluate flux  
188 inversion errors; however, as shown in Section 2.2, this approach does not attempt to attribute  
189 differences in results to either the model, data, or spatial resolution and hence it can be  
190 challenging to identify approaches to reduce overall uncertainty. Another approach is to use  
191 different data sets but the same model and inversion setup to quantify emissions, as different  
192 sensitivities of the model to the different observed concentrations are affected by model error  
193 (Jiang *et al.* 2015; Yin *et al.* 2021). A third approach is to mitigate model and transport error. For  
194 example, Jiang *et al.* (2015) assimilates observed CO concentrations over ocean regions before  
195 inverting for continental source emissions to ensure that model/data mismatch over the ocean  
196 does not affect the emissions estimates. As discussed in the next section our flux inversion  
197 jointly estimates OH (the primary methane sink) with methane emissions to mitigate the impact  
198 of OH variability on CH<sub>4</sub> emissions estimates. A latitudinal correction is also applied to both  
199 data and model to ensure that errors in stratospheric chemistry and transport have less of an  
200 impact on the estimated fluxes. However, the residual systematic errors from model transport  
201 and chemistry are not characterized although there is no evidence to suspect significant  
202 systematic errors based on comparing posterior concentrations with independent data as  
203 discussed in the next section. Nonetheless, as stated in the abstract, differences between top-  
204 down emissions reported in this manuscript with those from bottom-up efforts should be  
205 considered as a starting point for new investigation as opposed to confirmation or falsification of  
206 the top-down or bottom up estimate.

207 Smoothing error is also a significant but challenging component of the emissions error  
208 budget to quantify for top-down estimates. This uncertainty depends on the spatial and temporal  
209 resolution of the top-down estimate combined with the prior uncertainty of the emissions  
210 (Rodgers 2000). The spatial resolution of the estimate in turn depends on the sampling, pixel  
211 size, measurement uncertainty, and lifetime of the gas. As typical top-down estimates do not  
212 quantify the terms needed to quantify smoothing error, smoothing error is not usually represented  
213 in top-down error budgets. However, this term can be the largest of the error sources, as  
214 discussed further in Section 2.1, especially if the *a priori* uncertainties for emissions are poorly

characterized. Our Bayesian, optimal estimation approach (Rodgers 2000) described here allows us to quantify smoothing error for the sectoral emissions presented here (Sections 2.2. and 2.3). Furthermore, by reporting the averaging kernel matrices and fluxes we can remove smoothing error in comparisons between top-down fluxes and bottom-up models (Ma *et al.* 2021) or greatly reduce the smoothing error component in comparisons between two different instruments (e.g. Cusworth *et al.* 2021).

Related to the problem of calculating smoothing error is that many top-down fluxes are projected back to emissions by assuming that all emissions within a grid can be uniformly scaled by the ratio of posterior to prior flux (e.g., Maasakkers *et al.* 2019 and references therein). This method, while computationally expedient, diverts from the Bayesian assumptions used with top-down inversions, potentially adding poorly characterized uncertainty and potentially unphysical biases (Cusworth *et al.* 2021) to the emissions estimates, because it does not account for the structure of the errors or their correlations and instead assumes that different types of emissions within a grid cell (e.g. fires, fossil, livestock, wetlands) are 100% correlated. Shen *et al.* (2021) addresses this problem by weighting the posterior emissions estimate by their prior uncertainty. Our approach used here is derived in Cusworth *et al.* (2021) and summarized in Section 2.2, addresses this problem by accounting for the structure of the errors, following a Bayesian methodology from the start of the problem (calculation of fluxes using observations) to the end (calculation of emissions from fluxes).

234

## 235 **2.0 Approach for Quantifying “Top Down” Emissions Using Satellite Data**

Our emission quantification approach is described in this section. First optimal estimation is used (Section 2.1) to quantify methane fluxes on a 2x2.5 grid using the GEOS-Chem global chemistry transport model with GOSAT satellite data for the year 2019. For our purposes of emissions attribution, this first inverse step must report the prior as well as the posterior flux error covariance (or Hessian) matrices (Zhang *et al.* 2021, Qu *et al.* 2021). The posterior error covariance (or Hessian) can be computationally challenging to calculate so is typically not reported with variational or adjoint based top-down estimates and instead ensemble approaches are used to approximate flux uncertainties (e.g. Janadarnan *et al.* 2020). However in our approach, this first step uses analytic Jacobians derived from the GEOS-Chem model that relate emissions to concentrations and hence has been traditionally computationally expensive as

246 compared to ensemble or adjoint based inversion methods, but does allow for a straightforward  
247 calculation of the Hessian. The second step (Section 2.2) uses the prior fluxes, the corresponding  
248 constraint and Hessian covariance matrices, and priors and prior covariances for emissions by  
249 sector, to linearly project the fluxes to emissions by sector at 1 degree resolution while  
250 accounting for the prior uncertainty distributions, correlations in the posterior covariance, and  
251 varying spatial resolution. This step can use different prior emissions and prior covariances from  
252 that of the flux inversion as the information from the flux inversion is preserved (Rodgers and  
253 Connor 2003). Critical to this second step is that prior uncertainties and their correlations are  
254 provided for the emissions for the desired sector and spatial resolution (Section 2.3).

255

### 256       **2.1 Top Down Flux Estimates**

257

258       We estimate top-down fluxes based on the approach and results described in Maasakkers *et*  
259 *al.* (2021), Zhang *et al.* (2021) and Qu *et al.* (2021) and the reader is referred to these papers for  
260 a more extensive description of the approach and validation of these methane fluxes. To  
261 summarize, we optimize a state vector that consists of (1) 2019 methane emissions from all  
262 sectors on a global  $2^\circ \times 2.5^\circ$  grid (4020 elements); and (2) tropospheric OH concentrations in  
263 northern and southern hemispheres (2 elements). We assume the seasonal variations of methane  
264 emissions to be correct in the prior inventory and apply posterior/prior ratio equally to all months  
265 in each grid cell. The optimization of annual hemispheric OH concentrations avoids propagating  
266 biases in the simulated interhemispheric OH gradient to the solution for methane emissions  
267 (Zhang *et al.*, 2018). We solve this Bayesian problem analytically, which yields a best posterior  
268 estimate for the state vector, the posterior error covariance matrix, and the averaging kernel  
269 matrix. Unlike in Zhang *et al.* (2021) and Qu *et al.* (2021), wetland fluxes are not treated as  
270 separate elements in the state vector as we found that introduced uncertainties into the sectoral  
271 attribution because the wetland flux areas used in Qu *et al.* (2021) could overlap the different  
272 regions (Table 2) used in our approach to mitigate computational complexity.

273       The inverse problem is regularized by prior estimates for the state vector, which are compiled  
274 from multiple bottom-up studies. The EDGAR v4.3.2 global emission inventory for 2012  
275 (Janssens-Maenhout *et al.*, 2017) is used as default for anthropogenic emissions, superseded in  
276 the U.S. by Maasakkers *et al.* (2016) and for the fossil fuel exploitation sector by Scarpelli *et al.*  
277 (2020). Seasonalities of emissions from manure management and rice cultivation are specified

278 following Maasakkers et al. (2016) and B. Zhang et al. (2016), respectively. Monthly wetland  
279 emissions in 2019 are from the WetCHARTS v1.3.1 18-member ensemble mean (Bloom et al.,  
280 2017). Note that in Zhang *et al.* (2021) and Qu *et al.* (2021), wetland fluxes are not included in  
281 the gridded fluxes but instead estimated separately so as to better compare to bottom-up models  
282 (Ma *et al.* 2021). In the top-down flux inversion used here, wetland fluxes are included with the  
283 other emissions in each grid as we found that partitioning fluxes back to their sectoral  
284 contribution (next section) was challenging due to gridding errors when wetland fluxes are  
285 separately considered in the cost function. Daily global emissions from open fires are taken from  
286 GFEDv4s (van der Werf et al., 2017). Global geological emissions for the flux inversion are set  
287 to be 2 Tg a<sup>-1</sup> based on Hmiel et al. (2020) with the spatial distribution from Etiope et al. (2019).  
288 Termite emissions are from Fung et al. (1991). The prior estimates for the hemispheric  
289 tropospheric OH concentrations are based on a GEOS-Chem full chemistry simulation (Wecht et  
290 al., 2014).

