15 **Abstract.** The ambient OH and HO₂ concentrations were measured continuously during the STORM (STudy of the Ozone
16 foRmation Mechanism) campaign at the Shenzhen site, located in the Pearl River Delta in China, in autumn 2018. The diurnal
17 maximum OH and HO₂ concentrations, measured by laser-induced fluorescence, were $4.5 \times 10^6 \text{ cm}^{-3}$ and $4.5 \times 10^8 \text{ cm}^{-3}$,
18 respectively. The state-of-the-art radical chemical mechanism underestimated the observed OH concentration, similar to the
19 other warm-season campaigns in China. The OH underestimation was attributable to the missing OH sources, which can be
20 explained by the X mechanism. Good agreement between the observed and modeled OH concentrations was achieved when
21 an additional numerical X equivalent to 0.1 ppb NO concentrations was added to the base model. The modeled HO₂ could
22 reproduce the observed HO₂, indicating the HO₂ heterogeneous uptake on HO₂ chemistry was negligible. Photolysis reactions
23 dominated the ROx primary production rate. The HONO, O₃, HCHO, and carbonyls photolysis accounted for 29%, 16%, 16%,
24 and 11% during the daytime, respectively. The ROx termination rate was dominated by the reaction of OH + NO₂ in the
25 morning, and thereafter the radical self-combination gradually became the major sink of ROx in the afternoon. The atmospheric
26 oxidation capacity was evaluated, with a peak of $0.75 \times 10^8 \text{ molecules cm}^{-3} \text{ s}^{-1}$ around noontime. A strong positive correlation
27 between O₃ formation rate and atmospheric oxidation capacity was achieved, illustrating the atmospheric oxidation capacity
28 was the potential tracer to indicate the secondary pollution.

29

30 **1 Introduction**

31 Severe ambient ozone (O_3) pollution is one of China's most significant environmental challenges, especially in urban areas
32 (Shu et al., 2020; Li et al., 2019; Wang et al., 2020; Ma et al., 2019b; Wang et al., 2017). Despite the reduction in emissions of
33 O_3 precursors, O_3 concentration is increasing, especially in urban cities. The O_3 average trends for the focus megacity clusters
34 are 3.1 ppb a^{-1} , 2.3 ppb a^{-1} , 0.56 ppb a^{-1} , and 1.6 ppb a^{-1} for North China Plain (NCP), Yangtze River Delta (YRD), Pearl River
35 Delta (PRD), and Szechwan Basin (SCB), respectively (Li et al., 2019). The nonlinearity between O_3 and precursors illustrates
36 that it is necessary to explore the cause of O_3 production. The tropospheric O_3 is only generated in the photolysis of nitrogen
37 dioxide (NO_2), produced as the by-product within the radical cycling. Thus, the investigation of radical chemistry is critical to
38 controlling secondary pollution.

39 Hydroxyl radicals (OH), the dominant oxidant, control the atmospheric oxidation capacity (AOC) in the troposphere. The
40 OH radicals convert primary pollutants to secondary pollutants and are simultaneously transformed into peroxy radicals (HO_2
41 and RO_2). Within the interconvert of RO_x (= OH, HO_2 , and RO_2), secondary pollutants are generated, and thus the further
42 exploration of radical chemistry is significant. The radical closure experiment, an effective indicator for testing our
43 understanding of radical chemistry, has been conducted since the central role of OH radicals was recognized in the 1970s (Levy,
44 1971; Hofzumahaus et al., 2009). The underestimation of OH radicals at environments characterized by low nitrogen oxides
45 (NO) and high volatile organic compounds (VOCs) has been identified (Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan et
46 al., 2019; Yang et al., 2021; Hofzumahaus et al., 2009; Lelieveld et al., 2008; Whalley et al., 2011). New radical mechanisms
47 involving unclassical OH regeneration have been proposed, including Leuven Isoprene Mechanism (LIM) and X mechanism
48 (Peeters and Muller, 2010; Peeters et al., 2014; Peeters et al., 2009; Hofzumahaus et al., 2009). The LIM has been cooperated
49 with the current mechanism and is still not sufficient to explain the OH missing sources. The X mechanism was identified
50 several times, but the amount of the numerical species, X, varied in different environments, and the nature of X is unknown
51 (Hofzumahaus et al., 2009; Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan et al., 2019; Yang et al., 2021). Therefore, further
52 exploration of radical regeneration sources is necessary.

53 Owing to the strong photochemistry influenced by high temperatures, high O_3 pollution appeared to occur in YRD and PRD,
54 especially in PRD (Ma et al., 2019b; Wang et al., 2017). Radicals, the dominant oxidant in the troposphere, has been measured
55 during warm seasons in NCP (Yufa 2006, Wangdu 2014, and Beijing 2016), YRD (Taizhou 2018), SCB (Chengdu 2019), and
56 PRD (Backgarden 2006, and Heshan 2014) in China (Lu et al., 2013; Lu et al., 2012; Tan et al., 2017; Tan et al., 2019; Yang et
57 al., 2021; Tan et al., 2021). The radical observations in PRD, where the cities are suffering from severe O_3 pollution, have not
58 been conducted since 2014, and thus the oxidation capacity here has not been clear in recent years. Therefore, we carried out
59 a continuous comprehensive field campaign (STudy of the Ozone foRmation Mechanism - STORM) involving radical
60 observations in Shenzhen, one of the megacities in PRD, in autumn 2018. Overall, the following will be reported in this study.

- 61 (1) The observed OH and HO₂ radicals, and the comparison between the observed and modeled radical concentrations.
62 (2) The exploration of the unclassical OH regeneration sources based on the experimental budget.
63 (3) The sources and sinks of radicals.
64 (4) The evaluation of AOC and the quantitative relationship between O₃ formation and AOC.

