Abstract. The ambient OH and HO₂ radical concentrations were measured continuously by laser-induced fluorescence during the STORM (STudy of the Ozone foRmation Mechanism) campaign at the Shenzhen site, located in the Pearl River Delta in China, in autumn 2018. The diurnal maximum-maxima were OH and HO₂ concentrations, measured by laser-induced fluorescence, were $4.5 \times 10^6 \text{ cm}^{-3}$ for OH and $4.5 \times 10^8 \text{ cm}^{-3}$ for HO₂ (including an estimated interference of 23%-28% from RO₂ radicals during the daytime), respectively. The state-of-the-art radical-chemical mechanism underestimated the observed OH concentration, similar to the other warm-season campaigns in China. The OH underestimation was attributable to the missing OH sources, which can be explained by the X mechanism. Good agreement between the observed and modeled OH concentrations was achieved when an additional numerical X equivalent to 0.1 ppb NO concentrations was added to the base model. The isomerization mechanism of RO₂ derived from isoprene contributed approximately 7% to the missing OH sources and the oxidation of isoprene oxidation products (MACR and MVK) had no significant impact on the missing OH sources, demonstrating further exploration of unknown OH sources is necessary. The modeled HO₂ could reproduce the observed HO₂, indicating the HO₂ heterogeneous uptake on HO₂ chemistry was negligible. Photolysis reactions dominated the ROx primary production rate. The HONO, O₃, HCHO, and carbonyls photolysis accounted for 29%, 16%, 16%, and 11% during the daytime, respectively. The ROx termination rate was dominated by the reaction of OH + NO₂ in the morning, and thereafter the radical self-combination gradually became the major sink of ROx in the afternoon. As the sum of the respective oxidation rates of the pollutants via reactions with oxidants. The atmospheric oxidation capacity was evaluated, with a peak of $0.75 \times 10^8 \text{ molecules cm}^{-2} \text{ s}^{-1} 11.8 \text{ ppb h}^{-1}$ around noontime. The ratio of $P(\text{O}_3)$ to AOC_{VOCs} , which indicates the O₃ production from VOCs oxidation, trended to increase and then decrease as the NO concentration increased. Additionally, the maximum of the ratios existed when the NO concentration was approximately 1 ppb, with a median of about 2, indicating that the yield of ozone production from

34 ~~VOCs oxidation was about 2 in this campaign. A strong positive correlation between O₃ formation rate and atmospheric~~
35 ~~oxidation capacity was achieved, illustrating the atmospheric oxidation capacity was the potential tracer to indicate the~~
36 ~~secondary pollution.~~

37

38 1 Introduction

39 Severe ambient ozone (O₃) pollution is one of China's most significant environmental challenges, especially in urban areas
40 (Shu et al., 2020; Li et al., 2019; Wang et al., 2020; Ma et al., 2019b; Wang et al., 2017). Despite the reduction in emissions of
41 O₃ precursors, O₃ concentration is increasing, especially in urban cities. The O₃ average trends for the focus megacity clusters
42 are 3.1 ppb a⁻¹, 2.3 ppb a⁻¹, 0.56 ppb a⁻¹, and 1.6 ppb a⁻¹ for North China Plain (NCP), Yangtze River Delta (YRD), Pearl River
43 Delta (PRD), and Szechwan Basin (SCB), respectively (Li et al., 2019). The nonlinearity between O₃ and precursors illustrates
44 that it is necessary to explore the cause of O₃ production. The tropospheric O₃ is only generated in the photolysis of nitrogen
45 dioxide (NO₂), produced as the by-product within the radical cycling. Thus, the investigation of radical chemistry is critical to
46 controlling secondary pollution.

47 Hydroxyl radicals (OH), the dominant oxidant, control the atmospheric oxidation capacity (AOC) in the troposphere. The
48 OH radicals convert primary pollutants to secondary pollutants and are simultaneously transformed into peroxy radicals (HO₂
49 and RO₂). Within the interconvert of ROx (= OH, HO₂, and RO₂), secondary pollutants are generated, and thus the further
50 exploration of radical chemistry is significant. The radical closure experiment, an effective indicator for testing our
51 understanding of radical chemistry, has been conducted since the central role of OH radicals was recognized in the 1970s (Levy,
52 1971; Hofzumahaus et al., 2009). The underestimation of OH radicals ~~in~~at-environments characterized by low nitrogen oxides
53 (NO) and high volatile organic compounds (VOCs) has been identified (Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan
54 et al., 2019; Yang et al., 2021; Hofzumahaus et al., 2009; Lelieveld et al., 2008; Whalley et al., 2011). New radical mechanisms
55 involving unclassical OH regeneration have been proposed, including Leuven Isoprene Mechanism (LIM) and X mechanism
56 (Peeters and Muller, 2010; Peeters et al., 2014; Peeters et al., 2009; Hofzumahaus et al., 2009). The LIM has ~~been~~
57 ~~incooperated into the current mechanism and is still insufficient~~~~been cooperated with the current mechanism and is still not~~
58 ~~suffieient~~ to explain the OH missing sources. The X mechanism was identified several times, but the amount of the numerical
59 species, X, varied in different environments, and the nature of X is unknown (Hofzumahaus et al., 2009; Lu et al., 2013; Lu et
60 al., 2012; Tan et al., 2017; Tan et al., 2019; Yang et al., 2021). Therefore, further exploration of radical regeneration sources is
61 necessary.

62 ~~Owing-Due~~ to the strong photochemistry influenced by high temperatures, high O₃ pollution appeared to occur in YRD and
63 PRD, especially in PRD (Ma et al., 2019b; Wang et al., 2017). Radicals, the dominant oxidant in the troposphere, has ~~ve~~ been
64 measured during warm seasons in NCP (Yufa 2006, Wangdu 2014, and Beijing 2016), YRD (Taizhou 2018), SCB (Chengdu
65 2019), and PRD (Backgarden 2006, and Heshan 2014) in China (Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan et al.,
66 2019; Yang et al., 2021; Tan et al., 2021). The radical observations in PRD, where the cities are suffering from severe O₃
67 pollution, have not been conducted since 2014, and thus the oxidation capacity here has not been clear in recent years.
68 Therefore, we carried out a continuous comprehensive field campaign (STudy of the Ozone foRmation Mechanism - STORM)

69 involving radical observations in Shenzhen, one of the megacities in PRD, in autumn 2018. Overall, the following will be
70 reported in this study.

- 71 (1) The observed OH and HO₂-radical concentrations, and the comparison between the radical observations and
72 simulations modeled radical concentrations.
- 73 (2) The exploration of the unclassical OH regeneration sources based on the experimental budget.
- 74 (3) The sources and sinks of radicals.
- 75 (4) The evaluation of AOC the atmospheric oxidation capacity and the quantitative relationship between O₃ formation and
76 AOC.

77 2 Methodology

78 2.1 Measurement site and instrumentation

79 The STORM campaign was conducted from September to October 2018 in Peking University Shenzhen Graduate School
80 (22.60 deg N, 113.97 deg E), in the west of Shenzhen, Guangdong province. As shown in Fig. 1, this site,
81 which belongs to the urban site, was is located in the university town, which was and is surrounded by residential and
82 commercial areas. The northwest of the site is close to the Shenzhen Wildlife Park, and the northeast is close to the Xili Golf
83 Club (Yu et al., 2020). The Tanglang Mountain Park with active biogenic emissions is located about 1 km southeast of the site.
84 Overall, this site has no significant local pollution sources nearby, but can represent the urban pollution characteristics (Huang
85 et al., 2012b; Huang et al., 2012a; Gao et al., 2018).