291 The GEOS-Chem CTM v12.5.0 (10.5281/zenodo.3403111) is used as forward model for  
292 the inversion. The simulation is driven by MERRA-2 meteorological fields (Gelaro et al., 2017)  
293 from the NASA Global Modeling and Assimilation Office (GMAO) with 2°×2.5°  
294 horizontal resolution and 47 vertical layers (~ 30 layers in the troposphere). We excluded  
295 observations poleward of 60°, where low Sun angles and extensive cloud cover make the  
296 retrieval more difficult, and stratospheric CTM bias can affect the inversion (Turner *et al.*, 2015).  
297

298 The posterior estimate as defined by Bayesian inference assuming Gaussian error  
299 statistics is obtained by minimizing the cost function  $J(x)$ :

300

$$301 J(x) = (\mathbf{x} - \mathbf{x}_A)^T \mathbf{S}_A^{-1} (\mathbf{x} - \mathbf{x}_A) + \gamma (\mathbf{y} - \mathbf{Kx})^T \mathbf{S}_y^{-1} (\mathbf{y} - \mathbf{Kx}), \quad (1)$$

302

303

304 where  $\mathbf{K}$  is the Jacobian matrix describing the sensitivity of the observations to the state vector as  
305 simulated by GEOS-Chem. The vector  $\mathbf{x}_A$  is the prior flux estimate.  $\mathbf{S}_A$  is the *a priori*  
306 covariance matrix for this inversion and is a diagonal matrix that is constructed by assuming  
307 50% prior error standard deviation for emissions on the 2°×2.5° grid and 10% prior error  
308 standard deviation for hemispheric annual mean OH concentrations.  $\mathbf{S}_y$  is the observational error

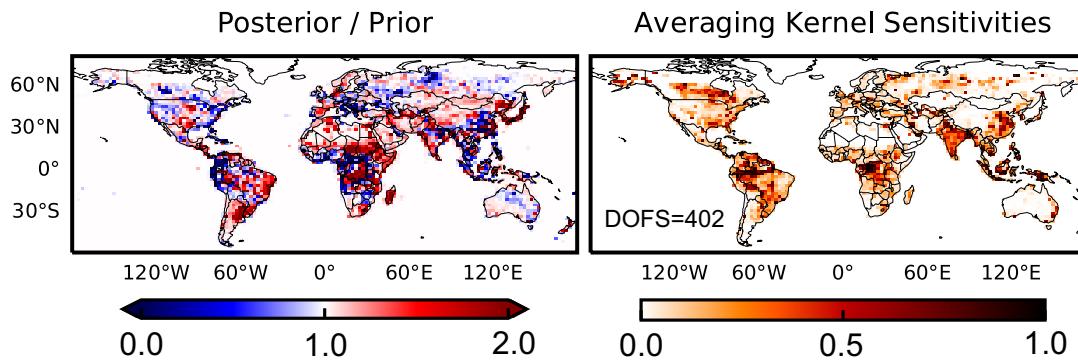

Figure 2. (left panel) Corrections to prior estimates of methane emissions on the  $2^\circ \times 2.5^\circ$  grid and corresponding averaging kernel sensitivities. (right panel) The averaging kernel sensitivities are the diagonal elements of the averaging kernel matrix for the inversion. The trace of the averaging kernel matrix defines the degrees of freedom for signal (DOFS) for the inversion, shown in the inset.

309 covariance matrix. Diagonal elements of  $\mathbf{S}_y$  are calculated using the residual error method (Heald  
 310 et al., 2004) as the variance of the residual difference between observations and the GEOS-Chem  
 311 prior simulation on the  $2^\circ \times 2.5^\circ$  grid after subtracting the mean difference. We use a  
 312 regularization parameter  $\gamma$  (Hansen et al., 1999; Y. Zhang et al., 2018, 2020; Maasakkers et al.,  
 313 2019; Lu et al., 2021) to account for the off-diagonal structure missing in  $\mathbf{S}_y$ . Based on the corner  
 314 of the L-curve (Hansen et al., 1999) and the expected chi-square distribution of the cost function  
 315 (Lu et al., 2021), we choose  $\gamma = 0.5$  (Qu et al., 2021).

316 Assuming that the problem for quantifying methane fluxes from observed concentrations  
 317 is linear, or only moderately non-linear, then the fluxes,  $\hat{\mathbf{x}}$ , can be related to observed methane  
 318 concentrations using the following equation: (Rodgers 2000):  
 319

$$320 \quad \hat{\mathbf{x}} = \mathbf{x}_A + \hat{\mathbf{S}} \mathbf{K}^T \mathbf{S}_y^{-1} (\mathbf{y} - \mathbf{K} \mathbf{x}_A) \quad (2)$$

321

322

323 The posterior error covariance matrix  $\hat{\mathbf{S}}$  is given by:

324

$$325 \quad \hat{\mathbf{S}} = (\mathbf{K}^T \mathbf{S}_y^{-1} \mathbf{K} + \mathbf{S}_A^{-1})^{-1}. \quad (3)$$

326

327 This top-down flux inversion also provides the spatial resolution matrix or Averaging Kernel  
328 Matrix  $\mathbf{A}$ , which defines the sensitivity of the solution to the true state:

329  
330

331  $\mathbf{A} = \mathbf{I} - \hat{\mathbf{S}}\mathbf{S}_A^{-1}$ , (4)

332

333 Summing the diagonal elements of the averaging kernel for a given region provides the  
334 Degrees of Freedom for Signal (or DOFS), a useful metric for the sensitivity of the observing  
335 system to the underlying fluxes as it describes the sensitivity of the estimated fluxes to the actual  
336 distribution of fluxes (Rodgers 2000). Figure 2 (right panel) shows the averaging kernel  
337 sensitivities (or diagonal elements of the averaging kernel matrix) of the inversions. The  
338 averaging kernel sensitivities are highest over major anthropogenic source regions, where the  
339 methane emissions are the largest and the observations have a good ability to determine the  
340 posterior solution independently of the prior estimate. The inversion has ~402 DOFS for  
341 methane emissions, meaning that it contains 402 independent pieces of information on the  
342 distribution of methane emissions. Although our flux inversion is based on the top-down setup  
343 described in Qu *et al.* (2021), this value is larger than the DOFS reported in Qu et al. (2021)  
344 because that estimate separates wetlands from non-wetlands in the inversion scheme whereas the  
345 flux estimate used here does not. The posterior / prior ratios for the 2019 inversion in Figure 2  
346 (left panel) show consistent upward adjustments in the south-central US, Venezuela, and the  
347 Middle East and downward adjustments in the western US and North China Plain, consistent  
348 with Qu et al. (2021) and Zhang et al. (2021).

349 If the matrix  $\mathbf{S}_A$  in equations 1 and 3 represents the actual *a priori* uncertainty  
350 corresponding to the *a priori*  $\mathbf{x}_A$ , then the posterior error covariance describes the total error for  
351 the estimate (Rodgers 2000). In practice, the matrix  $\mathbf{S}_A$  represents a “constraint matrix” that is  
352 either a best guess for uncertainties of fluxes (e.g., assumed here to be 50%) within a grid and/or  
353 it is constructed to ensure the inversion converges, typically because systematic errors in the data  
354 and/or the model or numerical instabilities make it challenging to find a global minimum in the  
355 cost function as shown in Equation 1 (Bowman *et al.* 2006). In the case where  $\mathbf{S}_A$  represents a  
356 constraint matrix, the total posterior error becomes:

357

358  $\mathbf{S}_{\text{tot}} = (\mathbf{I} - \mathbf{A})\mathbf{S}_A^{\text{true}}(\mathbf{I} - \mathbf{A})^T + \hat{\mathbf{S}}\mathbf{K}^T\mathbf{S}_y^{-1}\mathbf{K}\hat{\mathbf{S}}$  (5)

359

360 Where the  $\mathbf{S}_A^{\text{true}}$  is the *a priori* uncertainties for the estimate. In practice,  $\mathbf{S}_A^{\text{true}}$  can be  
361 challenging to calculate due to lack of information about the emissions or fluxes and may not  
362 even be invertible because of correlations within the matrix. However, we use a set of informed  
363 inventories and models to generate a prior covariance for methane emissions as described in the  
364 next section. As discussed Worden *et al.* (2004), the smoothing error in the estimate is the first  
365 term on the right side and the error due to measurement uncertainty is the second/middle term.  
366 While the variables in Equation 5 are representative here of the top-down flux estimate, the  
367 formulation can be generalized for any estimate to support interpretation of the results. For  
368 example, in a system with perfect resolution the averaging kernel matrix becomes the identity  
369 matrix and the smoothing error becomes zero, hence the reason that improving the spatial  
370 resolution reduces the smoothing error, an important goal which can be realized with the  
371 increased observation density of up-coming satellites such as CO2M, methane-sat, and Carbon  
372 Mapper. Equation 5 also demonstrates that poorly characterized prior uncertainties in one region  
373 affect an estimate in another regions because of cross-terms in the averaging kernel matrix  $\mathbf{A}$ .  
374 This aspect of top-down inversions must therefore be accounted for when interpreting the  
375 seasonality and magnitude of top-down fluxes (e.g. Ma *et al.* 2021).

376 Systematic errors can be included by adding the following term:  $\hat{\mathbf{S}}\mathbf{K}_{\text{sys}}^T \mathbf{S}_{\text{sys}}^{-1} \mathbf{K}_{\text{sys}}^T \hat{\mathbf{S}}$ ,  
377 where  $\mathbf{K}_{\text{sys}}$  is the Jacobian that describes the sensitivity of the modeled concentrations to different  
378 parameters in the model that relate emissions to concentrations and  $\mathbf{S}_{\text{sys}}$  is a matrix containing  
379 uncertainties for the model or data parameters. In this manuscript we do not explicitly calculate  
380 systematic errors for the fluxes. We are currently studying how to empirically evaluate  
381 systematic errors in the flux estimate, following the approach in Jiang *et al.* (2015) for use in  
382 quantifying uncertainties in methane fluxes and emissions.