65 2 Methodology

66 2.1 Measurement site and instrumentation

67 The STORM campaign was conducted from September to October 2018 in Peking University Shenzhen Graduate School
68 (22°60 N, 113°97 E), in the west of Shenzhen, Guangdong province. As shown in Fig. 1, this site was located in the university
69 town, which was surrounded by residential and commercial areas. The northwest of the site is close to the Shenzhen Wildlife
70 Park, and the northeast is close to the Xili Golf Club (Yu et al., 2020). The Tanglang Mountain Park with active biogenic
71 emissions is located about 1 km southeast of the site.

72
73 **Figure 1: Geographical location and surrounding environmental conditions of the measurement site in STORM campaign (The**
74 **maps are from <https://map.baidu.com>).**

75 Most instruments were set up on the top of a four-story academic building (about 20 m). Besides HO_x radicals measured by
76 the Peking University Laser-Induced Fluorescence system (PKU-LIF) (see the details in Sect. 2.2), a comprehensive set of
77 trace gases was conducted to support the exploration of the radical chemistry, including meteorological parameters
78 (temperature, pressure, relative humidity), photolysis frequency, and the trace gases (NO, NO₂, O₃, VOCs, *etc.*). Most of the
79 inorganic trace gases (O₃, CO, NO, NO₂, and SO₂) were simultaneously measured by two sets of instruments, and good
80 agreement was achieved within the uncertainty. VOCs (aldehydes, alkenes, aromatics, isoprene, and oxygenated VOCs
81 (OVOCs)) were measured using a gas chromatograph following a mass spectrometer (GC-MS). In addition, HONO and HCHO
82 were measured as well. Table S1 in the Supplementary Information describes the experimental details of the meteorological
83 and chemical parameters during this campaign.

84 2.2 The OH and HO₂ measurements

85 The OH and HO₂ radicals were measured by Peking University laser-induced fluorescence system (PKU-LIF) based on the
86 fluorescence assay by gas expansion (FAGE) technique. The principle has been reported in previous studies (Lu et al., 2012; Tan
87 et al., 2017; Heard and Pilling, 2003; Lu et al., 2013; Ma et al., 2019a; Tan et al., 2019; Tan et al., 2018; Yang et al., 2021), only a
88 brief description of the instrument is presented here.

89 In principle, OH resonance fluorescence is released in the OH excitation by a 308 nm pulsed laser, and then OH radicals are
90 detected directly. HO₂ radicals are converted into OH via NO, and then they are detected. The system contains a laser module
91 and a detection module. Ambient air was drawn into two independent, parallel, low-pressure (3.5 mBar) cells through two
92 parallel nozzles with 0.4 mm diameter pinhole. The OH radicals are excited into resonance fluorescence in the OH detection
93 cell and detected by micro-channel plate detectors (MCP). In the HO₂ detection cell, NO is injected and converts HO₂ to OH
94 radicals, which then are excited by the laser and release resonance fluorescence. Besides, an OH reference cell in which a large
95 OH concentration is generated by pyrolysis of water vapor on a hot filament is applied to automatically correct the laser
96 wavelength.

97 Owing to the failure of the reference cell in this study, the NO mixing ratios injected into the HO₂ cell were set to be higher
98 than that in other campaigns in China because the HO₂ cell needed to be used as a reference cell to correct laser wavelength.
99 Here, NO mixing ratios were switched between 10 ppm and 20 ppm. There was no obvious difference in HO₂ signals under
100 the above two NO mixing ratios, indicating that the interference of RO₂ to HO₂ measurements was negligible despite the higher
101 NO mixing ratio than other campaigns in China.

102 2.3 Closure experiment

103 As an effective tool to explore the atmospheric radical chemistry, the radical closure experiment can investigate the state-of-
104 the-art chemical mechanism because of the extremely short lifetime of radicals (Stone et al., 2012; Lu et al., 2019). A zero-
105 dimensional box model was used to conduct the radical closure experiment, and the overall framework was reported by Lu et
106 al. (2019). In this work, we conducted the radical closure experiment based on the Regional Atmospheric Chemical Mechanism
107 updated with the lasted isoprene chemistry (RACM2-LIM1), as Tan et al. (2017) described in detail. The model was
108 constrained to the measured meteorological, photolysis frequency, and the critical chemical parameters (CO, NO, NO₂, VOCs,
109 *etc.*). The H₂ and CH₄ mixing ratios were set to 550 ppb and 1900 ppb, respectively. The model was operated in time-dependent
110 mode with a 5-min time resolution, and a 2-d spin-up time was used to reach steady-state conditions for long-lived species.

111 As Lu et al. (2012) described, there are two types of radical closure experiment. One is the comparison of observed and
112 modeled radical concentrations, and the other is the comparison of radical production and destruction rates. The most
113 significant difference between the above is that the latter is conducted with the radical concentrations and k_{OH} constrained. The
114 comparison of radical production and destruction rates, also called radical experimental budget, can test the accuracy of the

115 state-of-the-art chemistry mechanisms based on the equivalent relationship between the radical production and destruction
116 rates. The production rates of OH, HO₂, and RO₂ radicals are quantified from all the known sources. The destruction rates of
117 HO₂ and RO₂ radicals are the sum of the known sources. The OH destruction rate can be directly calculated as the product of
118 the observed OH concentrations and the observed k_{OH} (Tan et al., 2019; Yang et al., 2021). The OH destruction rate is the total
119 sinks of OH radicals because of the direct k_{OH} observation, and thus the discrepancy between the OH destruction and production
120 rates denotes the missing OH sources. The detailed reactions and the reaction rate constants related to OH, HO₂, and RO₂
121 radicals can be found in Tan et al. (2019) and Yang et al. (2021).