86
87 **Figure 1: Geographical location and surrounding environmental conditions of the measurement site in STORM campaign (The**
88 **maps are from <https://map.baidu.com>).**

89 Most instruments were set up on the top of a four-story academic building (about 20 m). Besides HOx radicals measured by
90 the Peking University Laser-Induced Fluorescence system (PKU-LIF) (see the details in Sect. 2.2), a comprehensive set of
91 trace gases was conducted to support the exploration of the radical chemistry, including meteorological parameters

(temperature, pressure, relative humidity), photolysis frequency, OH reactivity (k_{OH}) and the trace gases (NO, NO₂, O₃, VOCs, etc.). k_{OH} was measured by the laser flash photolysis-laser induced fluorescence (LP-LIF) system. Most of the inorganic trace gases (O₃, CO, NO, NO₂, and SO₂) were simultaneously measured by two sets of instruments, and good agreement was achieved within the uncertainty. VOCs (aldehydes, alkenes, aromatics, isoprene, and oxygenated VOCs (OVOCs)) were measured using a gas chromatograph following a mass spectrometer (GC-MS). In addition, HONO and HCHO were measured as well. Table S1 in the Supplementary Information describes the experimental details of the meteorological and chemical parameters during this campaign.

2.2 The OH and HO₂ measurements

The OH and HO₂ radicals were measured by Peking University laser-induced fluorescence system (PKU-LIF) based on the fluorescence assay by gas expansion (FAGE) technique. The principle has been reported in previous studies, only a brief description of the instrument is presented here. Further detailed information on the instrument can be found in previous studies (Heard and Pilling, 2003; Fuchs et al., 2008; Holland et al., 1995; Hofzumahaus et al., 1996; Fuchs et al., 2011).

In principle, OH resonance fluorescence is released in the OH excitation by a 308 nm pulsed laser, and then OH radicals are detected directly. HO₂ radicals are converted into OH via NO, and then they are detected. The system contains a laser module and a detection module. Ambient air was drawn into two independent, parallel, low-pressure (3.5 mBar) cells through two parallel nozzles with 0.4 mm diameter pinhole. The OH radicals are excited into resonance fluorescence in the OH detection cell and detected by micro-channel plate detectors (MCP). In the HO₂ detection cell, NO is injected and converts HO₂ to OH radicals, which then are excited by the laser and release resonance fluorescence. Besides, an OH reference cell in which a large OH concentration is generated by pyrolysis of water vapor on a hot filament is applied to automatically correct the laser wavelength.

Owing to the failure of the reference cell in this study, the NO mixing ratios injected into the HO₂ cell were set to be higher than that in other campaigns in China because the HO₂ cell needed to be used as a reference cell to correct laser wavelength.

In this campaign, NO mixing ratios were switched between 25 ppm (low NO mode) and 50 ppm (high NO mode). We calculated the HO₂ conversion rates under the two different NO concentrations by calibrating the PKU-LIF system. HO₂ conversion rates in low NO mode ranged within 80%-95%, while those in high NO mode were over 100%, demonstrating that the HO₂ measurement was affected by RO₂ radicals. Prior studies have reported the relative detection sensitivities (α_{RO_2}) for the major RO₂ species, mainly from alkenes, isoprene and aromatics, when the HO₂ conversion rate was over 100% (Fuchs et al., 2011; Lu et al., 2012; Lu et al., 2013). Therefore, only the HO₂ observations in high NO mode were chosen and they were denoted as [HO₂], which was the sum of the true HO₂ concentration and a systematic bias from the mixture of RO₂ species i which were detected with different relative sensitivities $\alpha_{RO_2}^i$, as shown in Eq. (1) (Lu et al., 2012). The true HO₂ concentration was difficult to be calculated because the RO₂ concentration measurements and their speciation were not available. Herein, we

设置了格式: 字体: 倾斜

设置了格式: 下标

123 simulated the HO₂ and HO₂^{*} concentrations by the model. The interference from RO₂ radicals was estimated to be the
124 difference between the modeled HO₂ and HO₂^{*} concentrations. Here, NO mixing ratios were switched between 10 ppm and
125 20 ppm. There was no obvious difference in HO₂ signals under the above two NO mixing ratios, indicating that the interference
126 of RO₂ to HO₂ measurements was negligible despite the higher NO mixing ratio than other campaigns in China.

$$127 [\text{HO}_2^*] = [\text{HO}_2] + \sum(\alpha_{\text{RO}_2}^i \times [\text{RO}_2]_i) \quad (1)$$

128 Additionally, prior studies reported that OH measurement might be affected by the potential interference, when the sampled
129 air contained ozone, alkenes and BVOCs (Mao et al., 2012; Fuchs et al., 2016; Novelli et al., 2014), indicating the
130 environmental conditions are important to the production of interference. The pre-injector is usually used to test the potential
131 OH interference, and has been applied to our PKU-LIF system to quantify the possible interferences for several campaigns,
132 including the campaigns conducted in Wangdu, Heshan, Huairou, Taizhou and Chengdu sites (Tan et al., 2017; Tan et al., 2019;
133 Tan et al., 2018; Yang et al., 2021). No significant internal interference was found in the prior studies, demonstrating the
134 accuracy of the PKU-LIF system has been determined for several times. Moreover, to further explore the potential interference
135 in this campaign, we compared the major environmental conditions, especially O₃, alkenes and isoprene, between Shenzhen
136 and Wangdu sites, as shown in the Supplementary Information. The environmental condition in Shenzhen was less conducive
137 to generating interference than that in Wangdu, and the details were presented in the Supplementary Information. Therefore, it
138 is not expected that the OH measurements in this campaign were affected by the internal interference. Overall, the measurement
139 uncertainties of OH and HO₂^{*} radicals were 11% and 15%, respectively, as shown in Table S1 in the Supplementary
140 Information.

142 2.3 Closure experiment

143 As an effective tool to explore the atmospheric radical chemistry, the radical closure experiment can investigate the state-of-
144 the-art chemical mechanism because of the extremely short lifetime of radicals (Stone et al., 2012; Lu et al., 2019). A zero-
145 dimensional box model was used to conduct the radical closure experiment, and the overall framework was reported by Lu et
146 al. (2019). In this work, we conducted the radical closure experiment based on the Regional Atmospheric Chemical Mechanism
147 updated with the ~~latest~~ isoprene chemistry (RACM2-LIM1), as Tan et al. (2017) described in detail. The model was
148 constrained to the measured meteorological, photolysis frequency, and the critical chemical parameters (CO, NO, NO₂, VOCs,
149 etc.). The H₂ and CH₄ mixing ratios were set to 550 ppb and 1900 ppb, respectively. The model was operated in time-dependent
150 mode with a 5-min time resolution, and a 2-d spin-up time was ~~to make the unconstrained species approach the steady state~~
151 ~~relative to the constrained species used to reach steady-state conditions for long-lived species.~~

152 As Lu et al. (2012) described, there are two types of radical closure experiment. One is the comparison of observed and
153 modeled radical concentrations, and the other is the comparison of radical production and destruction rates. The most

设置了格式: 字体: 10 磅

设置了格式: 字体: 10 磅

154 significant difference between the above is that the latter is conducted with the observed radical concentrations and k_{OH}
155 constrained. The comparison of radical production and destruction rates, also called radical experimental budget, can test the
156 accuracy of the state-of-the-art chemistry mechanisms based on the equivalent relationship between the radical production and
157 destruction rates. The production rates of OH, HO₂, and RO₂ radicals are quantified from all the known sources. The destruction
158 rates of HO₂ and RO₂ radicals are the sum of the known sources. The OH destruction rate can be directly calculated as the
159 product of the observed OH concentrations and the observed k_{OH} (Tan et al., 2019; Yang et al., 2021). The OH destruction rate
160 is the total sinks of OH radicals because of the direct k_{OH} observation, and thus the discrepancy between the OH destruction
161 and production rates denotes the missing OH sources. The detailed reactions and the reaction rate constants related to OH,
162 HO₂, and RO₂ radicals can be found in Tan et al. (2019) and Yang et al. (2021).