383

384 **Evaluation of Top-Down Flux Estimates:** The combination of model (GEOS-chem)  
385 and data (GOSAT) used to quantify methane fluxes have been evaluated previously by  
386 comparing prior and posterior model concentrations to independent data. Maasakkers et al  
387 (2019) finds that posterior methane concentrations have correlations ( $R^2$ ) of 0.76, 0.81, and 0.91  
388 with data from surface sites, aircraft, and total column data respectively. These correlations are  
389 essentially the same as those for the GEOS-chem prior concentrations, likely because these

measurements are taken in background regions away from sources. These comparisons between posterior concentrations with independent data sets demonstrate that the GEOS-Chem model with GOSAT data has skill in quantifying atmospheric methane concentrations and that assimilating GOSAT data into GEOS-Chem for the purpose of quantifying fluxes is at least as skillful as using prior information when looking at background regions away from emissions sources. Changes in fluxes based on GOSAT data are therefore driven entirely by differences in satellite observed concentrations over source regions.

397

398

399 *2.2 Projecting Fluxes To Emissions And Their Uncertainties*

400

The derivation that describes how to project top-down fluxes back to emissions by sector at arbitrary resolution is described in Cusworth *et al.* (2021) and summarized in this section. For policy-relevance and CH<sub>4</sub> budget quantification, we wish to optimize emissions ( $\mathbf{z}$ ) using atmospheric observations, i.e., we want to compute the explicit posterior representation without re-simulation of an atmospheric transport model. The relationship we use between emissions  $\mathbf{z}$  and fluxes  $\mathbf{x}$  is simple aggregation (the total flux within a grid box is the sum of emissions), and can be represented by matrix  $\mathbf{M}$ :

408

$$409 \quad \mathbf{x} = \mathbf{Mz}. \quad (6)$$

410

411 The solution for projecting fluxes back to emissions takes the form (Cusworth *et al.* 2021):

412

$$413 \quad \hat{\mathbf{z}} = \mathbf{z}_A + \hat{\mathbf{Z}}\mathbf{M}^T\hat{\mathbf{S}}^{-1} \left[ (\mathbf{I} - \hat{\mathbf{S}}\hat{\mathbf{S}}_A^{-1})(\mathbf{x}_A - \mathbf{M}\mathbf{z}_A) + (\hat{\mathbf{x}} - \mathbf{x}_A) \right] \quad (7)$$

414

415 where the  $(\hat{\mathbf{z}})$  is the posterior emissions vector with error covariance  $(\hat{\mathbf{Z}})$  and  $\mathbf{I}$  is the identity matrix,  
 416 The posterior emission error covariance matrix  $\hat{\mathbf{Z}}$  is calculated explicitly given  $\mathbf{M}$ ,  $\mathbf{S}_A$ ,  $\hat{\mathbf{S}}$ , and prior  
 417 emissions error covariance matrix  $\mathbf{Z}_A$ :

418

$$419 \quad \hat{\mathbf{Z}} = \left( \mathbf{M}^T (\hat{\mathbf{S}}^{-1} - \mathbf{S}_A^{-1}) \mathbf{M} + \mathbf{Z}_A^{-1} \right)^{-1} = \left( \mathbf{M}^T (\mathbf{K}^T \mathbf{S}_y^{-1} \mathbf{K}) \mathbf{M} + \mathbf{Z}_A^{-1} \right)^{-1} \quad (8)$$

420

421 This solution depends on the top-down flux inversion providing the inversion characterization  
 422 products (i.e., the flux prior  $\mathbf{x}_A$  and flux constraint matrix  $\mathbf{S}_A$  and the flux Hessian  $\hat{\mathbf{S}}$ ). Note that  
 423 here we must use the Hessian as described in Equation 3, not the total posterior covariance as  
 424 described by Equation 5 (Cusworth *et al.* 2021). To quantify the set of sectoral emissions  $\hat{\mathbf{z}}$ , a  
 425 corresponding prior emissions  $\mathbf{z}_A$ , and covariance matrix  $\mathbf{Z}_A$ , must be provided at the desired  
 426 spatial grid; in this study we choose a 1 degree lon/lat grid. Note that the emissions and their  
 427 prior uncertainties used to generate prior fluxes for the top-down flux inversion ( $\mathbf{x}_A$ ) can be  
 428 different from those used to project the top-down fluxes back to sectoral emissions for linear or  
 429 moderately non-linear problems (e.g. Rodgers and Connor 2003; Bowman *et al.* 2006) as the  
 430 information from the measurement is preserved in the  $\mathbf{K}^T \mathbf{S}_y^{-1} \mathbf{K}$  term which is contained in  
 431  $\hat{\mathbf{S}}^{-1} - \mathbf{S}_A^{-1}$  as shown in Equation 8. This means that  $\mathbf{Mz}_A$  can be different from  $\mathbf{x}_A$ , and their  
 432 corresponding covariances, as long as the inversion problem is linear or only moderately  
 433 nonlinear (Bowman *et al.* 2006; Cusworth *et al.* 2021). However, the interpretation of fluxes will  
 434 be different if these matrices ( $\mathbf{S}_A$  and  $\mathbf{Z}_A$ ) are inconsistent (e.g. Shen *et al.* 2021), that is  $\mathbf{S}_A \neq$   
 435  $\mathbf{MZ}_A \mathbf{M}^T$ .

436 The uncertainty for any given element of the state vector  $\mathbf{z}$  is generally given by the  
 437 square root of the diagonal element of the total error covariance and includes the effects of the  
 438 limited spatial resolution of the top-down flux and how this projects uncertainties from one grid  
 439 box and sector into another grid box and sector as discussed in the previous section. For  
 440 example, the estimate for the emissions for some emissions sector “ $i$ ” at some lon/lat grid box “ $j$ ”  
 441 is given by (Rodgers and Connor 2003; Worden *et al.* 2004):

442

$$443 \hat{z}_{ij} = z_a^{ij} + A_{ij,ij}(z_{ij} - z_a^{ij}) + \mathbf{A}_{ij,xy}(\mathbf{z}_{xy} - \mathbf{z}_a^{xy}) + \delta_{ij} \quad (9)$$

444

445 Where the italicized variables in Equation 9 are scalar representations of the variables in  
 446 Equations 7 and 8, the index “ $x$ ” represents all sectors and the index “ $y$ ” represents all other  
 447 lat/lon elements and matrices and vectors are boldfaced. Note that the paired indices  $x$  and  $y$   
 448 exclude the paired indices  $i$  and  $j$ . The variable “ $z_{xy}$ ” represents the “true” value corresponding  
 449 to the estimate “ $\hat{z}_{ij}$ ” and the variable  $\delta_{ij}$  represents the error due to random noise (we exclude  
 450 systematic error here to simplify the math but Equation 9 can be expanded to include this term).

451 Of course we do not actually know the true value and its errors but Equation 9 allows us to  
452 represent them in a manner than allows us to calculate their statistics. The total error for  $\hat{z}_{ij}$ ,  
453 equivalent to an element of the total error in Equation 8, is:

454

455  $E \left| \left| \hat{z}_{ij} - z_{xy} \right| \right| = (1 - A_{ij}) Z_a^{ij} (1 - A_{ij})^T + \mathbf{A}_{ij,xy} \mathbf{Z}_a^{xy} \mathbf{A}_{ij,xy}^T + S_{ij}^n \quad (10)$

456

457 Where the  $E \left| \left| \cdot \right| \right|$  term describes the expectation operator for calculating the statistics of the  
458 quantity of interest (Bowman *et al.* 2006). The diagonal elements of the total error covariance  
459 therefore include the effect of the limited spatial resolution through the second term on the right  
460 hand side of Equation 10, which projects prior uncertainties from one region and sector (x,y) into  
461 the region and sector of interest (i,j). The last term is the covariance due to measurement noise.  
462 As the spatial resolution increases, the averaging kernel matrix converges towards the identity  
463 matrix; in this limit the first and second terms on the right side converge to zero such that the  
464 total error is due to noise (last term in Equation 10) and any residual systematic errors (not  
465 shown in Equation 10 but discussed in the previous section). Improving the spatial resolution of  
466 the methane emissions estimate therefore improves the accuracy.

467

468 In order to calculate the uncertainty for an aggregation of the elements of the state vector  
469  $\mathbf{z}$  (e.g. the coal sector for a country), instead of an individual element, we must sum the desired  
470 set of elements  $[z_i]$  that represent this sector and region. The uncertainty for this sum (squared) is  
471 then:

472

473  $\sigma_{ij}^2 = \mathbf{h} \hat{\mathbf{Z}}_{ij} \mathbf{h}^T \quad (11)$

474

475 where  $\mathbf{h}$  is a vector that is the same length as  $[z_{ij}]$ , with values of one in each element and  $\hat{\mathbf{Z}}_{ij}$  is  
476 the square sub-matrix of the covariance matrix  $\mathbf{Z}$  corresponding  $[z_{ij}]$  (e.g. the country and  
477 emission sector of interest).