122 2.4 AOC evaluation

123 The life time of the trace gases is controlled not only by the oxidant concentration but also by its second-order rate constant,
124 so the atmospheric oxidation capacity (AOC) proposed by Geyer et al. (2001) is most suitable to evaluate the relative
125 importance of each oxidant (Elshorbany et al., 2009). AOC is the core driving force of complex air pollution, and determines
126 the removal rate of trace gases and the production rates of secondary pollutants (Liu et al., 2021). As an effective indicator for
127 atmospheric oxidation intensity, the evaluation of AOC can provide crucial information on the atmospheric composition of
128 harmful and climate forcing species (Elshorbany et al., 2009). AOC is defined as the sum of the respective oxidation rates of
129 the pollutants via reactions with oxidants (Elshorbany et al., 2009; Geyer et al., 2001). According to the definition of AOC, it
130 can be calculated by the Eq. (1).

$$131 \text{AOC} = \sum_i k_{Y_i} [Y_i] [X] \quad (1)$$

132 where Y_i are the pollutants (CO, NO, NO₂, and VOCs), X are the main atmospheric oxidants (OH, O₃, NO₃), and k_{Y_i} is the
133 bi-molecular rate constant for the reaction of Y_i with X . The higher AOC, the higher removal rate of the most pollutants, and
134 thus the higher production rate of secondary pollutants (Yang et al., 2020a). Simultaneous measurements of OH and the key
135 trace gases are available in the study. NO₃ concentration could be simulated by the box model with the observed parameters
136 constrained.

137 3. Results

138 3.1 Meteorological and chemical conditions

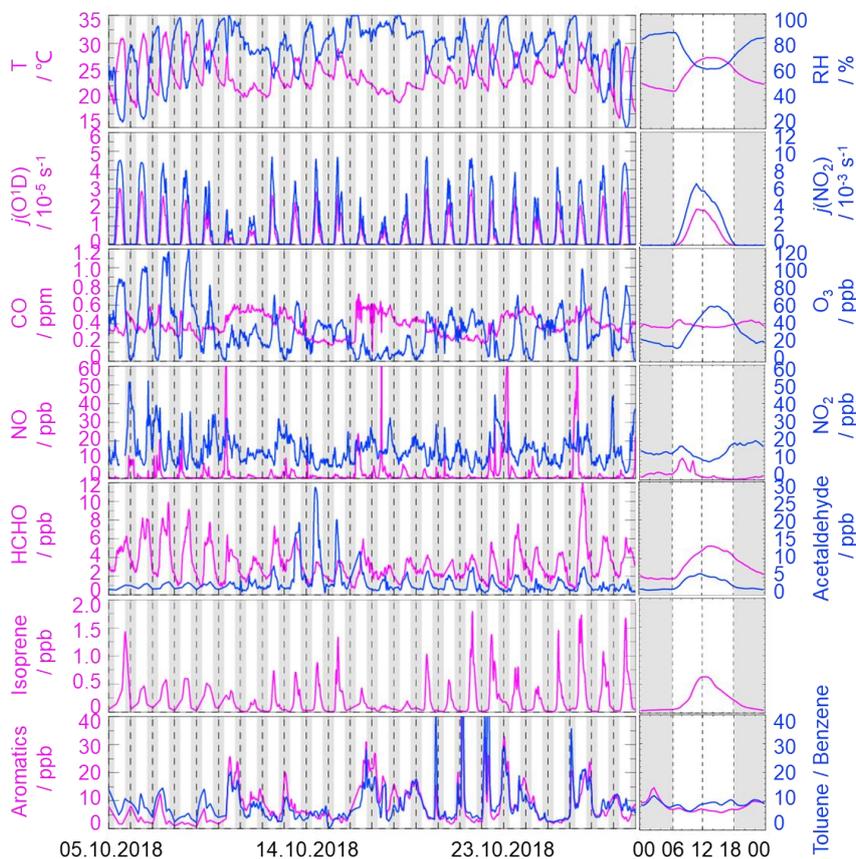

139 Figure 2 gives an overview of the meteorological and chemical parameters from 05 October to 28 October 2018, when OH
140 and HO₂ radicals were measured. The diurnal variations of the temperature (T), relative humidity (RH), $j(\text{O}^1\text{D})$, and $j(\text{NO}_2)$
141 followed a regular pattern from day to day. The overall meteorological conditions were characterized by high temperature
142 (about 20~30 °C), high relative humidity (60~80%), and intensive radiation with $j(\text{O}^1\text{D})$ up to $2.0 \times 10^{-5} \text{ s}^{-1}$ and $j(\text{NO}_2)$ up to
143 $6.0 \times 10^{-3} \text{ s}^{-1}$. The relative humidity and photolysis-frequency in this autumn campaign were similar to those in the summer

144 campaign conducted at Chengdu site (Yang et al., 2021). The temperature in this campaign was lower than that at Chengdu
145 site, but similar to that in the autumn campaign at Heshan site located in PRD as well (Tan et al., 2019; Yang et al., 2021).

146 The concentration of CO showed weak diurnal variation, indicating there was the non-obvious accumulation of
147 anthropogenic emissions on a regional scale. NO concentration peaked at 12 ppb during morning rush hour when the traffic
148 emission was severe, and thereafter, O₃ concentration started to increase with the decreasing of NO concentration. The maxima
149 of O₃ hourly concentration were high up to 120 ppb. According to the updated National Ambient Air Quality Standard of China
150 (GB3095-2012), O₃ concentration exceeded the Class-II limit values (hourly averaged limit 93 ppb) on several days (6, 7, 8,
151 and 26 October) when the environmental condition was characterized by high temperature and low relative humidity. NO₂
152 concentration was high at night because of the titration effect of O₃ with NO.

153 Along with the high O₃ concentration on 6, 7, 8, and 26 October, high HCHO concentration was also recorded during the
154 corresponding periods, indicating HCHO was mainly produced as secondary pollutions because of the active photochemistry
155 in this campaign. Isoprene, mostly derived from biogenic emissions and mainly affected by temperature, peaked around
156 noontime. Tan et al. (2019) reported the median concentration of HCHO and isoprene concentrations were 6.8 ppb and 0.6 ppb
157 during 12:00-18:00 at Heshan site. Similarly, the median concentration of HCHO and isoprene concentrations in this study
158 were 4.9 ppb and 0.4 ppb during the corresponding periods, respectively. As a proxy for traffic intensity, the toluene to benzene
159 ratio (T/B), which is below 2, means the traffic emissions are the major sources of VOCs (Brocco et al., 1997). The T/B
160 gradually dropped from 07:00 until it reached the minimum value at 09:00, indicating traffic emission contributed more to
161 VOCs during morning rush hour than during other periods. However, the T/B, which varied within a range of 7-12, was above
162 2, and thus VOCs emission during this campaign was mainly from other sectors such as those involving solvent evaporation.