163 2.4 AOC evaluation

164 The life time of the trace gases is controlled not only by the oxidant concentration but also by its second-order rate constant,
165 so the atmospheric oxidation capacity (AOC) proposed by Geyer et al. (2001) is most suitable to evaluate the relative
166 importance of each oxidant (Elshorbany et al., 2009). AOC is the core driving force of complex air pollution, and determines
167 the removal rate of trace gases and the production rates of secondary pollutants (Liu et al., 2021). As an effective indicator for
168 atmospheric oxidation intensity, the evaluation of AOC can provide crucial information on the atmospheric composition of
169 harmful and climate forcing species (Elshorbany et al., 2009). AOC is defined as the sum of the respective oxidation rates of
170 the pollutants via reactions with oxidants (Elshorbany et al., 2009; Geyer et al., 2001; Zhu et al., 2020). According to the
171 definition of AOC, it can be calculated by the Eq. (24).

$$172 AOC = \sum_i k_{Y_i} [Y_i] [X] \quad (24)$$

173 where Y_i are the pollutants (CO, NO, NO₂, CH₄, and VOCs), X are the main atmospheric oxidants (OH, O₃, NO₃), and k_{Y_i}
174 is the bi-molecular rate constant for the reaction of Y_i with X. AOC includes all combination of pollutants Y and oxidants X.
175 The higher AOC, the higher removal rate of the most pollutants, and thus the higher production rate of secondary pollutants
176 (Yang et al., 2020a). Simultaneous measurements of OH and the key trace gases are available in the study. NO₃ concentration
177 could be simulated by the box model with the observed parameters constrained.

178 3. Results

179 3.1 Meteorological and chemical conditions

180 Figure 2 gives an overview of the meteorological and chemical parameters from 05 October to 28 October 2018, when OH
181 and HO₂ radicals were measured. The diurnal variations of the temperature (T), relative humidity (RH), $j(O^1D)$, and $j(NO_2)$
182 followed a regular pattern from day to day. The overall meteorological conditions were characterized by high temperature

设置了格式: 下标

设置了格式: 字体: 倾斜

设置了格式: 字体: 倾斜

183 (about 20–30 °C), high relative humidity (60–80%), and intensive radiation with $j(\text{O}^1\text{D})$ up to $2.0 \times 10^{-3} \text{ s}^{-1}$ and $j(\text{NO}_2)$ up to
184 $6.0 \times 10^{-3} \text{ s}^{-1}$. The relative humidity and photolysis-frequency in this autumn campaign were similar to those in the summer
185 campaign conducted at Chengdu site (Yang et al., 2021). The temperature in this campaign was lower than that at Chengdu
186 site, but similar to that in the autumn campaign at Heshan site located in PRD as well (Tan et al., 2019; Yang et al., 2021).

187 The concentration of CO showed weak diurnal variation, indicating there was the non-obvious accumulation of
188 anthropogenic emissions on a regional scale. NO concentration peaked at 12 ppb during morning rush hour when the traffic
189 emission was severe, and thereafter, O₃ concentration started to increase with the decreasing of NO concentration. The maxima
190 of O₃ hourly concentration were high up to 120 ppb. According to the updated National Ambient Air Quality Standard of China
191 (GB3095-2012), O₃ concentration exceeded the Class-II limit values (hourly averaged limit 93 ppb) on several days (6, 7, 8,
192 and 26 October) when the environmental condition was characterized by high temperature and low relative humidity. NO₂
193 concentration was high at night because of the titration effect of O₃ with NO.

194 Along with the high O₃ concentration on 6, 7, 8, and 26 October, high HCHO concentration was also recorded during the
195 corresponding periods, indicating HCHO was mainly produced as secondary pollutions because of the active photochemistry
196 in this campaign. Isoprene, mostly derived from biogenic emissions and mainly affected by temperature, peaked around
197 noontime. Tan et al. (2019) reported the median concentration of HCHO and isoprene concentrations were 6.8 ppb and 0.6 ppb
198 during 12:00-18:00 at Heshan site. Similarly, the median concentration of HCHO and isoprene concentrations in this study
199 were 4.9 ppb and 0.4 ppb during the corresponding periods, respectively. As a proxy for traffic intensity, the toluene to benzene
200 ratio (T/B), which is below 2, means the traffic emissions are the major sources of VOCs (Brocco et al., 1997). The T/B
201 gradually dropped from 07:00 until it reached the minimum value at 09:00, indicating traffic emission contributed more to
202 VOCs during morning rush hour than during other periods. However, the T/B, which varied within a range of 7-12, was above
203 2, and thus VOCs emission during this campaign was mainly from other sectors such as those involving solvent evaporation.

Figure 2: Timeseries and diurnal profiles of the observed meteorological and chemical parameters in STORM campaign. The grey areas denote nighttime.

Moreover, we compared the environmental conditions between the Backgarden (rural site), Heshan (suburban site), and Shenzhen (urban site) campaigns conducted in PRD in Table S3 in the Supplementary Information. No significant discrepancy in temperature was found in the Shenzhen and Heshan campaigns, which were both conducted in autumn. The temperature in the Backgarden campaign conducted in summer was higher than those in Shenzhen and Heshan. The relative humidity in Shenzhen and Backgarden was higher than that in Heshan. Compared to the chemical conditions in the Heshan campaign conducted in autumn as well, the concentrations of CO, NO, NO₂, HONO, alkenes, aromatics, and HCHO in Shenzhen were lower, which might be because there were no significant local pollution sources nearby in the Shenzhen site although it was an urban site. However, the concentration of O₃ which is the typical secondary pollutant in Shenzhen was higher than that in Heshan. Compared to the environmental conditions in Heshan, the higher O₃ concentration in Shenzhen might benefit from the weather condition which was characterized by the stronger solar radiation and slightly higher temperatures.

3.2 Observed and modeled OH and HO₂ radicals

The OH and HO₂ radicals were measured during 05-28 October 2018. The timeseries of the observed and modeled HOx concentrations are displayed in Fig. S1 (a and b) in the Supplementary Information. Data gaps were caused by the rain,

带格式的: 缩进: 首行缩进: 1 字符, 段落间距段前: 6 磅, 段后: 0 磅, 行距: 多倍行距 1.15 字行

220 calibration, and maintenance. The daily maxima of the observed OH and HO₂/HO₂- concentrations varied in the range of (2-
221 9) × 10⁶ cm⁻³ and (2-14) × 10⁸ cm⁻³, respectively. As in previous campaigns, the largest OH concentrations appeared around
222 noontime and showed a high correlation with j(O¹D), a proxy for the solar UV radiation driving much of the primary radical
223 production (Tan et al., 2019).

224 Figure 3 (a-b) shows the diurnal profiles of the observed and modeled HOx concentrations (a and b). The HOx radicals
225 showed similar diurnal behavior to those reported in other campaigns (Ma et al., 2019a; Tan et al., 2017; Tan et al., 2019; Tan
226 et al., 2018; Yang et al., 2021). The observed OH and HO₂/HO₂- concentrations reached a maximum around 12:00 and 13:30,
227 respectively. The diurnal maximum of the observed and modeled OH concentrations were 4.5 × 10⁶ cm⁻³ and 3.5 × 10⁶
228 cm⁻³. Compared to the other campaigns conducted in PRD (Backgarden and Heshan), the diurnal maximum of the observed
229 OH concentration in Shenzhen was equal to that observed in Heshan, and much lower than that observed in Backgarden where
230 the observed OH concentration was nearly 15 × 10⁶ cm⁻³ (Hofzumahaus et al., 2009; Tan et al., 2019). The higher OH
231 concentration in Backgarden site was closely correlated to the stronger solar radiation, as shown in Table S3 in the
232 Supplementary Information. There was an agreement between the diurnal profiles of the diurnal observed and modeled OH
233 concentrations agreed within their 1-σ uncertainties of measurement and simulation errors of (11% and 40%), respectively.
234 However, when the NO mixing ratio (Fig. 2) dropped from 10:00 gradually, a systematic difference existed with the
235 decreasing of NO concentration with the observed OH concentration being about 1 × 10⁶ cm⁻³ higher than the modeled OH
236 concentration. The model could reproduce the observed OH concentrations well only in the early morning before 10:00.
237 However, the model would underestimate the observed OH concentration after 10:00 when NO concentration dropped 2 ppb.
238 The OH concentrations observed in the environments with low NO levels were underestimated by the state-of-the-art models
239 at Backgarden (summer) and Heshan (autumn) sites in PRD as well, and the OH underestimation was identified to be universal
240 at low NO conditions in China (Lu et al., 2013; Lu et al., 2012; Ma et al., 2019a; Tan et al., 2017; Yang et al., 2021). The
241 reasons on OH underestimation was further discussed in Section 4.1.