478

479 **2.3 Generation of Prior Emissions, Covariances, and Uncertainties**

480

481        In order to project fluxes from a top-down inversion back to emissions using the  
482 approach described in Section 2.2, sectoral emissions and their covariances, or  $\mathbf{z}_A$  and  $\mathbf{Z}_A$ , at the  
483 desired spatial resolution are required. One challenge with the flux to emissions projection is that  
484 the *a priori* covariance matrix  $\mathbf{Z}_A$  must be inverted (Equation 8), which can be computationally  
485 expensive because this matrix can be quite large as the number of sectors and spatial resolution  
486 of the emissions increases and because correlations within the matrix (next section) make it  
487 challenging to invert. In order to reduce computational expense for our chosen spatial resolution  
488 of 1 degree resolution (prior to calculating country wide emissions), we dis-aggregate global  
489 emissions into eight regions (Table 2) chosen by regions with peaks in the inversion sensitivity  
490 to the underlying fluxes as shown by the averaging kernel diagonals in Figure 2. The different  
491 categories are shown in Table 2 for each region and by sector along with the provenance (or  
492 manuscript reference) in the second column. Cross-terms in the averaging kernel (Equations 5,  
493 9, and 10) matrix demonstrate that the change in emissions in one region affect the estimated  
494 emissions in another. Subdividing the fluxes into these eight regions therefore introduces an  
495 extra error term in the total error covariance for each region; however this extra error is  
496 automatically included in the total error covariance for each region as demonstrated by Equation  
497 10.

498 Table 2: *A priori* emissions by source and region used with sectoral attribution

Source Tg CH <sub>4</sub> /yr	Ref	N. America (15%)	S. America (30%)	Africa (30%)	Europe W. Russia N. Africa Mid-East (15%)	E. Russia (30%)	India Eurasia (30%)	Asia (30%)	Indonesia Australia (20%)	Total

499

500 Table 2: Prior emissions by source and regions. Single values for uncertainties are calculated by projecting the  
 501 corresponding covariance to a single number for the indicated lon/lat region and taking the square root. Total values  
 502 show a range of uncertainty with the lower bound being the sum (squared) of the individual region or sector  
 503 (assumes errors are un-correlated) and the upper bound being the sum of the errors (assumes errors are completely  
 504 correlated). The following references indicate the source for each emission type: 1) NASA CMS V1.0 (Wolf *et al.*  
 505 2017), 2) EDGAR 6.0 (Crippa *et al.* 2020), 3) NASA GFEI V1 (Scarpelli *et al.* 2020), 4) GFED 4.1 (van der Werf *et*  
 506 *al.* 2017), 5) WETCHARTS 1.3.1 (Bloom *et al.* 2017), 6) GCP (Poulter *et al.* 2017), 7) Etiope *et al.* (2019). The  
 507 target uncertainty for each region and sector is given in brackets underneath each region.

508

509 Our prior emission distribution and magnitude represents, by necessity, a set of ad hoc  
510 choices that are informed by the scientific literature and experience of the co-authors of this  
511 paper with developing top-down flux estimates. For example, our chosen resolution for  
512 reporting sectoral emissions is 1 degree, which represents a compromise between computational  
513 expense while minimizing representation errors when quantifying emissions for each country,  
514 which in turn is needed for these estimates to inform the global stock take. Future research will  
515 evaluate if higher-resolution emissions estimates by sector can be quantified given the  
516 computational expense of inverting Equation 8; our motivation for reporting top-down estimates  
517 at a higher resolution are because many of the inventories are at these scales (e.g. 0.1 degree) and  
518 also to better utilize high-resolution emissions estimates now available by aircraft data (e.g.  
519 Duren *et al.* 2019) and from upcoming satellites such as Carbon Mapper (e.g. Cusworth *et al.*  
520 2019; 2021).

521 We make the following choices for which sectoral emission type is represented: wastewater  
522 is not explicitly estimated as these emissions are spatially correlated with landfill emissions  
523 based on inspection of EDGAR inventories when projected to 1 degree resolution. The waste  
524 category should therefore be interpreted as a combination of landfill and wastewater. We also did  
525 not consider biofuels or termites for this estimate as they represent a small component of the  
526 budget. For these reasons, the biofuel and termite components of the methane budget will  
527 slightly bias our other sectoral estimates by 15–30 Tg CH<sub>4</sub>/yr based on bottom up estimates  
528 reported in (Saunois *et al.* 2020). On the other hand, emissions for seeps are included as bottom-  
529 up inventories suggest these could be as large as 30 Tg CH<sub>4</sub>/yr; however given the co-location of  
530 seep emissions with oil and coal (Figure 3), care must be taken in interpreting our results for  
531 Seep emissions estimates. Our prior emissions for livestock are from a NASA Carbon  
532 Monitoring System product (Wolf *et al.* 2017) and is found from post-processing to be too low  
533 by ~25% due to not including a scaling factor in the overall emissions. Nonetheless we keep the  
534 current set of (low) prior livestock emissions of ~89 Tg CH<sub>4</sub>/yr as they demonstrate (along with  
535 the analysis in Section 3.3, Figure 6) that our total results are largely independent of the choice  
536 of priors because of the sensitivity of the fluxes to the underlying emissions as shown in the right  
537 panel of Figure 2. A future version of these estimates will have an updated prior for livestock  
538 emissions and will include termites, wastewater, and biofuels. Although there can be many

539 emissions within a single grid box, uncertainty can still decrease for each emission type as shown  
540 in Equation 8, which shows that these correlations are quantified in the posterior covariance.  
541 Uncertainty reduction of a particular emission therefore depends on the magnitude of the  
542 emission and its uncertainty, its correlations with nearby emissions of the same type (next  
543 section) and the magnitude and uncertainty of emissions within the same grid box.

544 Prior wetland emissions are based on an ensemble of process models from the  
545 WETCHARTS system and the Global Carbon Project (Bloom *et al.* 2017; Poulter *et al.* 2017;  
546 Ma *et al.* 2021) and include the effects of lakes and rivers. A future version of this system will  
547 separately estimate these other sectors of the methane budget if further analysis using other  
548 satellite data (e.g. TROPOMI) shows that they can be distinguished from these other sectors.

549 **Covariance Generation:** Generating representative prior covariances is challenging as there  
550 are few global studies that allow for accurate representation of uncertainties for emissions across  
551 the globe and their correlations that are based on data and/or well calibrated models. This  
552 problem exists not just for methane emissions but with other inverse problems where there is  
553 little data representative of the quantities of interest (e.g. with remote sensing; Worden *et al.*  
554 2004). For this reason we need to make another set of ad-hoc choices that is based on prior  
555 research in order to generate the covariances for each sector. We therefore use the following  
556 approach: first we assume that the total anthropogenic emissions (by sector) in “Annex 1”  
557 countries have an uncertainty of 15%. For example, we assume the total error for the N.  
558 American Coal sector is ~15%, and so on for each anthropogenic sector. Similarly, the total error  
559 for Annex 2 regions is 30%. These targeted uncertainties are listed underneath the label for each  
560 region in Table 2. These uncertainties are reported in Janssens *et al.* (2019) and are based on  
561 “expert opinion” as quantifying uncertainties over a country or region using bottom up-  
562 approaches can be challenging. Total regional uncertainty for a specific sector is calculated using  
563 Equation 11. In order for sectoral emissions at 1 degree resolution to project to a total regional  
564 uncertainty of 15%, there must be significant uncertainty of any given emission within that 1  
565 degree grid cell. However, even assuming very large uncertainties for an emission within a 1  
566 degree grid cell (e.g. 100%), the regional total uncertainty can be much smaller than 15% once  
567 projected over a large enough number of grid cells if the emission errors are assumed to be  
568 uncorrelated. To address this issue we also add correlations between nearby emissions; we start  
569 the diagonal values at 0.7 (squared) of the prior emissions, or 70% uncertainty, and with a

correlation of 0.7 between neighboring emissions of the same type that are within 400 km (or four grid cells). The diagonal values and correlations are then adjusted until the projected uncertainty reaches 15% (for Annex 1) or 30% (Annex 2). Final values typically range from 0.6 (squared) to 1.0 for the diagonal and 0.7 to 0.9 for the off-diagonal values with variations in these numbers because of the different spatial distributions of the emissions. These numbers for the correlation and length scale are based on regional studies for N. America which also indicate that uncertainties for nearby emissions should be correlated (e.g. Maasakkers *et al.* 2016, 2019).

For wetlands, we use a slightly different approach for generating covariances. Here we calculate the root mean square (RMS) of an ensemble of different wetland process models (Bloom *et al.* 2017; Poulter *et al.* 2017; Ma *et al.* 2021) for a given region. We then follow a similar covariance generation approach as used for the anthropogenic emissions, iterating with different diagonal and off-diagonal values until the projected uncertainty for a region is approximately the same as the corresponding variance of the models.

While generating representative prior covariances is challenging, Equations 7 and 8 from the previous section allow us to swap in better priors and prior covariances as these become available. For example, if a researcher finds that the uncertainties expressed in  $\mathbf{Z}_A$  over a given region for a given sector should be 10% instead of the value used (approximately 70%), then it is straightforward to update the covariance matrix to reflect this improved knowledge so that the attribution to each sector is improved. Of course this improved information could also be used to improve the  $\mathbf{S}_A$  constraint matrix in Equation 1 to improve convergence of the top-down flux estimate. Furthermore the updated posterior covariances can be used for the next flux inversion based on other independent data and at some point these covariances, because they are based on observations, will best reflect our knowledge of the methane emission. Covariances and prior emissions are all publicly available, as well as python code that demonstrates how to use these files, so that a researcher can determine how other priors and changes to their uncertainty structure affects this top-down result or to use them for their own top-down inversions. Links to these data and codes are in the Data Repository section (Section 5).