163
164 **Figure 2: Timeseries and diurnal profiles of the observed meteorological and chemical parameters in STORM campaign. The grey**
165 **areas denote nighttime.**

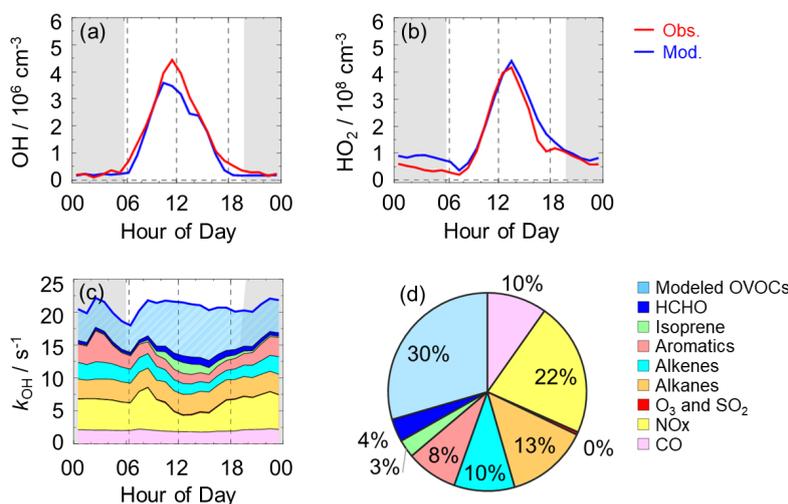

166 3.2 Observed and modeled OH and HO₂ radicals

167 The OH and HO₂ radicals were measured during 05-28 October 2018. The timeseries of the observed and modeled HOx
168 concentrations are displayed in Fig. S1 (a and b) in the Supplementary Information. Data gaps were caused by the rain,
169 calibration, and maintenance. The daily maxima of the observed OH and HO₂ concentrations varied in the range of (2-9) × 10⁶
170 cm⁻³ and (2-14) × 10⁸ cm⁻³, respectively. As in previous campaigns, the largest OH concentrations appeared around noontime
171 and showed a high correlation with *j*(O¹D), a proxy for the solar UV radiation driving much of the primary radical production
172 (Tan et al., 2019).

173 Figure 3 shows the diurnal profiles of the observed and modeled HOx concentrations (a and b). The HOx radicals showed
174 similar diurnal behavior to those reported in other campaigns (Ma et al., 2019a; Tan et al., 2017; Tan et al., 2019; Tan et al.,
175 2018; Yang et al., 2021). The observed OH and HO₂ concentration reached a maximum around 12:00 and 13:30, respectively.
176 The diurnal maximum of the observed and modeled OH concentration was 4.5 × 10⁶ cm⁻³ and 3.5 × 10⁶ cm⁻³. There was an

177 agreement between the diurnal profiles of the observed and modeled OH concentrations within their errors of 11% and 40%,
178 respectively. A systematic difference existed with the decreasing of NO concentration. The model could reproduce the observed
179 OH concentrations well only in the early morning before 10:00. However, the model would underestimate the observed OH
180 concentration after 10:00 when NO concentration dropped 2 ppb. The OH concentrations observed in the environments with
181 low NO levels were underestimated by the state-of-the-art models at Backgarden (summer) and Heshan (autumn) sites in PRD
182 as well, and the OH underestimation was identified to be universal at low NO conditions in China (Lu et al., 2013; Lu et al.,
183 2012; Ma et al., 2019a; Tan et al., 2017; Yang et al., 2021).

184
185 **Figure 3: The diurnal profiles of the observed and modeled OH (a) and HO₂ (b) concentrations, the diurnal profiles of the modeled**
186 **k_{OH} (c), and the composition of the modeled k_{OH} (d). The grey areas denote nighttime.**

187 The diurnal maximum of the observed HO₂ concentration was $4.5 \times 10^8 \text{ cm}^{-3}$, and the modeled HO₂ concentration could
188 match well with the observed HO₂ concentration within the uncertainties, indicating the HO₂ heterogeneous uptake on HO₂
189 chemistry was negligible. The observed HO₂ concentration around noontime (11:00-15:00) was high, thereby yielding a mean
190 HO₂ to OH ratio (HO₂/OH) of about 112, which was similar to that at Backgarden site and was higher than that at Chengdu
191 site (Lu et al., 2012; Yang et al., 2021). The modeled HO₂/OH ratio was about 138. Prior studies indicated that the measured
192 HO₂/OH ratios were agreed well with the simulations under polluted conditions, but under clean conditions, the measured
193 ratios were lower than simulated (Stevens et al., 1997). The comparison of the measured HO₂/OH ratio and the modeled
194 HO₂/OH ratio in this campaign indicated the pollution was not severe during the observation period. As an indicator that can
195 reflect the interconversion reaction between OH and HO₂, the conversion efficiency in this campaign was equal to that at
196 Backgarden site and was slightly slower than that at Chengdu site.

197 3.3 Modeled k_{OH}

198 k_{OH} is the pseudo-first-order loss rate coefficient of OH radicals, and it is equivalent to the reciprocal OH lifetime (Fuchs et
199 al., 2017; Lou et al., 2010; Yang et al., 2019). In this campaign, k_{OH} was not measured continuously, so we only showed the
200 timeseries of modeled values in Fig. S1 (c) in the Supplementary Information, the diurnal profile of the modeled k_{OH} in Fig. 3
201 (c), and the composition of k_{OH} in Fig. 3 (d). The modeled k_{OH} showed weak diurnal variation and varied from 18 s^{-1} to 22 s^{-1} .