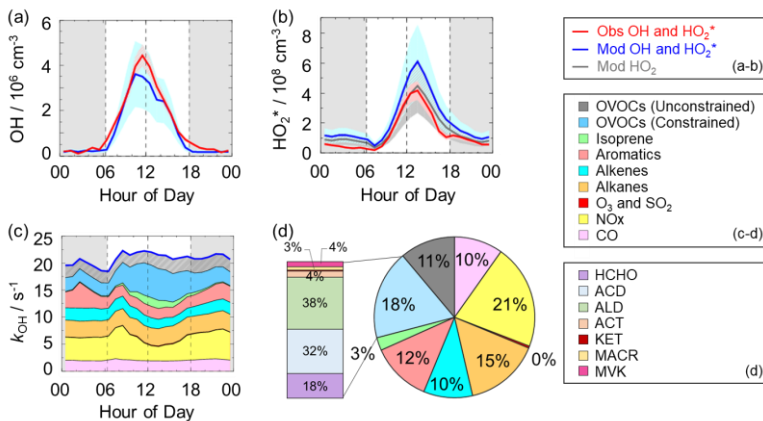

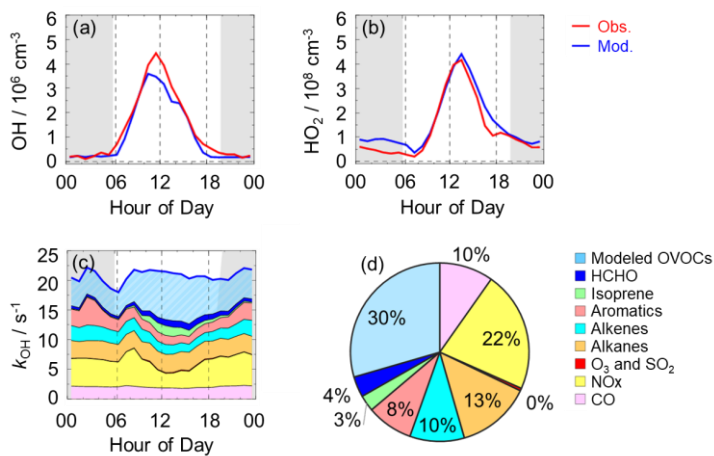

Figure 3: (a-b) The diurnal profiles of the observed and modeled OH_2 (a) and HO_2^* and HO_2 (b) concentrations, (c) the diurnal profiles of the modeled k_{OH} (c), (d) and the composition of the modeled k_{OH} (d). The red areas in (a-b) denote 1- σ uncertainties of the observed OH and HO_2^* concentrations. The blue areas in (a-b) denote 1- σ uncertainties of the modeled OH and HO_2^* concentrations, and the grey area in (b) denotes 1- σ uncertainties of the modeled HO_2 concentrations. The grey areas in (a-c) denote nighttime. ACD denotes acetaldehydes. ALD denotes the C3 and higher aldehydes. ACT and KET denote acetone and ketones. MACR and MVK denote methacrolein and methyl vinyl ketone.

The diurnal maximum of the observed HO_2^* , the modeled HO_2^* and the modeled HO_2 concentrations were $4.2 \times 10^8 \text{ cm}^{-3}$, $6.1 \times 10^8 \text{ cm}^{-3}$, and $4.4 \times 10^8 \text{ cm}^{-3}$, respectively. The difference between the modeled HO_2^* and HO_2 concentrations can be considered a modeled HO_2 interference from RO_2 (Lu et al., 2012). The RO_2 interference was small in the morning, while it became larger in the afternoon. It ranged within 23%-28% during the daytime (08:00-17:00), which was comparable with those in the Backgarden and Yufa sites in China, Borneo rainforest in Malaysia (OP3 campaign, aircraft), and UK (RONOCO campaign, aircraft) (Lu et al., 2012; Lu et al., 2013; Jones et al., 2011; Stone et al., 2014). The observed HO_2^* was

设置了格式: 下标

带格式的: 段落间距段前: 12 磅

256 overestimated by the model, indicating the HO₂ heterogeneous uptake might have a significant impact during this campaign.
 257 The diurnal maximum of HO₂ concentration observed in Shenzhen was much lower than those observed in the Yufa and
 258 Backgarden sites (Hofzumahaus et al., 2009; Lu et al., 2012; Lu et al., 2013). The diurnal maximum of the observed HO₂
 259 concentration was $4.5 \times 10^8 \text{ cm}^{-3}$, and the modeled HO₂ concentration could match well with the observed HO₂ concentration
 260 within the uncertainties, indicating the HO₂ heterogeneous uptake on HO₂ chemistry was negligible. The high modeled
 261 HO₂/OH ratio. The observed HO₂ concentration around noontime (11:00-15:00), which was about 138, was found in this
 262 campaign was high, thereby yielding a mean HO₂ to OH ratio (HO₂/OH) of about 112, which was higher than those similar to
 263 that at in the Backgarden and Chengdu sites and was higher than that at Chengdu site (Yang et al., 2021; Hofzumahaus et al.,
 264 2009). High HO₂/OH ratio is normally found only in clean air at low concentrations of NO_x (Hofzumahaus et al., 2009; Stevens
 265 et al., 1997). The modeled HO₂/OH ratio was about 138. Prior studies indicated that the measured HO₂/OH ratios were agreed
 266 well with the simulations under polluted conditions, but under clean conditions, the measured ratios were lower than simulated
 267 (Stevens et al., 1997). The comparison of the measured HO₂/OH ratio and the modeled HO₂/OH ratio in this campaign indicated
 268 the pollution was not severe during the observation period. As an indicator that can reflect the interconversion reaction between
 269 OH and HO₂ and OH, the conversion efficiency in this campaign was equal to that at Backgarden site and was slightly slower
 270 than that in the Backgarden and at Chengdu sites.

271 **3.3 Modeled k_{OH} reactivity**

272 k_{OH} is the pseudo-first-order loss rate coefficient of OH radicals, and it is equivalent to the reciprocal OH lifetime (Fuchs et
 273 al., 2017; Lou et al., 2010; Yang et al., 2019). In this campaign, k_{OH} was measured only for several days (05-19 October 2018)
 274 by the LIP-LIF system, which has been reported in the previous study (Liu et al., 2019). The timeseries of the observed and
 275 modeled k_{OH} during 05-19 October 2018 are presented in Fig. S2 in the Supplementary Information. A good agreement between
 276 the observed k_{OH} and modeled k_{OH} within the uncertainties was achieved, and thus the model can be believed to reproduce the
 277 observed k_{OH} values within the whole campaign. k_{OH} was not measured continuously, so we only showed the timeseries of
 278 modeled values in Fig. S1 (e) in the Supplementary Information, the diurnal profile of the modeled k_{OH} in Fig. 3 (e), and the
 279 composition of k_{OH} in Fig. 3 (d). Moreover, to reflect the k_{OH} in the whole campaign, the modeled values were shown in the
 280 k_{OH} diurnal profiles (Fig. 3c) during 05-28 October 2018. The modeled k_{OH} showed weak diurnal variation and varied from 18
 281 s^{-1} to 22 s^{-1} . Compared to the k_{OH} variation in Shenzhen, the k_{OH} observed in Backgarden and Heshan sites in PRD showed a
 282 stronger diurnal variation, with a minimum value at around noontime and a maximum value at daybreak. The k_{OH} ranges in
 283 Backgarden and Heshan sites were 20-50 s^{-1} and 22-32 s^{-1} (Lou et al., 2010; Tan et al., 2019). Similar with the good agreement
 284 between the observed and modeled k_{OH} during the several days in Shenzhen, the observed k_{OH} in Backgarden was matched
 285 well with the modeled k_{OH} which has included the OVOCs reactivity. In terms of the k_{OH} in Heshan, Tan et al. (2019) reported
 286 that only half of the observed k_{OH} was explained by the calculated k_{OH} which was calculated from the measured trace gas

287 concentrations. The missing k_{OH} in Heshan was likely caused by unmeasured VOCs, demonstrating the necessary to measure
288 more abundant VOCs species, especially OVOCs species.