**Uncertainty Calculation Approach:** The uncertainties shown in the Tables 1 and 2 are calculated in the following manner. First the prior uncertainties for each sector and for each region shown in Table 2 are calculated by projecting the regional (e.g. N. America, S. America) posterior error covariance to a single number corresponding to the mean emissions for that

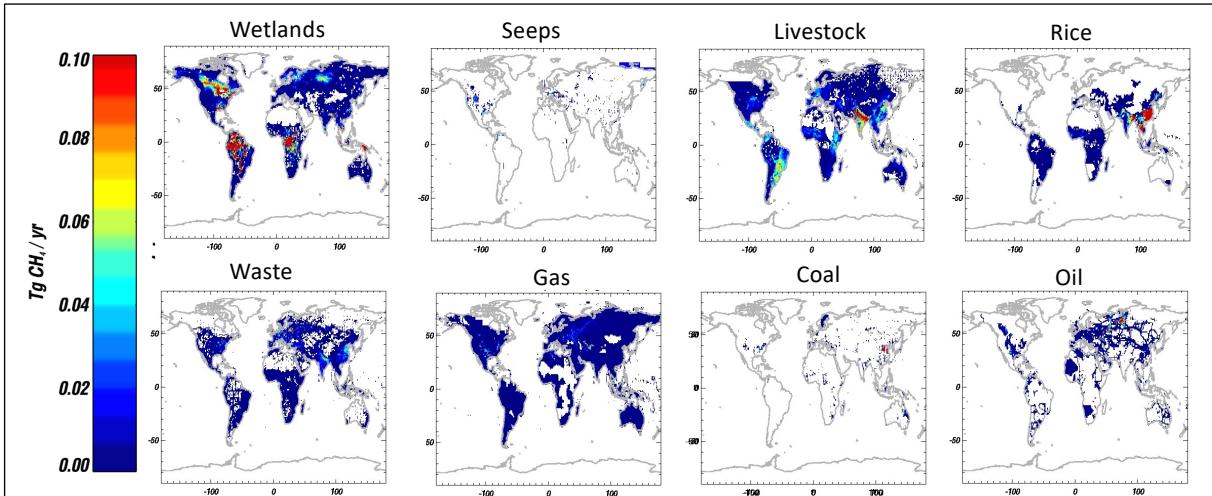

Figure 3: The square root of the diagonal of the *a priori* covariance for the eight largest sectors used in our analysis.

region using Equation 11. One approach is to then assume that these uncertainties are independent of each other in which case they are added in quadrature to get the total value; this is the smaller uncertainty shown in the **Total** column in Table 2. However, another method is to assume that the uncertainties are 100% correlated such that they should be added linearly; these are the values shown as the larger value in Table 2. We expect that the actual uncertainty is somewhere between these values. However, to be conservative we only report the larger value in Table 1 and for the remainder of the paper.

The prior uncertainties generated using the method described here are consistent with those reported in the literature even though the methodology differs. For example the values shown in the “prior” column of Table 1 are consistent (within reported ranges or uncertainties) of the equivalent sectors discussed in Saunois *et al.* (2020) and with the regional EDGAR v4.3.2 inventories as discussed in Janssens-Maaenhout *et al.* (2019). A caveat is that Janssens-Maaenhout *et al.* (2019) also reports global totals for each sector, from a range of inventories and models, that are 2-3 times larger for each sector than those shown here. Another caveat is that Saunois *et al.* (2020) includes a freshwater category with a  $120 \pm 60 \text{ Tg CH}_4/\text{yr}$  uncertainty whereas this category is subsumed into our Wetlands / Aquatic sector.

Figure 3 shows the (square root) diagonal of the covariance for each sector; as discussed previously, these are generally correlated with the magnitude of the emissions but also the chosen value for the regional total error (Table 2). Most of the sectors have enhancements and corresponding uncertainties that are spatially distinct. For example, the largest uncertainties for

621 oil are located in Eastern Europe and Russia; the largest uncertainties for coal are in China, and  
622 the largest uncertainties for gas are in N. America and Central Asia. In turn, these fossil  
623 emissions are spatially distinct from wetlands and livestock. However, the largest uncertainties  
624 for rice and waste can spatially overlap those of livestock, especially in India and Asia, which  
625 indicates that remote sensing will be challenged to distinguish these emissions.

626

### 627 **3.0 Results**

628

629 In this next section we first present global estimates, followed by a discussion of the  
630 sectoral emissions for the top-10 emitting countries, then emissions for all countries. Finally we  
631 test if different assumptions about bottom-up emissions as discussed in recent literature, i.e.  
632 larger wetland/aquatic emissions (Rosentreter *et al.* 2021), and larger fossil emissions  
633 (Schweitzke *et al.* 2017) affect our conclusions about the top-down results presented here.

634

635

636

638

### 3.1 Global Methane Budget By Sector

639 Emissions by sector and their uncertainty at 1 degree resolution are shown in Figure 4  
 640 with the top set of panels showing the posterior emissions and the bottom showing the  
 641 uncertainty. As in Figure 3, the uncertainty at each longitude/latitude grid element is given by  
 642 the square root of the diagonal of the total error covariance. Uncertainty can decrease for  
 643 emissions even when there is more than one type of emission in a grid box. As shown in  
 644 Equation 8, this uncertainty reduction depends on the magnitude of the emission and its  
 645 uncertainty, its correlations with nearby emissions of the same type (Section 2.3) and the  
 646 magnitude and uncertainty of emissions within the same grid box.

647 Inspection of Figure 4 (bottom panel) and Figure 3 shows reduction of uncertainty in  
 648 many parts of the world relate to the prior such as the larger wetlands and agricultural regions in

649 India and Asia. The right panel of Table 1 shows the global total posterior emissions by sector.  
650 The increase in sectoral emissions relative to the prior for the agriculture sector and reduction in  
651 fossil emissions reflect the top-down flux estimates (Figure 2) which show a lower posterior flux  
652 relative to the prior in fossil emitting regions such as Russia and N. America (with the exception  
653 of Southern USA) and increases in regions where livestock and rice emissions are expected to be  
654 the largest source relative to other emissions such as in India, Brazil, Argentina, and East Africa.

655 **Comparisons to Previous Top-Down Inversions Using GOSAT and GEOS-Chem:** Our  
656 results are consistent with previous top-down estimates based on the satellite GOSAT data. For  
657 example, the results here are based on the inversion framework from Zhang *et al.* (2021) and Qu  
658 *et al.* (2021), and are therefore generally consistent for the larger emissions such as wetlands, and  
659 livestock, or the emissions which are spatially distinct from other sources and therefore easier to  
660 resolve with remote sensing such as oil and coal. However, our estimates for rice, waste, seeps  
661 are very different and this is likely because our choice of priors for these sectors are different and  
662 because Qu *et al.* (2021) uses a uniform scaling approach to project fluxes to emissions whereas  
663 we account for the prior uncertainties. Similarly, our results for wetlands, livestock, and fossil  
664 emissions are consistent with previous GOSAT based inversions (e.g. Maasakkers *et al.* 2019;  
665 Zhang *et al.*, 2021) with the caveat that these estimates are for earlier time periods and changes  
666 in emissions can affect interpretation of any differences. Ma *et al.* (2021) uses GOSAT based  
667 wetland estimates to show that wetland emissions for the years 2010-2018 are likely even lower  
668 than our results. As with results presented here they take into account the spatial resolution and  
669 prior of the top-down fluxes but use a different approach to quantify emissions; they select  
670 “high” performing wetland models based on comparison of an ensemble of models with mean  
671 wetland emissions and temporal variability. The total emissions for these highest performing  
672 models 117 – 189 Tg CH<sub>4</sub>/yr is lower, but within the uncertainty of the results here. These  
673 difference in results, even when using similar models and data, highlight the importance of the  
674 choice of priors as well as the methodology by which fluxes are projected back to emissions as  
675 estimates for sectoral emissions can be very different from one estimate to the other depending  
676 on these choices.

677 **Comparisons to Top-Down Inversions from GCP:** Emissions in Table 4 can be compared  
678 to top-down inversions from the Global Carbon Project (GCP) when aggregated into combined  
679 categories (Saunois *et al.* 2020). For example our agriculture and waste emissions are ~263 +/-

24 Tg CH<sub>4</sub>/yr, anthropogenic fossil emissions are 82 +/- 12 Tg CH<sub>4</sub>/yr, and natural wetland/aquatic emissions are 180 +/- 10 Tg CH<sub>4</sub>/yr. These are within the reported uncertainties of top-down inversions in GCP which are [205-246 Tg CH<sub>4</sub>/yr], [91-121 Tg CH<sub>4</sub>/yr], and [155-217 Tg CH<sub>4</sub>/yr] respectively, but on the high side for agriculture and waste and on the low side for fossil emissions. These differences between GCP and emissions reported here likely represent the differences in information content and sampling from satellite versus ground-based data as most of top-down ensembles reported in Saunois *et al.* (2020) are based on in situ measurements which are typically in background regions and which are therefore not as sensitive to the spatial distribution of emissions as the satellite based estimates (e.g. Figure 6 from Yin *et al.* 2021). However, one set of results included with the top-down GCP results that is based on GOSAT data (i.e. Tsuruta *et al.* 2017) is consistent with our results as they report biospheric emissions of ~172 +/- 29 Tg CH<sub>4</sub>/yr. Note the other paper citations in the GCP methane paper that indicate use GOSAT data describe the model setup and results for CO emissions or for regional results so we cannot explicitly compare to their results.