202 The inorganic compounds contributed approximately 32% to k_{OH} , in which the CO and NO_x reactivity accounted for 10%
203 and 22%, respectively. The NO_x reactivity is displayed versus time, with a maximum during the morning peak. The peak
204 concentration during the morning peak is associated with traffic emissions.

205 The larger fraction of k_{OH} comes from the VOCs group compared with inorganics reactivity, with a contribution of 68% to
206 k_{OH} . OVOCs reactivity was equivalent to the other VOCs reactivity, and the contributions of them to k_{OH} were both 34%. The
207 contribution of alkanes, alkenes, and aromatics were 13%, 10%, and 8%, respectively. The isoprene reactivity related to
208 temperature was mainly concentrated during the daytime, whereas the aromatics reactivity at night was higher. As for OVOCs
209 species, about 4% of k_{OH} could be attributed to HCHO. The remaining OVOCs was attributed to the simulated species in the
210 box model, with a contribution of up to 30% of k_{OH} . High OVOCs reactivity occurred in the afternoon, which was attributed
211 to the strong photochemical activity during this period.

212 4. Discussion

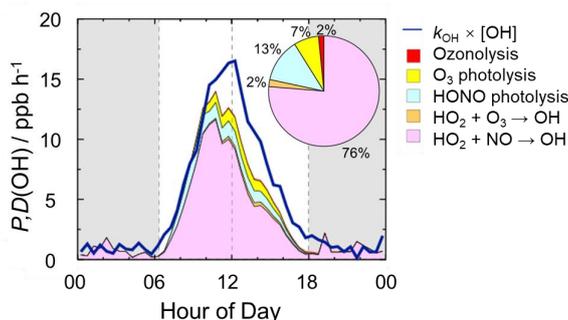

213 4.1 Radical closure experiment

214 In this study, we conducted OH radical closure experiment which is called OH experimental budget. The exploration of OH
215 experimental budget was based on the premise that the modeled k_{OH} could match well with the observed k_{OH} due to the lack
216 of the continuous k_{OH} observations in this campaign. Several studies in China indicated that the modeled k_{OH} which has
217 included OVOCs reactivity could match well with the observed k_{OH} , especially during daytime (Fuchs et al., 2017; Lou et al.,
218 2010), but missing k_{OH} existed in some environmental conditions despite the inclusion of OVOCs (Whalley et al., 2021; Yang
219 et al., 2017). Thus, the OH destruction rate is the lower limit due to the possible missing k_{OH} in this study, so the missing OH
220 source, which is the difference between the OH destruction and production rates, is the lower limit as well. The diurnal profiles
221 of OH production and destruction rates, and compositions of OH production rate were displayed in Fig. 4, with maxima of 14
222 ppb h⁻¹ and 17 ppb h⁻¹ around noontime, respectively. The OH production rate from known sources is quantified from the
223 primary sources (photolysis of HONO, photolysis of O₃, ozonolysis of alkenes) and secondary sources (dominated by HO₂ +
224 NO, and HO₂ + O₃). The primary and secondary sources were account for 78% and 22% of the total calculated production rate,
225 respectively. Similar with the prior studies, the largest fraction of OH production rate comes from HO₂ + NO, with a
226 contribution up to 76% of the known OH production rate. The contributions of HONO and O₃ photolysis were 13% and 7% to

227 the primary production rate.

228 The OH production rate matched well with the destruction rate only in the early morning to about 10:00. Thereafter, the OH
229 destruction rate was larger than the production rate, which could explain the underestimation of OH concentration by the model.
230 The discrepancy between the OH production and destruction rates was attributed the missing OH source. The biggest additional
231 OH source was approximately 4.6 ppb h^{-1} , which occurred at about 12:00, when the OH production and destruction rates were
232 11.9 ppb h^{-1} and 16.5 ppb h^{-1} , respectively. The unknown OH source could explain about one third of the total OH production
233 rate, indicating the exploration of missing OH source was significant to study the radical chemistry. Details are given below
234 (Sect. 4.2).

235
236 **Figure 4: The diurnal profiles of OH production and destruction rates and the proportions of different known sources in the**
237 **calculated production rate during the daytime. The blue line denotes the OH destruction rate, and the colored areas denote the**
238 **calculated OH production rates from the known sources. The grey areas denote nighttime.**

239 4.2 Radical chemistry in low NO regime

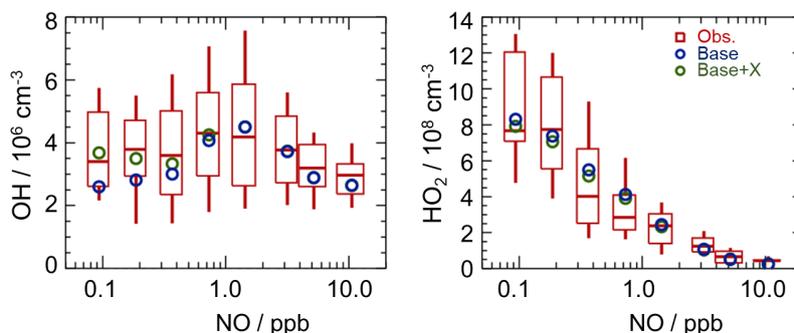

240 4.2.1 Influencing factors of OH underestimation

241 As analyzed in Sect. 4.1, the underestimation of OH concentration was attributable to the missing OH source. It is necessary
242 to explore the influencing factor for gaining further insight into the missing source. Scientists reported that more significant
243 OH underestimation would appear with the decreasing NO concentration and increasing isoprene concentration (Lu et al.,
244 2012;Ren et al., 2008;Hofzumahaus et al., 2009;Lelieveld et al., 2008;Whalley et al., 2011;Tan et al., 2017;Yang et al., 2021).
245 A new OH source was suggested, such as the LIM, which was proposed based on *ab initio* calculation (Peeters et al.,
246 2014;Peeters et al., 2009). We have applied the latest LIM into the base model in this study, and Tan et al. (2017) described
247 the modified LIM in detail. However, the model was not sufficient to explain the higher OH observations after 10:00.