289 As shown in Fig. 3(d), we presented the composition of modeled k_{OH} . The inorganic compounds contributed approximately
290 3231% to k_{OH} , in which the CO and NOx reactivity accounted for 10% and 2221%, respectively. The NOx reactivity ~~is was~~
291 displayed versus time, with a maximum during the morning peak. The peak concentration during the morning peak ~~is was~~
292 associated with traffic emissions.

293 The larger fraction of k_{OH} comes from the VOCs group compared with inorganics reactivity, with a contribution of 68% to
294 k_{OH} . OVOCs reactivity was equivalent to the other VOCs reactivity, and the contributions of them to k_{OH} were both 34%. The
295 contribution of alkanes, alkenes, and aromatics were 13%, 10%, and 8%, respectively. The isoprene reactivity related to
296 temperature was mainly concentrated during the daytime, whereas the aromatics reactivity at night was higher. As for OVOCs
297 species, about 4% of k_{OH} could be attributed to HCHO. The remaining OVOCs was attributed to the simulated species in the
298 box model, with a contribution of up to 30% of k_{OH} . High OVOCs reactivity occurred in the afternoon, which was attributed
299 to the strong photochemical activity during this period. Compared with the inorganics reactivity, the larger fraction of k_{OH} came
300 from the VOCs group, with a contribution of 69% to k_{OH} . The contribution of alkanes, alkenes, and aromatics were 15%, 10%,
301 and 12%, respectively. The isoprene reactivity related to temperature was mainly concentrated during the daytime, whereas
302 the aromatics reactivity at night was higher. As for the OVOCs species, we measured several OVOCs species, including HCHO,
303 acetaldehydes (ACD) and higher aldehydes (ALD), acetone (ACT), ketones (KET) and isoprene oxidation products (MACR
304 and MVK), so we constrained these species in the model. The constrained OVOCs species accounted for 18% in the total k_{OH} ,
305 where HCHO, ACD, and ALD were the major contributors, with contributions of 18%, 32%, and 38% to the constrained
306 OVOCs, respectively. The contribution of aldehydes in this study (16%) was larger than that in Beijing (Whalley et al., 2021)
307 and smaller with that in Wangdu (Fuchs et al., 2017). The remaining reactivity was attributed to the unconstrained OVOCs
308 reactivity, which came from the model-generated intermediate species (glyoxal, methylglyoxal, methyl ethyl ketone, methanol,
309 etc.), with a contribution of 11% to the total k_{OH} . Large fraction of OVOCs reactivities in k_{OH} was also found in some previous
310 studies (Lou et al., 2010; Lu et al., 2013; Fuchs et al., 2017; Whalley et al., 2021). About 50% of k_{OH} was explained by OVOCs
311 in Backgarden site, and HCHO, ACD and ALD, and oxygenated isoprene products were the most important OH reactants in
312 OVOCs, with a contribution of 30-40%, and other 10-20% came from other oxygenated compounds (ketones, dicarbonyl
313 compounds, alcohols, hydroperoxides, nitrates etc.) (Lou et al., 2010). HCHO, ACD, MVK, MVCR and glyoxal accounted for
314 one-third of the total k_{OH} in Wangdu site (Fuchs et al., 2017). The large unconstrained OVOCs reactivity indicated it is
315 necessary to measure more VOCs species in the future.

316 **4. Discussion**

317 **4.1 Radical closure experiment**

318 In this study, we conducted OH radical closure experiment which is called OH experimental budget as well. As discussed in
319 Section 3.3, it is believed that the model can reproduce the observed k_{OH} . Herein, to conduct the OH experiment budget in the
320 whole campaign, we used the modeled k_{OH} to calculate the OH destruction rate because the k_{OH} was only measured on several
321 days. The exploration of OH experimental budget was based on the premise that the modeled k_{OH} could matched well with the
322 observed k_{OH} due to the lack of the continuous k_{OH} observations in this campaign. Several studies in China indicated that the
323 modeled k_{OH} which has included OVOCs reactivity could match well with the observed k_{OH} , especially during daytime (Fuehs
324 et al., 2017; Lou et al., 2010), but missing k_{OH} existed in some environmental conditions despite the inclusion of OVOCs
325 (Whalley et al., 2021; Yang et al., 2017). Thus, the OH destruction rate is the lower limit due to the possible missing k_{OH} in
326 this study, so the missing OH source, which is the difference between the OH destruction and production rates, is the lower
327 limit as well. The diurnal profiles of OH production and destruction rates, and compositions of OH production rate were
328 displayed in Fig. 4, with maxima of 14 ppb h⁻¹ and 17 ppb h⁻¹ around noontime, respectively. The OH production rate from
329 known sources is quantified from the primary sources (photolysis of HONO, photolysis of O₃, ozonolysis of alkenes) and
330 secondary sources (dominated by HO₂ + NO, and HO₂ + O₃). The primary and secondary sources were account for 78% and
331 22% of the total calculated production rate, respectively. Similar with the prior studies, the largest fraction of OH production
332 rate comes from HO₂ + NO, with a contribution up to 76% of the known OH production rate. The contributions of HONO and
333 O₃ photolysis were 13% and 7% to the primary production rate.

334 The OH production rate matched well with the destruction rate only in the early morning to about 10:00. Thereafter, the OH
335 destruction rate was larger than the production rate, which could explain the underestimation of OH concentration by the model.
336 The discrepancy between the OH production and destruction rates was attributed the missing OH sources. The biggest
337 additional OH source was approximately 4.6 ppb h⁻¹, which occurred at about 12:00, when the OH production and destruction
338 rates were 11.9 ppb h⁻¹ and 16.5 ppb h⁻¹, respectively. The unknown OH source ~~could explain~~ accounted for about one third of
339 the total OH production rate, indicating the exploration of missing OH source was significant to study the radical chemistry. It
340 is noted that the OH production rate was overestimated because we used HO_2^* concentrations instead of HO₂ concentrations
341 here. Thus, the missing OH source was the lower limit here, demonstrating more unknown OH sources need to be further
342 explored. Details on unknown OH sources are given below (Sect. 4.2).

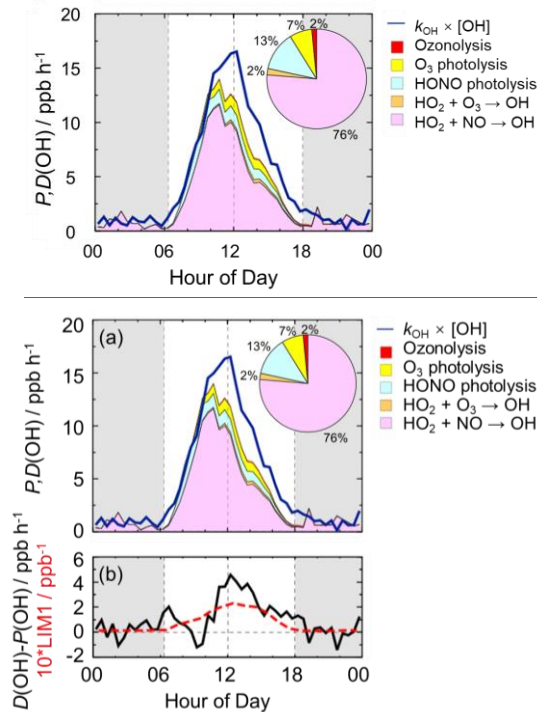

Figure 4: (a) The diurnal profiles of OH production and destruction rates and the proportions of different known sources in the calculated production rate during the daytime. The blue line denotes the OH destruction rate, and the colored areas denote the calculated OH production rates from the known sources. (b) The missing OH source which was the discrepancy between the OH destruction and production rates, and the OH production rate which was ten times the production rate derived from LIM1 mechanism. The grey areas denote nighttime.