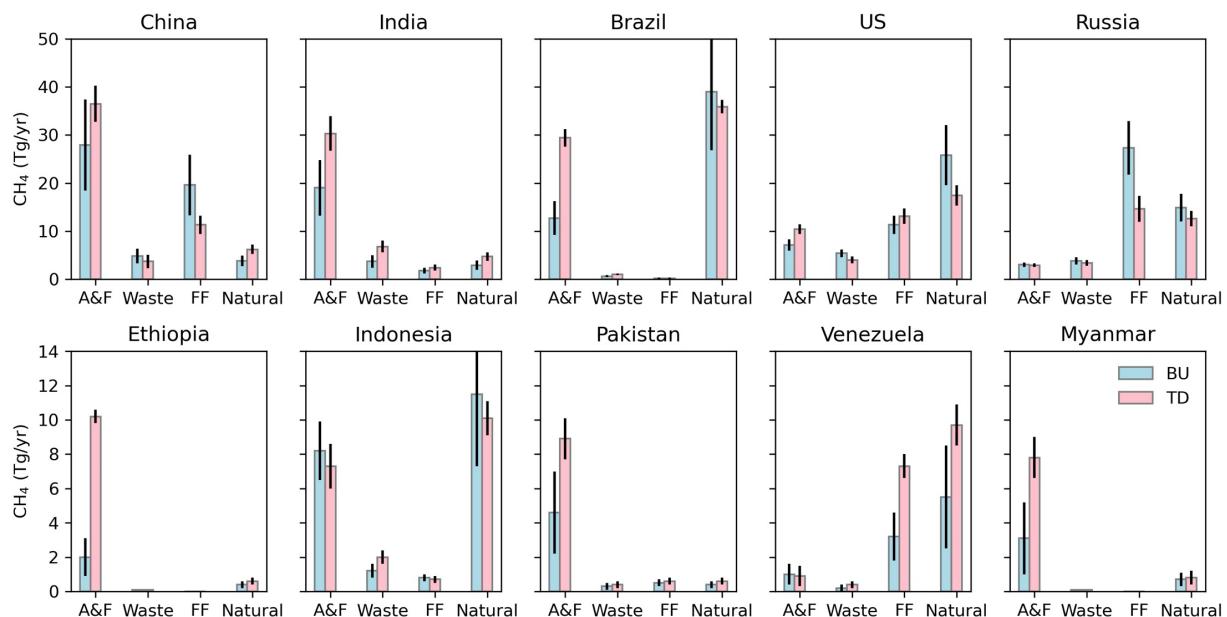

**Fossil Emissions:** Our posterior results for anthropogenic fossil emissions (82 +/- 12 Tg CH<sub>4</sub>/yr) and natural (22.5 +/- 3.8) are lower than our prior and in general do not reflect recent papers that suggest much higher fossil emissions using measurements of δ<sup>13</sup>CH<sub>4</sub> (e.g. Schwietzke *et al.* 2016 indicates 211 +/- 33 Tg CH<sub>4</sub>/yr for anthro + natural fossil emission) or upscaled from aircraft measurements over USA basins (e.g. Alvarez *et al.* 2018). However, as discussed in Turner *et al.* (2019), care must be taken in using isotope measurements to infer the partitioning of methane sources because of large uncertainties in the emission factors of different sources at different latitudes. Upscaling also can have large uncertainties as emission factors that relate activity data to emissions can vary significantly from region to region. Our global posterior fossil emissions are consistent with more recent reports of fossil emissions, ~84 Tg CH<sub>4</sub>/yr, to the UNFCCC (Scarpelli *et al.* 2022) for 2019, suggesting that our lower posterior estimates of fossil emissions are not unreasonable.

Onshore geological seeps represent another largely uncertain source of fossil emissions with values ranging from 2 to 30 Tg CH<sub>4</sub>/yr. For example, the top-down flux estimate, used as a basis for the sectoral emissions attribution, assumes a prior of ~2 Tg CH<sub>4</sub>/yr. However, our choice of prior (part of the  $\mathbf{z}_A$  vector, Equation 7) is based on Etiope *et al.* (2019) with a value of 32.0 +/- 6.2, resulting in a posterior of 22.5 +/- 3.8 Tg CH<sub>4</sub>/yr. This reduction in uncertainty is

711 substantial suggesting that remote sensing is providing good information about this source. A  
 712 caveat is that seep emissions tend to overlap those from coal and oil (Figure 4) suggesting a  
 713 potential equifinality between these emissions estimates. Combining fossil emissions from the  
 714 seep category with anthropogenic fossil emissions increases the overall fossil total and would  
 715 make the total fossil emissions (natural + anthropogenic) consistent with top-down results from  
 716 GC. Based on these results, we suggest this category attention deserves measurements, especially  
 717 from the up and coming high-resolution greenhouse gas measurements such as Carbon Mapper.  
 718

### 719       3.2 Top 10 Emitting Countries

720  
 721

722 Figure 5: Emissions by sector for the top 10 emitters. AF represents agricultural and fires. FF  
 723 represents fossil fuels or coal, oil, and gas. Natural represents wetlands, aquatic sources, and  
 724 geological seeps. Bottom up (BU) inventory estimates are shown as blue bars and the remote  
 725 sensing / top-down (TD) estimates are shown as the pink bars. The uncertainties in both  
 726 quantities are shown as black lines. Uncertainty calculations for bottom up and top-down  
 727 estimates are discussed in Section 2.

722

723

724       Figure 5 lists the top 10 emitting Countries ranked by total anthropogenic emissions as  
 725 calculated using this remote sensing system. Sectoral attribution is based on the nine categories

726 in Table 3; here we combine categories so that they are similar to what is being reported for the  
727 CO<sub>2</sub> based carbon inventories. The different categories are AF, which includes the sectors for  
728 agriculture (livestock and rice) and fires. This category is similar to the Agriculture, Forestry,  
729 and Land Use category or “AFOLU” as used in CO<sub>2</sub> based carbon inventories. W is the waste  
730 category, FF is the fossil category, which includes extraction, transport and use of coal, oil, and  
731 natural gas (Scarpelli *et al.* 2020; 2021). The Natural category, includes wetlands and geological  
732 seeps. The top five emitting countries are essentially the same from the bottom-up and top-down.  
733 However, top emitting countries with most emissions from the agriculture sector, likely due to  
734 livestock (see table in Section 4). While top-down and inventory emissions for China, USA, and  
735 Indonesia are consistent; there are major differences between our top-down results and  
736 inventories for the other countries. We next compare these results to those of previous studies;  
737 however, as stated earlier, these results should be treated cautiously and as a starting point for  
738 future research as differences can also be due to unquantified uncertainties in either the remote  
739 sensing data or the transport model used to relate concentrations to fluxes.

740 Our results are consistent with those from Maasakkers *et al.* (2019), Zhang *et al.* (2021)  
741 and Qu *et al.* (2021); however this is not too surprising as emissions that are reported here are  
742 based on the flux inversion system from these studies. A notable difference in methodology is  
743 that Qu *et al.* (2021) who also derives fluxes based on total column data from the Tropospheric  
744 Monitoring Instrument (TROPOMI). However, Qu *et al.* (2021) finds that country totals for the  
745 top-5 are essentially the same based on GOSAT and TROPOMI except for Brazil, but attributed  
746 large differences between TROPOMI and GOSAT to systematic errors in the TROPOMI total  
747 column data related to low surface albedo over Brazil; consequently, the TROPOMI based  
748 estimates in this region should be treated more cautiously.

749 Comparisons of these results to other estimates discussed in the literature can show  
750 substantial differences in either total emissions or attribution or both. For example Ganesan *et al.*  
751 (2017), using in situ and satellite atmospheric methane data, finds much lower total Indian  
752 emissions of 22 +/- 2.3 Tg CH<sub>4</sub>/yr for the 2010-2015 time period as compared to 39.5 +/- 5.4 for  
753 our study (and the Qu *et al.* 2021, Zhang *et al.* 2021 studies) and 36.5 +/- 5.3 from Janardanan *et*  
754 *al.* (2020). Miller *et al.* (2019) provides similar total emissions for China of 61.5 +/- 2.7 Tg  
755 CH<sub>4</sub>/yr but different partitioning; for example they find that Coal is the largest source of  
756 emissions based on comparison of top-down fluxes to EDGAR emissions and using a relative

757 weighting attribution flux to emissions attribution approach, whereas we find that agriculture  
758 (primarily Rice, Table 3 Section 4) is the largest sector. A major caveat is that attribution of  
759 emissions from total fluxes is challenging for China because many of the strongest emissions  
760 (e.g. coal, livestock, and rice as shown in Figures 3 and 4) overlap within the spatial resolution of  
761 the top-down estimate which is less than 2.5 degrees based on gridding used for the flux  
762 inversion and the variable sensitivity of the averaging kernel. While in principal these  
763 uncertainties due to limited spatial resolution are quantified based on our assumed prior  
764 covariance for each sector, it is quite possible that both our choice of the location of the  
765 emissions and corresponding prior covariance are incorrect due to less confidence in the  
766 emissions characterization in this region (Janssens-Maenhout *et al.* 2019). Our results are  
767 consistent (within uncertainties) for recent results by Deng *et al.* (2021); total anthropogenic  
768 emissions from Table 3 are within uncertainty of reported bottom-up and top-down total  
769 anthropogenic emissions shown in Figure 4 of Deng *et al.* (2021), even if the attribution of  
770 emissions may differ. Similarly, top-down based country level anthropogenic emissions from  
771 Stavert *et al.* (2022) are consistent, when we are able to directly compare emissions country to  
772 country, although many of their emissions only agree at the outer edge of the reported  
773 uncertainties.