248 We further explored the effect of NO concentration on missing OH source. NO dependence of OH and HO₂ radicals was
249 illustrated in Fig. 5. The base model can reproduce the observed OH concentration at high NO conditions (above 1 ppb) and
250 underestimate OH concentration at low NO conditions (below 1 ppb). As for HO₂ radical, the modeled HO₂ concentration by
251 the base model matched well with the observed HO₂ concentration within the whole NO regime. Therefore, NO concentration

252 played the significant role in the OH underestimation, especially under low NO regime.

253

254 **Figure 5: NO dependence of OH and HO₂ radicals.** The red box-whisker plots give the 10%, 25%, median, 75%, and 90% of the
255 HO_x observations. The blue circles show the median values of the HO_x simulations by the base model, and the green circles show
256 the HO_x simulations by the model with X mechanism. The OH concentrations were normalized by the averaged $j(\text{O1D})$ to eliminate
257 the influence of radiation on the OH radicals. Only daytime values and NO concentration above the detection limit of the instrument
258 were chosen.

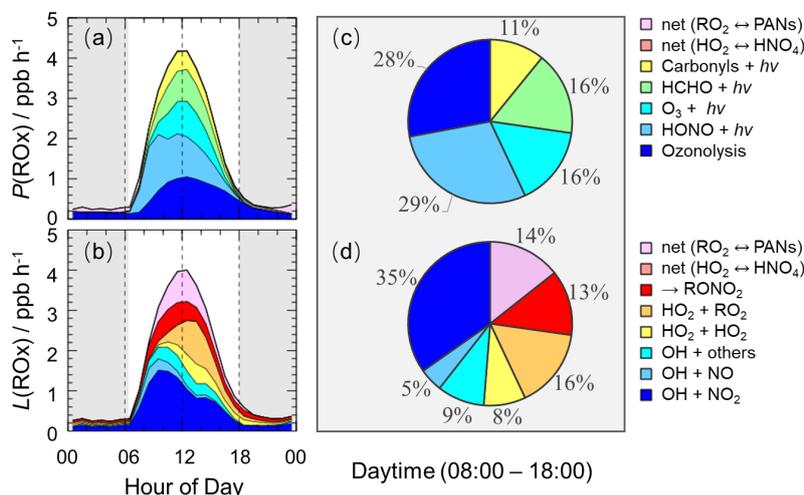

259 4.2.2 Quantification of missing OH sources

260 Hofzumahaus et al. (2009) proposed an existence of a pathway for the regeneration of OH independent of NO, including the
261 conversions of $\text{RO}_2 \rightarrow \text{HO}_2$ and $\text{HO}_2 \rightarrow \text{OH}$ by a numerical species called X. With a retrospective analysis, the unclassical
262 OH recycling pathway was identified to be universal at low NO conditions in China. The amount of X varies with
263 environmental conditions, and the X concentrations were 0.85 ppb, 0.4 ppb, 0.1 ppb, 0.4 ppb, and 0.25 ppb at Backgarden,
264 Yufa, Wangdu, Heshan, and Chengdu sites (Hofzumahaus et al., 2009; Lu et al., 2012; Lu et al., 2013; Tan et al., 2017; Yang et
265 al., 2021).

266 In this study, we tested this unclassical X mechanism. Good agreement between observations and simulations of both OH
267 and HO₂ was achieved when a constant mixing ratio of 0.1 ppb of X was added into the base model. As shown in Fig. 5, the
268 model with X mechanism could agree with the observed OH concentrations even at low NO conditions. Unclassical OH
269 recycling was identified again in this study. However, X is an artificial species that behaves like NO, and thus the nature of X
270 is still unknown to us. Further exploration on this unclassical OH recycling is needed to improve our understanding of radical
271 chemistry.

272 4.3 Sources and sinks of RO_x

273 The detailed analysis of radical sources and sinks was crucial to exploring radical chemistry. The experimental budget for HO₂
274 and RO₂ radicals could not be conducted because RO₂ was not measured during this campaign. Herein, we showed the
275 simulated results by the base model. Figure 6 illustrates the diurnal profiles of RO_x primary production rate ($P(\text{RO}_x)$) and
276 termination rate ($L(\text{RO}_x)$), and the contributions of different channels during the daytime.

277

278 **Figure 6: The diurnal profiles of ROx primary production rate (a) and termination rate (b) simulated by the base model, and the**
 279 **contributions of different channels to ROx primary production rate (c) and termination rate (d) during the daytime (08:00-18:00).**
 280 **The grey areas denote nighttime.**

281 The ROx primary production and termination rates were basically in balance for the entire day, with maxima of 4 ppb h⁻¹
 282 around noontime. The ROx primary production rate was similar to those at Heshan (4 ppb h⁻¹) and Wangdu (5 ppb h⁻¹) sites,
 283 but lower than those at Backgarden (11 ppb h⁻¹), Yufa (7 ppb h⁻¹), and Chengdu (7 ppb h⁻¹) sites (Lu et al., 2013; Lu et al.,
 284 2012; Tan et al., 2017; Tan et al., 2019; Yang et al., 2021). During daytime, the main constitution of $P(\text{ROx})$ was OH and HO₂
 285 primary production rate. HONO and O₃ photolysis mainly dominated the OH primary production rate, and HCHO photolysis
 286 constituted the major HO₂ primary production rate. $P(\text{ROx})$ was dominated by photolysis reactions, in which the photolysis of
 287 HONO, O₃, HCHO, and carbonyls accounted for 29%, 16%, 16%, and 11% during the daytime. In the early morning, HONO
 288 photolysis was the most important primary source of ROx, and the contribution of O₃ photolysis became progressively larger
 289 and was largest at noontime. A large discrepancy between the ratio of HONO photolysis rate to O₃ photolysis rate in
 290 summer/autumn and that in winter occurs generally. The vast majority of OH photolysis source is attributed to HONO
 291 photolysis in winter because of the higher HONO concentration and lower O₃ concentration. About half of $L(\text{ROx})$ came from
 292 OH termination, which occurred mainly in the morning, and thereafter, radical self-combination gradually became the major
 293 sink of ROx in the afternoon. OH + NO₂, OH + NO, and OH + others contributed 35%, 5%, and 9% to $L(\text{ROx})$, respectively.
 294 HO₂ + HO₂ and HO₂ + RO₂ accounted for 8% and 16% in $L(\text{ROx})$.