4.2 Radical chemistry in low NO regime

4.2.1 Influencing factors of OH underestimation

As analyzed in Sect. 4.1, the underestimation of OH concentration was attributable to the missing OH source. It is necessary to explore the influencing factor for gaining further insight into the missing source. Scientists reported that more significant OH underestimation would appear with the decreasing NO concentration and increasing isoprene concentration (Lu et al., 2012; Ren et al., 2008; Hofzumahaus et al., 2009; Lelieveld et al., 2008; Whalley et al., 2011; Tan et al., 2017; Yang et al., 2021). A new OH source was suggested, such as the LIM, which was proposed based on *ab initio* calculation (Peeters et al., 2014; Peeters et al., 2009). We have applied the latest LIM into the base model in this study, and Tan et al. (2017) described the modified LIM in detail. However, the model was not sufficient to explain the higher OH observations after 10:00. Herein, we further explored the effect of NO concentration on missing OH source. NO dependence of OH and HO₂ radicals was illustrated in Fig. 5. The OH concentrations were normalized by the averaged $\beta(O^1D)$ to eliminate the influence of radiation on

radicals. The OH concentration showed a increasing trend with the increase of NO concentrations in low NO regime (below 1 ppb) due to the increased OH radicals from propagation via peroxy reactions with NO, and then decreased with the increase of NO concentrations in high NO regime (above 1 ppb) due to the loss by the reaction of OH with NO₂ (Ehhalt, 1999). The base model can reproduce the observed OH concentration in high NO regime conditions (above 1 ppb) and underestimate OH concentration in low NO regime conditions (below 1 ppb). As for HO₂/HO₂-radicals, the observed and modeled HO₂ concentrations decreased with the increase of NO concentrations. The model overestimated the observations, indicating the heterogeneous uptake might make a significant role in HO₂ sinks in this campaign. The modeled HO₂ concentration by the base model matched well with the observed HO₂ concentration within the whole NO regime. Therefore, NO concentration played the significant role in the OH underestimation, especially under low NO regime. Overall, NOx (= NO + NO₂) plays a crucial role in radical chemistry due to the impact of NO on radical propagation and termination reactions.

 375 **the HOx observations. The blue circles show the median values of the HOx simulations by the base model, and the green circles show**
 376 **the HOx simulations by the model with X mechanism. The OH concentrations were normalized by the averaged $j(\text{O}^3\text{D})$ to eliminate**
 377 **the influence of radiation on the OH radicals. Total VOCs reactivity and their organic speciation are presented by pie charts at the**
 378 **different NO intervals at the top. Only daytime values and NO concentration above the detection limit of the instrument were chosen.**
 379 **ACD and ACT denote acetaldehyde and acetone, respectively. ALD denotes the C3 and higher aldehydes. KET denotes ketones,**
 380 **MACR and MVK, which are both the isoprene oxidation products, denote methacrolein and methyl vinyl ketone, respectively.**

381 To further explore the influencing factors of OH underestimation, we presented the speciation VOCs reactivity under the
 382 different NO intervals, as shown in Fig. 5 and Table S4 in the Supplementary Information. The isoprene reactivity and total
 383 OVOCs reactivity (the sum of HCHO, ACD, ACT, ALD, KET, MACR, MVK and the modeled OVOCs) increased with the
 384 decrease of NO concentrations, while the anthropogenic VOCs reactivity (alkanes, alkenes and aromatics) was higher in high
 385 NO regime. Additionally, the O_3 concentration in low NO regime was significantly higher than those in high NO regime, and
 386 the temperature was slightly higher in low NO regime, demonstrating the photochemistry was more active in low NO regime
 387 in this campaign. Overall, the photochemistry and composition of VOCs reactivity, especially the isoprene and OVOCs species
 388 (mainly ACD, ACT and the modeled OVOCs), might closely impact the missing OH sources.

389 4.2.2 Quantification of missing OH sources

390 Hofzumahaus et al. (2009) proposed an existence of a pathway for the regeneration of OH independent of NO, including the
 391 conversions of $\text{RO}_2 \rightarrow \text{HO}_2$ and $\text{HO}_2 \rightarrow \text{OH}$ by a numerical species called X. With a retrospective analysis, the unclassical

设置了格式: 字体: 加粗

带格式的: 缩进: 首行缩进: 1 字符, 行距: 1.5 倍行距

392 OH recycling pathway was identified to be universal at low NO conditions in China. The amount of X varies with
393 environmental conditions, and the X concentrations were 0.85 ppb, 0.4 ppb, 0.1 ppb, 0.4 ppb, and 0.25 ppb at Backgarden,
394 Yufa, Wangdu, Heshan, and Chengdu sites (Hofzumahaus et al., 2009; Lu et al., 2012; Lu et al., 2013; Tan et al., 2017; Yang
395 et al., 2021).

396 In this study, we tested this unclassical X mechanism. Good agreement between observations and simulations of ~~both~~-OH
397 ~~radicals and HO₂~~ was achieved when a constant mixing ratio of 0.1 ppb of X was added into the base model. As shown in Fig.
398 5, the model with X mechanism ~~could~~ agreed with the observed OH concentrations even at low NO conditions. Unclassical
399 OH recycling was identified again in this study. However, X is an artificial species that behaves like NO, and thus the nature
400 of X is still unknown to us. Compared to Shenzhen site, the required X concentration in the Backgarden and Heshan sites in
401 PRD were higher, which might be affected by the different air masses in the three sites. The k_{OH} in Shenzhen site was much
402 lower than those in Backgarden and Heshan sites, and the weaker diurnal variation of k_{OH} in Shenzhen was observed. Under
403 the influence of the East Asian monsoon, the prevailing wind for PRD area is mostly southerly during the summer months and
404 mostly northerly during the winter months (Fan et al., 2005; Zhang et al., 2008). The Backgarden site is located in Guangzhou,
405 and the Heshan site is located in Jiangmen. The two cities are along the north-south axis, and thus the air masses of the
406 Backgarden and Heshan sites are intimately linked with each other, while the air mass in Shenzhen is more similar to Hongkong
407 (Zhang et al., 2008). Therefore, However, X is an artificial species that behaves like NO, and thus the nature of X is still
408 unknown to us. Further exploration on this unclassical OH recycling is needed to improve our understanding of radical
409 chemistry.

410 As discussed in Section 4.2.1, isoprene and OVOCs might have potential influence on the missing OH source. RO₂
411 isomerization reactions have also been shown to be of importance for the atmospheric fate of RO₂ from isoprene (Peeters et
412 al., 2009; Peeters et al., 2014). The latest isoprene isomerization mechanism, which is called LIM1, has been coupled into our
413 current base model. However, LIM1 mechanism was not included in the OH experimental budget which was conducted with
414 the observations constrained, as shown in Section 4.1. Herein, we evaluated the contribution of LIM1 mechanism to the missing
415 OH sources, as shown in Fig. 4(b). LIM1 mechanism can explain approximately 7% of the missing OH sources during 10:00-
416 16:00, when the missing OH production rate and the OH production rate derived from LIM1 mechanism were 2.47 ppb h⁻¹ and
417 0.17 ppb h⁻¹, respectively.

418 Additionally, prior studies also reported that OH regeneration might be achieved from the oxidation of MACR and MVK,
419 which are the major first-generated products of isoprene (Fuchs et al., 2018; Fuchs et al., 2014). As a potential explanation for
420 the high OH concentration, the impacts of MACR and MVK oxidation were evaluated here. The modification of MACR
421 oxidation scheme added the H-migration reactions of MACR oxidation products (Fuchs et al., 2014). The modification of
422 MVK oxidation scheme added the reactions of MVK oxidation products with HO₂ radicals and the H-migration reactions of
423 MVK oxidation products (Fuchs et al., 2018). As presented in Fig. S3 in the Supplementary Information, no significant of the

MACR and MVK oxidation schemes was found in this campaign.