774 We find that Myanmar has anonymously large agricultural emissions (primarily from  
775 livestock, Table 3 Section 4) relative to prior assumptions. Given that the DOFS reported for  
776 Mynamar is 2.7, we expect that the fluxes here are well resolved such that it is possible that  
777 poorly characterized prior emissions drive this difference between prior and posterior. For  
778 example, Janardanan *et al.* (2020) also reports similar top-down emissions of  $6.1 \pm 0.8$  Tg  
779 using a higher resolution satellite based flux inversion. However, an alternative explanation  
780 could be that errors in model transport could project to larger than expected fluxes (Equation 9)  
781 in this region as Jiang *et al.* (2013) finds that regions with substantial atmospheric convection  
782 can have large biases in top-down surface emission estimates.

783 Ethiopia also has larger than expected agricultural (livestock emissions) as compared to  
784 the prior. As with Mynamar, the prior emissions could be too low. For example, the amount of  
785 cattle and other livestock, between 80 and 90 million in 2015 and growing (Bachewe *et al.* 2018,  
786 statista.com) is not that different in size than USA livestock, ~93 million in 2021 (statista.com),  
787 suggesting that they could also have comparable livestock emissions. An alternative explanation

788 for this discrepancy are very low prior emissions in neighboring Sudan despite possible large  
789 numbers of cattle in this region as well (knoema.com) suggesting that livestock inventories in the  
790 E. African regions need to be re-examined.

791 Russian posterior fossil emissions are substantially lower than those initially reported in  
792 Scarpelli *et al.* (2020), which are based on reports to the UNFCCC in 2017. However, more recent  
793 reporting to the UNFCCC also suggest a much smaller bottom-up fossil estimate of ~7 Tg CH<sub>4</sub>/yr  
794 (Scarpelli *et al.* 2021). Table 3 (next section) indicates that remote sensing provides the best  
795 information about Russian oil and to some extent coal emissions as the reduction of uncertainty  
796 is largest for these sectors but has little change for gas emissions. Total emissions for oil and coal  
797 are 11.2 +/- 1.9 indicating that total fossil emissions are likely larger than expected for the latest  
798 reports to the UNFCCC but smaller than previous. As discussed previously, these top-down  
799 estimates should be treated cautiously and only as a starting point for future studies due to the  
800 limited sensitivity and potential uncertainties in both top down and bottom up.

801  
802       ***3.3 Results for all Countries***  
803

804       This section presents the complete table (Table 3, Appendix 1) of emissions by sector and  
805 country. As discussed previously in Section 2.1, we project the sectoral emissions in each 1  
806 degree grid to each country using a country map to quantify the emissions and their uncertainties  
807 for each country. The table is ordered by Degrees of Freedom for Signal (DOFS), which is a  
808 metric of sensitivity for inversion problems. As discussed in Section 2.1, the DOFS is a metric  
809 for the sensitivity of the flux estimate. For example, a DOFS of 1 means that this remote sensing  
810 system (GOSAT plus GEOS-Chem) can generally resolve the countries total emissions,  
811 assuming the sensitivity is evenly distributed across the country. More DOFS means that more  
812 emissions can be spatially resolved. However, even a DOFS of 0.5 means that half of the  
813 estimate is weighted by the measurement, with the estimate increasingly weighted by the *a priori*  
814 as the DOFS approaches zero. For these reasons we report estimates for all countries, even if the  
815 DOFS are effectively zero as information about the *a priori* inventories from the measurement  
816 might be useful even if not well informed by the satellite data. To distinguish these different  
817 levels of sensitivity, we color countries with corresponding DOFS greater than 1.0 as green,  
818 between 0.5 and 1.0 as yellow, and below 0.5 as red.

819        The DOFS are calculated from the Averaging Kernel matrix provided by the GEOS-  
820 Chem based inversion (Section 2.1). To calculate the DOFS for a given country we project the  
821 diagonal of the Averaging Kernel (Figure 2) to 1-degree resolution and then add up these values  
822 based on the 1-degree country map used in this study. Note that the total DOFS between the  
823 reduced resolution flux inversion and the 1-degree map is preserved. Table 3 indicates that the  
824 GOSAT based top-down estimate can quantify total emissions (i.e. reduce uncertainty) for  
825 approximately 57 countries as the DOFS for the 57<sup>th</sup> country is more than 1 and less than 1 for  
826 the 58<sup>th</sup> country. As discussed previously, As DOFS approaches zero there is less reduction in  
827 uncertainty using the top-down system discussed here. Furthermore, inspection of Table 3 shows  
828 that even countries where DOFS are between 1 and 2 show little reduction of uncertainty; this  
829 happens because of cross-terms in the sensitivity project uncertainty from one sector or region  
830 into another as shown in Equation 10.

831        The astute reader will notice negative emissions in some countries in Table 3. Negative  
832 emissions are a possible solution for inverse problems using linear updates, such as used here,  
833 even if they are not physically possible. Typically negative emissions occur when there are  
834 limited constraints on emissions in one region with large values in the state vector in a  
835 neighboring region; this is also known as “jack-knifing” in the inverse community. For example,  
836 livestock emissions for Peru are shown to be negative in Table 3, likely because Peru is near the  
837 Amazon basin which has substantive wetland emissions and the cross-correlations between these  
838 regions result in negative values in Peru livestock. In this case we would assume there is no  
839 information from this remote sensing system on this category and ignore these results.

840

#### 841        ***3.4 What Happens to (Top Down) Methane Budget if Priors for Wetland/Aquatic and*** 842        ***Fossil Emissions are Substantially Increased?***

843

844        Equations 7 and 8 also allow us to test other prior emission inventories to determine if  
845 they are consistent with top-down fluxes. This approach is similar to the “prior swapping”  
846 approach described in Rodgers and Connor (2003) but can also include “prior covariance  
847 swapping” as discussed in Cusworth *et al.* (2021). This approach involves replacing the  $\mathbf{z}_A$  and  
848  $\mathbf{Z}_A$  shown in Section 2.2 with different formulations. In this section we test what happens if we  
849 inflate the prior emissions for the wetland or fossil fuel categories such that they are consistent  
850 with other studies indicating much higher values than expected from top-down estimates, e.g.