295 4.4 AOC evaluation

296 AOC controls the abundance of precursors and the production of secondary pollutants (Yang et al., 2020b; Elshorbany et al.,
 297 2009). It is necessary to quantify AOC for understanding photochemical pollution. The AOC has been evaluated in previous
 298 studies, as shown in Table 1. Overall, the AOC values in summer are higher than those in autumn and winter, and the values

299 at lower latitudes are higher than those at higher latitudes for the same reason. The vast majority of AOC in previous studies
300 are evaluated based on the non-observed radical concentrations.

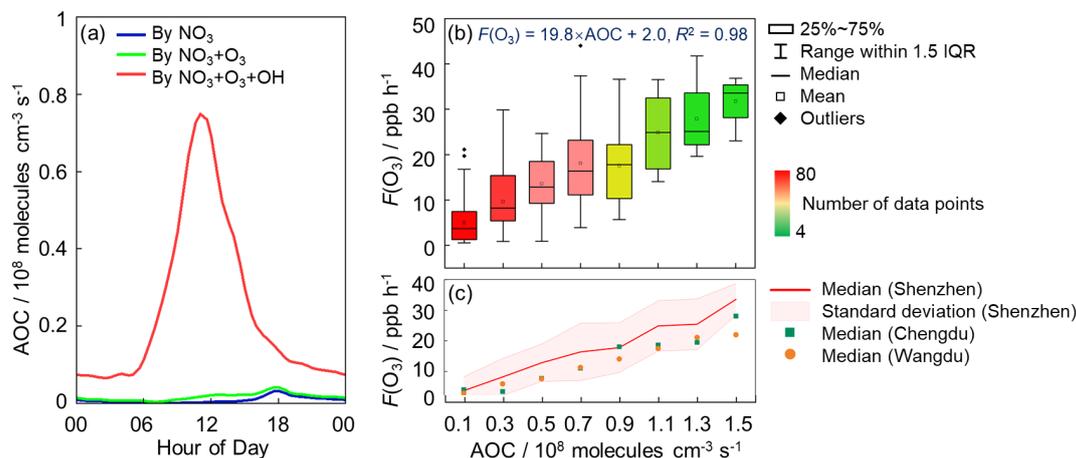

301 **Table 1: Summary of OH concentrations and AOC values reported in previous field campaigns.**

Location	Season, year	Site	Observed or non-observed radicals	of OH molecules	AOC / 10^8 $\text{cm}^{-3} \text{s}^{-1}$	References
Beijing, China	summer, 2018	urban	non-observed values		0.89 ^a	(Liu et al., 2021)
Beijing, China	summer, 2018	suburban	non-observed values		0.85 ^a	(Liu et al., 2021)
Beijing, China	winter, 2018	urban	non-observed values		0.21 ^a	(Liu et al., 2021)
Beijing, China	winter, 2018	suburban	non-observed values		0.16 ^a	(Liu et al., 2021)
Hongkong, China	summer, 2011	suburban	non-observed values		2.04 ^{a,b}	(Xue et al., 2016)
Santiago, Chile	summer, 2005	urban	non-observed values		3.4 ^a	(Elshorbany et al., 2009)
Hong Kong, China	late summer, 2012	coastal	non-observed values		1.4 ^c	(Li et al., 2018)
Hong Kong, China	autumn, 2012	coastal	non-observed values		0.62 ^c	(Li et al., 2018)
Hong Kong, China	winter, 2012	coastal	non-observed values		0.41 ^c	(Li et al., 2018)
Shanghai, China	summer, 2018	urban	non-observed values		1.0 ^c	(Zhu et al., 2020)
Berlin, Germany	summer, 1998	suburban	non-observed values		0.14 ^d	(Geyer et al., 2001)
Xianghe, China	autumn, 2019	suburban	non-observed values		0.49 ^c	(Yang et al., 2020b)
Beijing, China	summer, 2014	urban	non-observed values		1.7 ^a	(Feng et al., 2021)

302 Note that:

303 ^a Peak values in the diurnal profiles; ^b Values on 25 August 2021; ^c Maximum over a period of time; ^d Maximum on some day.

304 Herein, we explored the AOC in Shenzhen based on the observed radical concentrations for the first time. As illustrated in
305 Fig. 7 (a), the diurnal profile of AOC exhibits a unimodal pattern, which is the same as the diurnal profile of OH concentration
306 and $j(\text{NO}_2)$, with a peak around noontime. The diurnal peak of AOC was 0.75×10^8 molecules $\text{cm}^{-3} \text{s}^{-1}$. Comparatively, AOC
307 in this study can be comparable to those evaluated in Beijing (summer, 2018) and Hong Kong (autumn, 2012) (Li et al.,
308 2018;Liu et al., 2021), but much lower than those evaluated in Hong Kong (summer, 2011) and Santiago (summer, 2005) (Xue
309 et al., 2016;Elshorbany et al., 2009).