Overall, a large part of missing OH sources was not explained by the isoprene chemistry. In the future, the impact of OVOCs species which was another potential OH source on missing OH sources need to be further evaluated.

4.3.3 Sources and sinks of ROx

The detailed analysis of radical sources and sinks was crucial to exploring radical chemistry. The experimental budget for HO₂ and RO₂ radicals could not be conducted because RO₂ was not measured during this campaign. Herein, we showed the simulated results by the base model. Figure 66 illustrates the diurnal profiles of ROx primary production rate ($P(\text{ROx})$) and termination rate ($L(\text{ROx})$), and the contributions of different channels during the daytime.

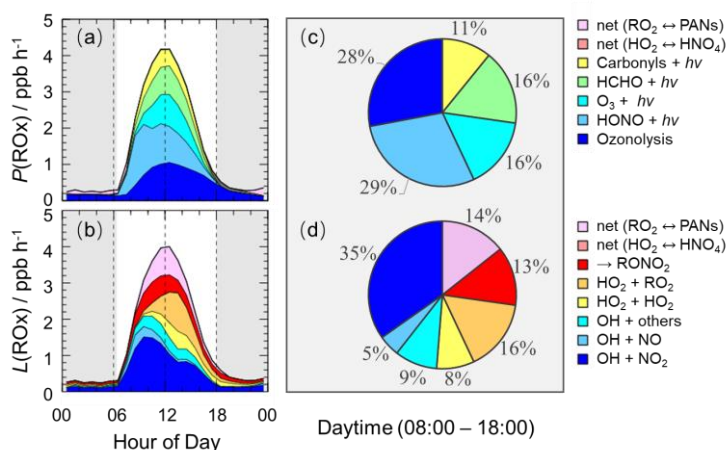

Figure 66: The diurnal profiles of ROx primary production rate (a) and termination rate (b) simulated by the base model, and the contributions of different channels to ROx primary production rate (c) and termination rate (d) during the daytime (08:00-18:00). The grey areas denote nighttime.

The ROx primary production and termination rates were basically in balance for the entire day, with maxima of 4 ppb h^{-1} around noontime. The ROx primary production rate was similar to those at Heshan (4 ppb h^{-1}) and Wangdu (5 ppb h^{-1}) sites, but lower than those at Backgarden (11 ppb h^{-1}), Yufa (7 ppb h^{-1}), and Chengdu (7 ppb h^{-1}) sites (Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan et al., 2019; Yang et al., 2021). During the daytime, the main-constitution-of- $P(\text{ROx})$ mainly came from the was OH and HO₂ primary production-rate. HONO and O₃ photolysis mainly-dominated the OH primary production rate, and HCHO photolysis dominated-constituted-the major-HO₂ primary production-rate. Thus, $P(\text{ROx})$ was dominated by the photolysis reactions, in which the photolysis of HONO, O₃, HCHO, and carbonyls accounted for 29%, 16%, 16%, and 11% during the daytime, respectively. In the early morning, HONO photolysis was the most important primary source of ROx, and the contribution of O₃ photolysis became progressively larger and was largest at noontime. A large discrepancy between the

带格式的: 缩进: 首行缩进: 0 字符

带格式的: 正文, 段落间距段前: 0 磅, 段后: 0 磅, 行距: 1.5 倍行距

446 ratio of HONO photolysis rate to O₃ photolysis rate in summer/autumn and that in winter occurs generally. The vast majority
 447 of OH photolysis source is attributed to HONO photolysis in winter because of the higher HONO concentration and lower O₃
 448 concentration. About half of L(ROx) came from OH termination, which occurred mainly in the morning, and thereafter, radical
 449 self-combination gradually became the major sink of ROx in the afternoon. OH + NO₂, OH + NO, and OH + others contributed
 450 35%, 5%, and 9% to L(ROx), respectively. HO₂ + HO₂ and HO₂ + RO₂ accounted for 8% and 16% in L(ROx).

451 4.4.4 AOC evaluation

452 AOC controls the abundance of precursors and the production of secondary pollutants (Yang et al., 2020b; Elshorbany et al.,
 453 2009), and thus it is necessary to quantify AOC for understanding photochemical pollution. The AOC has been evaluated in
 454 previous studies, as shown in Table 1. Overall, the AOC values in summer are higher than those in autumn and winter, and the
 455 values at lower latitudes are higher than those at higher latitudes for the same season. The vast majority of AOC in previous
 456 studies are evaluated based on the non-observed radical concentrations.

457 **Table 1: Summary of OH concentrations and AOC values reported in previous field campaigns.**

Location	Season, year	Site	Observed or non-observed radicals		AOC / 10 ⁸	References
			of OH	of OH	cm ⁻³ s ⁻¹	
Beijing, China	summer, 2018	urban	non-observed	values	0.89 ^a	(Liu et al., 2021)
Beijing, China	summer, 2018	suburban	non-observed	values	0.85 ^a	(Liu et al., 2021)
Beijing, China	winter, 2018	urban	non-observed	values	0.21 ^a	(Liu et al., 2021)
Beijing, China	winter, 2018	suburban	non-observed	values	0.16 ^a	(Liu et al., 2021)
Hongkong, China	summer, 2011	suburban	non-observed	values	2.04 ^{a,b}	(Xue et al., 2016)
Santiago, Chile	summer, 2005	urban	non-observed	values	3.4 ^a	(Elshorbany et al., 2009)
Hong Kong, China	late summer, 2012	coastal	non-observed	values	1.4 ^c	(Li et al., 2018)

458 Note that:

459 ^a Peak values in the diurnal profiles; ^b Values on 25 August 2021; ^c Maximum over a period of time; ^d Maximum on some day.

460 Herein, we explored the AOC in Shenzhen based on the observed radical concentrations for the first time. As illustrated in

461 Fig. 77(a), the diurnal profile of AOC exhibits a unimodal pattern, which is the same as the diurnal profile of OH concentration
 462 and $j(\text{NO}_2)$, with a peak around noontime. The diurnal peak of AOC was $0.75 \times 10^8 \text{ molecules cm}^{-3} \text{ s}^{-1}$ (11.8 ppb h^{-1}).
 463 Comparatively, AOC in this study can be comparable to those evaluated in Beijing (summer, 2018) and Hong Kong (autumn,
 464 2012) (Li et al., 2018; Liu et al., 2021), but much lower than those evaluated in Hong Kong (summer, 2011) and Santiago
 465 (summer, 2005) (Xue et al., 2016; Elshorbany et al., 2009).

475 shows the fractional composition of the total AOC. The OH radical contributed about 95.7% of AOC during the daytime
 476 (08:00-18:00). O₃, as the second important oxidant, accounted for only 2.9% of AOC during the daytime. The contribution of
 477 NO₃ to AOC during the daytime can be ignored, with a contribution of 1.4%. At night, the contributions of O₃ and NO₃ to
 478 AOC were higher. OH, O₃ and NO₃ accounted for 75.7%, 6.4%, and 18% in the first half of night (18:00-24:00), and they
 479 accounted for 87.8%, 5%, and 7.3% in the second half of night (00:00-08:00).

480 As an indicator for secondary pollution, O₃ formation rate, $F(O_3)$, can be estimated from the production of NO₂ via the
 481 reactions of HO₂ and RO₂ with NO, as shown in Eq. (2):

$$482 F(O_3) = 9 \times 10^{-12} [HO_2][NO] + 9 \times 10^{-12} [RO_2][NO] \quad (2)$$

483 where the units of HO₂, RO₂, and NO are all em⁻³.

484 The correlation between $F(O_3)$ and AOC during the daytime (08:00-18:00) was explored, as shown in Fig. 7 (b). A strong
 485 positive correlation between $F(O_3)$ and AOC was found, indicating AOC plays a significant role in driving secondary pollution.
 486 Most data points in this campaign focused on low AOC (the median values below 0.7×10^8 molecules em⁻³s⁻¹) and low $F(O_3)$
 487 (the median values below 17 ppb h⁻¹) regimes. The correlation between $F(O_3)$ and AOC by fitting the median was denoted by
 488 Eq. (3):

$$489 F(O_3) = 19.8 \times AOC + 2.0, R^2 = 0.98 \quad (3)$$

490 where the $F(O_3)$ and AOC units are ppb h⁻¹ and 10^8 molecules em⁻³s⁻¹, respectively.