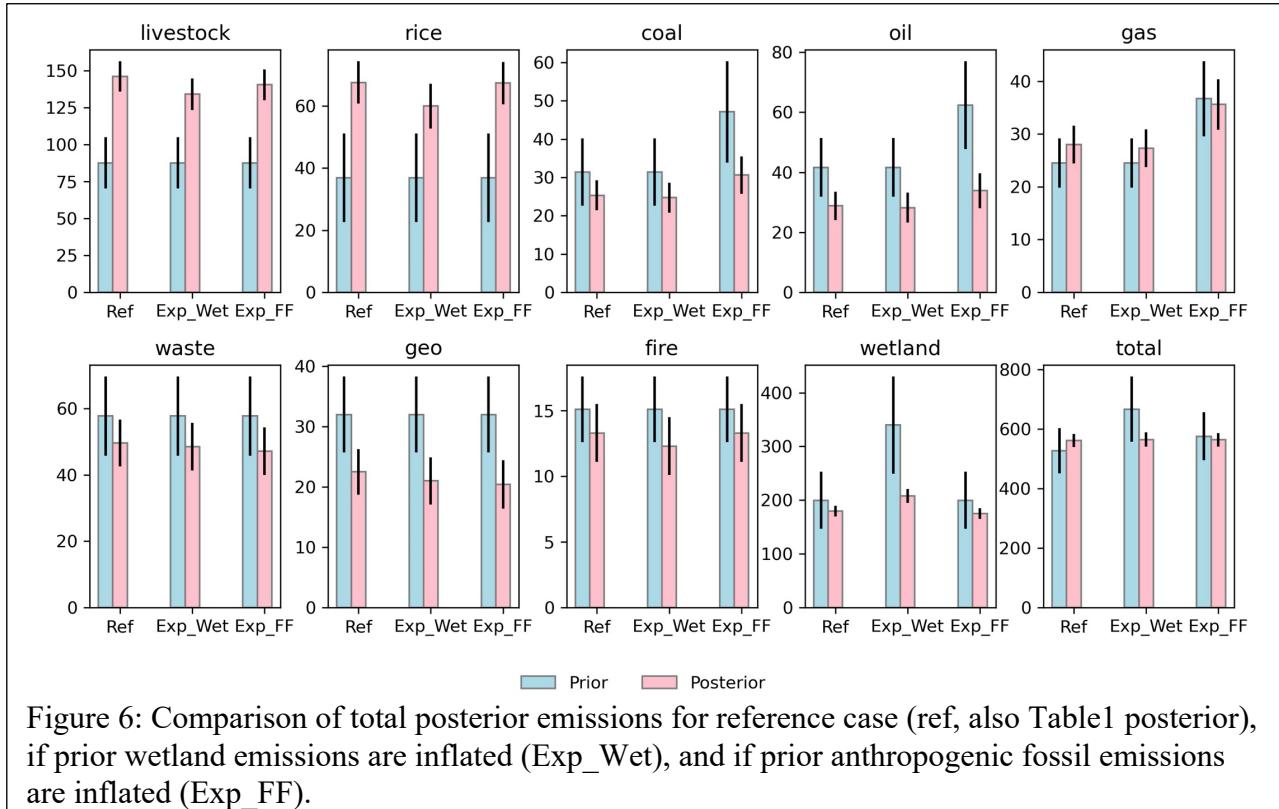

Figure 6: Comparison of total posterior emissions for reference case (ref, also Table 1 posterior), if prior wetland emissions are inflated (Exp\_Wet), and if prior anthropogenic fossil emissions are inflated (Exp\_FF).

Rosentreter *et al.* (2021) for wetland/aquatic emissions and Schwietzke *et al.* (2017) for fossil emissions. Figure 6 shows the results of these two studies. The bars labeled “Ref” indicate the prior used for the results reported in this manuscript. The bars labeled “Wet” indicated the increased wetland study (which also includes increases to lake and river emissions as the wetland models include these categories, Bloom *et al.* 2017) and the bars labeled “FF” indicate the study where anthropogenic fossil fuels are increased by 50%. We find that even with a very large prior emissions for wetland/aquatic sources, the posterior gives an estimate of  $208 \pm 12.8$  Tg CH<sub>4</sub>/yr as compared to  $179.8 \pm 10$  for the reference values. This decrease from the inflated prior of ~340 Tg CH<sub>4</sub>/yr to 208 Tg CH<sub>4</sub>/yr happens because the global total is constrained to ~560 Tg CH<sub>4</sub>/yr through knowledge of the methane sink and because wetland emissions tend to be spatially distinct from other sources. For the same reasons, fossil emissions, especially coal, oil, and geological seeps show a substantial decrease in uncertainty. Consequently, the posterior emissions difference between the reference and inflated fossil studies are consistent within uncertainty and generally these emissions are much less than either the reference or inflated priors. For these reasons, it is challenging to reconcile these inflated aquatic emissions or inflated fossil emissions with top-down results. As noted previously, these comparisons should still be

867 treated cautiously and as a starting point for further research because of poorly characterized  
868 systematic errors in the chemistry transport model used to related observed concentrations to  
869 fluxes and because sources that are not included in the prior state vector but co-located with  
870 other sectors cannot be distinguished. For example, if there are significant (unspecified) aquatic  
871 emissions that are co-located with livestock emissions then the corresponding livestock  
872 emissions estimate would be biased high.

873

## 874 **4.0 Summary and Future Directions**

875 In this paper we demonstrate, using a new Bayesian algorithm, estimates of emissions by  
876 sector at 1 degree resolution and by country, by using a combination of prior information of the  
877 emissions, satellite data, and a global chemistry transport model. Uncertainties are provided for  
878 representation (or smoothing) error and data precision but not for systematic errors in the  
879 transport model or data. Using a metric called the degrees-of-freedom for signal (DOFS), we  
880 show that the combination of GOSAT based satellite data with the GEOS-Chem model and prior  
881 uncertainties can estimate total emissions for about 57 of the 242 countries, with only partial  
882 information for the remaining countries. Our results can be used for comparison to country  
883 level, bottom-up inventories by sector that might be, for example, provided by the global stock  
884 take. However, any discrepancies between these top-down and inventory based estimates should  
885 be considered as a starting point for future investigations given the potential for systematic errors  
886 affecting the top-down results such as from accuracy limitations in the data or in the chemistry  
887 transport model used to estimate fluxes from the data (e.g. Buchwitz *et al.* 2015; Jiang *et al.*  
888 2015; McNorton *et al.* 2020; Schuh *et al.* 2019). Alternatively, countries with little capability for  
889 quantifying bottom-up emissions could use these results, along with other published top-down  
890 estimates (e.g. Deng *et al.* 2021; Stavert *et al.* 2022) for their contribution to the global stock  
891 take.

892 In the absence of systematic errors, we find robust estimates for livestock, coal, oil, seeps,  
893 fires, and wetlands as these can (on average) be distinguished from other sources using remote  
894 sensing given their distinct locations. Our results are consistent (within uncertainty) with  
895 previous top-down estimates such as the 2017 Global Carbon Project that are primarily based on  
896 in situ data. However, these remote sensing estimates are on the high side for agricultural and  
897 waste emissions and the low side for fossil and wetland emissions. On the other hand, total fossil

898 emissions reported here are consistent with recent reports of fossil emissions to the UNFCCC  
899 (Scarpelli *et al.* 2022).

900 The new Bayesian algorithm we demonstrate can be used to test if different prior emissions  
901 are consistent with our posterior emissions estimates. For example, we find that inflating the  
902 priors for wetland/aquatic fluxes, or alternatively fossil emissions do not fundamentally alter our  
903 estimates for these sectors. Consequently, the remote sensing estimates reported here show much  
904 lower wetland and fossil emissions than these studies based on bottom-up models and isotope  
905 data, and much larger agricultural and waste emissions. The largest differences between remote  
906 sensing and these other estimates occur in Brazil and India (primarily related to livestock),  
907 Russia (fossil emissions), and Central and E. Africa (livestock). These contrasting differences  
908 between the remote sensing based results and bottom-up models suggest that additional research  
909 is needed in these geographical areas to reconcile global methane budget estimates.

910 **Future Directions:** We are evaluating how to characterize systematic errors related to the  
911 atmospheric chemistry transport model (e.g. Schuh *et al.* 2019) and in the satellite data to our  
912 error analysis and we expect the next version of these estimates to contain these uncertainties. We  
913 also expect to add isotopic information through new flux estimates based on the surface network  
914 and the GEOS-Chem model; these independent data can be used to test the partitioning of  
915 biogenic, fossil, and pyrogenic emissions (e.g. Worden *et al.* 2017). We are also examining how  
916 to combine high-resolution emissions estimates based on aircraft data and imaging spectrometers  
917 such as GHG-Sat or Carbon Mapper to the top-down fluxes to improve inventory estimates at  
918 finer spatial scales than reported here. Finally, the posterior emissions and covariances  
919 demonstrated in this manuscript can be used as priors in subsequent emissions estimates using  
920 data from other measurements such as from the upcoming CO2M, Methane-Sat, and Carbon  
921 Mapper instruments.

922  
923

## 924 **5.0 Data Repositories**

925  
926 The prior and posterior emissions and covariances are stored on <https://cmsflux.jpl.nasa.gov/>.  
927  
928 Please refer to Qu *et al.* (2021) for data related to the top-down flux inversion.  
929

930 The provenance of individual inventories that are used to generate the emissions and inventories  
931 are shown in Table 2.

932

## 933 **6.0 Author Contributions**

934

935 JW led the integration of results and writing and developed the prior covariances. DC provided  
936 the emissions attribution with JW and AB and co-wrote Section 2.2. ZQ and YZ provided the  
937 flux estimates and co-wrote section 2.1. YY SM and AB supported the attribution derivation and  
938 analysis. BB and DC helped link results to the global stock take. TS and JM supported the  
939 inventory description and analysis. RD and DJ helped design the overall flux inversion and  
940 emissions attribution system described in the paper. All co-authors have read the paper and  
941 provided feedback.

942

943 **Competing Interests:** To our knowledge there are no competing interests

944

## 945 **7.0 Acknowledgements**

946

947 **Acknowledgments.** Part of this work research was carried out at the Jet Propulsion Laboratory,  
948 California Institute of Technology, under a contract with the National Aeronautics and Space  
949 Administration (80NM0018D0004). This research was motivated by CEOS (Committee on Earth  
950 Observing Satellites) activities related to quantifying greenhouse gas emissions. This research was  
951 supported by funding from NASA's Carbon Monitoring System (CMS) and AIST programs.  
952 Yuzhong Zhang acknowledges funding by NSFC (42007198).

956 **8.0 Appendix table of emissions for each country ordered by DOFS**

957

958 Table 3: Table of Emissions for Each Country.

959 This table provides the top-down and bottom up estimates for each sector based on the  
 960 methodology described in this paper. The table is ordered by DOFS which is the metric for  
 961 sensitivity for the remote sensing system described in this paper. The first row for each country  
 962 provides the top-down result and the second row is the bottom-up. Prior inventories are shown in  
 963 Table 2. Green are for results where DOFS > 1. Yellow corresponds to 0.5 < DOFS < 1. Red  
 964 corresponds to DOFS < 0.5