310

311 **Figure 7: (a) The diurnal profiles of AOC in this campaign. (b) The correlation between $F(O_3)$ and AOC during the daytime (08:00-**
 312 **18:00) in this campaign, and the formula was fitted by median values. (c) The comparison of the correlations between $F(O_3)$ and**
 313 **AOC at this site, Wangdu site and Chengdu site.**

314 As expected, the dominant contributor to the AOC during this campaign was OH, followed by O₃ and NO₃. Figure S2 shows
 315 the fractional composition of the total AOC. The OH radical contributed about 95.7% of AOC during the daytime (08:00-
 316 18:00). O₃, as the second important oxidant, accounted for only 2.9% of AOC during the daytime. The contribution of NO₃ to
 317 AOC during the daytime can be ignored, with a contribution of 1.4%. At night, the contributions of O₃ and NO₃ to AOC were
 318 higher. OH, O₃ and NO₃ accounted for 75.7%, 6.4%, and 18% in the first half of night (18:00-24:00), and they accounted for
 319 87.8%, 5%, and 7.3% in the second half of night (00:00-08:00).

320 As an indicator for secondary pollution, O₃ formation rate, $F(O_3)$, can be estimated from the production of NO₂ via the
 321 reactions of HO₂ and RO₂ with NO, as shown in Eq. (2).

$$322 \quad F(O_3) = 9 \times 10^{-12}[HO_2][NO] + 9 \times 10^{-12}[RO_2][NO] \quad (2)$$

323 where the units of HO₂, RO₂, and NO are all cm⁻³.

324 The correlation between $F(O_3)$ and AOC during the daytime (08:00-18:00) was explored, as shown in Fig. 7 (b). A strong
 325 positive correlation between $F(O_3)$ and AOC was found, indicating AOC plays a significant role in driving secondary pollution.
 326 Most data points in this campaign focused on low AOC (the median values below 0.7×10^8 molecules cm⁻³ s⁻¹) and low $F(O_3)$
 327 (the median values below 17 ppb h⁻¹) regimes. The correlation between $F(O_3)$ and AOC by fitting the median was denoted by
 328 Eq. (3).

$$329 \quad F(O_3) = 19.8 \times AOC + 2.0, R^2 = 0.98 \quad (3)$$

330 where the $F(O_3)$ and AOC units are ppb h⁻¹ and 10⁸ molecules cm⁻³ s⁻¹, respectively.

331 To explore the correlation between $F(O_3)$ and AOC in other regions, we have taken Wangdu and Chengdu sites as examples

332 to demonstrate the AOC values in NCP and SCB based on the observed radical concentrations reported by Tan et al. (2017)
333 and Yang et al. (2021) in Fig. 7 (c), respectively. Surprisingly, the relationships between $F(\text{O}_3)$ and AOC in Wangdu and
334 Chengdu were similar to those in the Shenzhen campaign. The vast majority of data points at Wangdu and Chengdu sites were
335 distributed within the standard deviation of Shenzhen site. The similarity of the gradients between $F(\text{O}_3)$ and AOC in different
336 regions indicates that AOC powerfully drives the production of O_3 , and the quantification of $F(\text{O}_3)$ can be achieved based on
337 the AOC values.

338 5 Conclusions

339 The STORM field campaign was carried out at Shenzhen site in autumn 2018, providing the continuous OH and HO_2
340 observations in PRD since the Heshan campaign in 2014. The maximum diurnal OH and HO_2 concentrations, measured by
341 laser-induced fluorescence (LIF), were $4.5 \times 10^6 \text{ cm}^{-3}$ and $4.5 \times 10^8 \text{ cm}^{-3}$, respectively. The observed OH concentration was
342 equal to that measured at Heshan site but was lower than those measured in summer campaigns in China (Backgarden, Yufa,
343 Wangdu, and Chengdu campaigns).

344 The base model (RACM2-LIM1) could reproduce the observed OH concentration before 10:00, and thereafter, OH was
345 underestimated by the model when NO concentration dropped to low levels. The results of the radical experimental budget
346 indicated that OH underestimation was likely attributable to an unknown missing OH source at low NO conditions. We
347 diagnosed the missing OH source by sensitivity runs, and unclassical OH recycling was identified again. A constant mixing
348 ratio of the numerical species, X, equivalent to 0.1 ppb NO, was added to the base model to achieve the agreement between
349 the modeled and observed OH concentrations. The amount of X related to the environmental conditions varied from 0.1 ppb
350 to 0.85 ppb in China, and thus the unclassical OH recycling needs further exploration. As for HO_2 radicals, good agreement
351 between the observed and modeled HO_2 concentrations was achieved for the entire day during this campaign, indicating the
352 HO_2 heterogeneous uptake on HO_2 chemistry was negligible.

353 The quantification of production and destruction channels of ROx radicals is essential to explore the chemical processes of
354 radicals. The ROx primary production and termination rates were balanced for the entire day, with maxima of 4 ppb h^{-1} , similar
355 to those in the Heshan and Wangdu campaigns. Photolysis channels dominated the ROx primary production rate. HONO, O_3 ,
356 HCHO, and carbonyls photolysis accounted for 29%, 16%, 16%, and 11% during the daytime, respectively. The most fraction
357 of ROx termination rate came from the reaction of $\text{OH} + \text{NO}_2$ in the morning. The radical self-combination gradually became
358 the major sink of ROx in the afternoon with the decreasing of NO concentrations. The reaction of $\text{OH} + \text{NO}_2$ and radical self-
359 combination accounted for 35% and 24% during the daytime, respectively.

360 In this campaign, AOC exhibited well-defined diurnal patterns, with a peak of $0.75 \times 10^8 \text{ molecules cm}^{-3} \text{ s}^{-1}$. As expected,
361 OH was the dominant oxidant accounting for 95.7% of the total AOC during the daytime. O_3 and NO_3 contributed 2.9% and

362 1.4% to total AOC during the daytime, respectively. The gradients at Shenzhen (PRD), Wangdu (NCP), and Chengdu (SBC)
363 sites were similar. The strong positive correlation between $F(\text{O}_3)$ and AOC makes the quantification of $F(\text{O}_3)$ achieved,
364 indicating AOC is the core driving force for the generation of secondary pollutants.