491 To explore the correlation between $F(O_3)$ and AOC in other regions, we have taken Wangdu and Chengdu sites as examples
 492 to demonstrate the AOC values in NCP and SCB based on the observed radical concentrations reported by Tan et al. (2017)
 493 and Yang et al. (2021) in Fig. 7 (c), respectively. Surprisingly, the relationships between $F(O_3)$ and AOC in Wangdu and
 494 Chengdu were similar to those in the Shenzhen campaign. The vast majority of data points at Wangdu and Chengdu sites were
 495 distributed within the standard deviation of Shenzhen site. The similarity of the gradients between $F(O_3)$ and AOC in different
 496 regions indicates that AOC powerfully drives the production of O₃, and the quantification of $F(O_3)$ can be achieved based on
 497 the AOC values.

498 As the indicator for secondary pollution, net O₃ production rate, $P(O_3)$, can be calculated from the O₃ formation rate ($F(O_3)$)
 499 and the loss rate ($L(O_3)$), as shown in Eq. (3-5) (Tan et al., 2017). The diurnal profiles of the speciation $F(O_3)$ and $L(O_3)$ were
 500 shown in Fig. S5 in the Supplementary Information. The diurnal maxima of the modeled $F(O_3)$ and $L(O_3)$ were 18.9 ppb h⁻¹
 501 and 2.8 ppb h⁻¹, with the maximum $P(O_3)$ of 16.1 ppb h⁻¹ at 11:00. The modeled $P(O_3)$ was comparable to that in Wangdu site
 502 in summer and much higher than that in Beijing in winter (Tan et al., 2017; Tan et al., 2018).

$$503 F(O_3) = k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_2i+NO}[RO_2]_i[NO] \quad (3)$$

$$504 L(O_3) = \theta j(O^1D)[O_3] + k_{O_3+OH}[O_3][OH] + k_{O_3+HO_2}[O_3][HO_2] + (\sum(k_{alkenes+O_3}^i [alkenes^i]))[O_3] \quad (4)$$

$$505 P(O_3) = F(O_3) - L(O_3) \quad (5)$$

506 where θ is the fraction of O^1D from ozone photolysis that reacts with water vapor,
507 Herein, we presented the NO dependence of $P(O_3)$, AOC_{VOCs} , and the ratio of $P(O_3)$ to AOC_{VOCs} in Fig. 7 (b-d), in which
508 AOC_{VOCs} denotes the atmospheric oxidation capacity only from the VOCs oxidation. An upward trend $P(O_3)$ was presented
509 with the increase of NO concentration when NO concentration was below 1 ppb, while a downward trend was shown with the
510 increase of NO concentration when NO concentration was above 1 ppb. In terms of the NO dependence of AOC_{VOCs} , no
511 significant variation was found, indicating VOCs oxidation was weakly impacted by NO concentrations in this campaign.
512 Since AOC_{VOCs} can represent the VOCs oxidant rate, and thus the ratio of $P(O_3)$ to AOC_{VOCs} can reflect the yield of ozone
513 production from VOCs oxidation. Similar to $P(O_3)$, the ratio increased with the increase of NO concentration when NO
514 concentration was below 1 ppb. When NO concentration was above 1 ppb, the ratio decreased with the increase of NO
515 concentration because NO_2 became the sink of OH radicals gradually. The maximum of the ratios existed when NO
516 concentration was approximately 1 ppb, with a median of about 2, indicating the yield of ozone production from VOCs
517 oxidation was about 2 in this study.

519 5 Conclusions

520 The STORM field campaign was carried out at Shenzhen site in autumn 2018, providing the continuous OH and HO_2/HO_2
521 observations in PRD since the Heshan campaign in 2014. The maximum diurnal OH and HO_2/HO_2 concentrations, measured
522 by laser-induced fluorescence (LIF), were $4.5 \times 10^6 \text{ cm}^{-3}$ and $4.5 \times 10^8 \text{ cm}^{-3}$, respectively. The observed OH concentration was
523 equal to that measured at Heshan site but was lower than those measured in summer campaigns in China (Backgarden, Yufa,
524 Wangdu, and Chengdu ~~campaignsites~~).

525 The base model (RACM2-LIM1) could reproduce the observed OH concentration before 10:00, and thereafter, OH was
526 underestimated by the model when NO concentration dropped to low levels. The results of the radical experimental budget
527 indicated that OH underestimation was likely attributable to an unknown missing OH source at low NO conditions. We
528 diagnosed the missing OH source by sensitivity runs, and unclassical OH recycling was identified again. A constant mixing
529 ratio of the numerical species, X, equivalent to 0.1 ppb NO, was added to the base model to achieve the agreement between
530 the modeled and observed OH concentrations. ~~The amount of X related to the environmental conditions varied from 0.1 ppb~~
531 ~~to 0.85 ppb in China, and thus the unclassical OH recycling needs further exploration. Additionally, we found isoprene and~~
532 ~~OVOCs might closely influence the missing OH sources by comparing the composition of VOCs reactivity under the different~~
533 ~~NO intervals. Isoprene isomerization mechanism (LIM1) can explain approximately 7% of the missing OH sources, and no~~
534 ~~significant contribution of MACR and MVK oxidation was found. As another potential OH source, OVOCs species should be~~
535 ~~further explored to explain the remaining missing OH sources. As for HO_2 radicals, the overestimation of HO_2 concentration~~

536 was found, indicating that HO₂ heterogeneous uptake might make a significant role in HO₂ sinks, good agreement between the
537 observed and modeled HO₂ concentrations was achieved for the entire day during this campaign, indicating the HO₂
538 heterogeneous uptake on HO₂ chemistry was negligible.

539 The quantification of production and destruction channels of ROx radicals is essential to explore the chemical processes of
540 radicals. The ROx primary production and termination rates were balanced for the entire day, with maxima of 4 ppb h⁻¹, similar
541 to those in the Heshan and Wangdu campaign sites. Photolysis channels dominated the ROx primary production rate. HONO,
542 O₃, HCHO, and carbonyls photolysis accounted for 29%, 16%, 16%, and 11% during the daytime, respectively. The most
543 fraction of ROx termination rate came from the reaction of OH + NO₂ in the morning. The radical self-combination gradually
544 became the major sink of ROx in the afternoon with the decreasing of NO concentrations. The reaction of OH + NO₂ and
545 radical self-combination accounted for 35% and 24% during the daytime, respectively.

546 In this campaign, AOC exhibited well defined diurnal patterns, with a peak of 0.75×10^8 molecules cm⁻³ s⁻¹. As expected,
547 OH was the dominant oxidant accounting for 95.7% of the total AOC during the daytime. O₃ and NO₂ contributed 2.9% and
548 1.4% to total AOC during the daytime, respectively. The gradients at Shenzhen (PRD), Wangdu (NCP), and Chengdu (SBC)
549 sites were similar. The strong positive correlation between $F(O_3)$ and AOC makes the quantification of $F(O_3)$ achieved,
550 indicating AOC is the core driving force for the generation of secondary pollutants. In this campaign, AOC exhibited well-
551 defined diurnal patterns, with a peak of 11.8 ppb h⁻¹. As expected, OH radicals, which were the dominant oxidant, accounted
552 for 95.7% of the total AOC during the daytime. O₃ and NO₂ contributed 2.9% and 1.4% to total AOC during the daytime,
553 respectively. The ratio of $F(O_3)$ to AOC_{VOCs} tended to increase and then decrease as NO concentration increased,
554 demonstrating the non-linear relationship between O₃ production and VOCs oxidation. The maximum of the ratios existed
555 when NO concentration was approximately 1 ppb, with a median of about 2, indicating that the yield of ozone production from
556 VOCs oxidation was about 2 in this campaign.
