Abstract. In this study, airborne measurements of the sum of hydroperoxyl (HO₂) and organic peroxy (RO₂) radicals that react with nitrogen monoxide (NO) to produce nitrogen dioxide, (NO₂), coupled with actinometry and other key trace gases measurements, have been used to test the current understanding of the fast photochemistry in the outflow of major population centres. The measurements were made during the airborne campaign of the EMeRGe (Effect of Megacities on the transport and transformation of pollutants on the Regional to Global scales) project in Europe on-board the High Altitude Long range research aircraft (HALO). The measurements of RO₂^{*} on HALO were made using the in-situ instrument Peroxy Radical Chemical Enhancement and Absorption Spectrometer (PeRCEAS). RO₂^{*} is to a good approximation the sum of peroxy radicals reacting with NO to produce NO₂. RO₂^{*} mixing ratios up to 120 pptv were observed in air masses of different origins and composition under different local actinometrical conditions during seven HALO research flights in July 2017 over Europe.

Radical production rates were estimated using knowledge of the photolysis frequencies and the RO₂^{*} precursor concentrations measured on-board, as well as the relevant rate coefficients. Generally, high RO₂^{*} concentrations were measured in air masses with high production rates. In the airmasses investigated RO₂^{*} is primarily produced by the reaction of O¹D with water vapour, and the photolysis of nitrous acid (HONO) and of the oxygenated volatile organic compounds (OVOC, e.g., formaldehyde (HCHO), and glyoxal (CHOCHO)). Due to their short lifetime in most environments, the RO₂^{*} concentrations are expected to be in a photostationary steady state (PSS), i.e., it is assumed a balance between production and loss rates. The RO₂^{*} production and loss rates and the suitability of PSS assumptions to estimate the RO₂^{*} mixing ratios and variability during the airborne observations are discussed. The PSS assumption for RO₂^{*} is considered robust enough to calculate RO₂^{*} mixing ratios for most conditions encountered in the air masses measured. The similarities and discrepancies between measured and PSS calculated RO₂^{*} mixing ratios are discussed. The dominant terminating processes for RO₂^{*} in the pollution plumes measured up to 2000 m are the formation of nitrous acid, nitric acid and organic nitrates. Above 2000 m, HO₂ – HO₂ and HO₂ – RO₂ reactions dominate the RO₂^{*} removal. RO₂^{*} calculations by the PSS analytical expression inside the pollution plumes probed often underestimated the measurements. The underestimation is attributed to the limitations of the PSS equation used for the analysis. In particular, this expression does not account for the yields of RO₂^{*} from the oxidation and photolysis of volatile organic compounds, VOCs, and OVOCs other than those measured during the EMeRGe research flights in Europe. In air masses with NO mixing ratios ≤ 50 pptv and low VOC/NO ratios, the overestimation of the RO₂^{*} measured observed may be caused by the formation of H₂O and O₂ from OH and HO₂, being about 4 times faster than the rate of the OH oxidation reaction of the dominant OVOCs considered.

40 1. Introduction

Hydroperoxyl (HO₂) and organic peroxy (RO₂, where R stands for any organic group) radicals are reactive species that play a key role in the chemistry of the troposphere. In combination with the hydroxyl (OH) radical, HO₂ and RO₂ take part in rapid chemical processes that control the lifetime of many key trace constituents in the troposphere. Examples of key tropospheric processes involving HO₂ and RO₂ are as follows:

- 45 • the catalytic cycles which produce and destroy ozone (O₃)
- the generation of inorganic acids, which are precursors of aerosol (e.g., sulphuric acid, H₂SO₄) and important chemical constituents (e.g., nitric acid, HNO₃) in both summer and winter smog
- the generation of organic acids; the production of hygroscopic hydrogen peroxide (H₂O₂) and organic peroxides (ROOH), which enter aerosol and cloud droplets
- 50 • the generation of organic peroxy nitrates (RO₂NO₂), peroxyacetyl nitrate (CH₃COO₂NO₂, PAN) and other summer smog constituents.

The abundance of HO₂ and RO₂ in the free troposphere has a non-linear and complex dependency on photochemistry, initiated by solar actinic radiation, and on the concentration of the precursors, such as carbon monoxide (CO), volatile organic compounds (VOCs), and peroxides. It also strongly depends on the amounts of nitrogen monoxide (NO) and nitrogen dioxide (NO₂) due to the gas-phase reactions of NO and NO₂ with the OH and organic oxy (RO) radicals formed during the radical interconversion. The main production and loss processes of HO₂ and RO₂ in the troposphere are summarised as follows:

a) Production processes of HO₂ and RO₂

70 (*) The CH₃ produced from the oxidation of CH₄ or the photolysis of VOCs further reacts with O₂ to form CH₃O₂. The net or overall reaction is used because the formation of CH₃O₂ is much faster than the CH₃ formation due to the high amount of O₂ present in the atmosphere.

(**) H and CHO formed through the VOC photolysis further react with O₂ to form HO₂. The net reaction is used, because the formation of HO₂ is much faster than the H and CHO formation due to the high amount of O₂ present in the atmosphere.

b) Loss processes of HO_2 and RO_2

In addition, HO_2 and RO_2 participate in radical interconversion reactions such as:

95 Reactions R23 and R25a are two of the most important reactions in the troposphere as they lead to O_3 formation via the reactions R27 and R28. The rate of the reaction R22 in the atmosphere compared to that of reaction R26 is negligible.

(**) H and CHO formed through the VOC photolysis further react with O_2 to form HO_2 . The net reaction is used, because the formation of HO_2 is much faster than the H and CHO formation due to the high amount of O_2 present in the atmosphere.

100 The sum of HO₂ and RO₂ that react with NO to produce NO₂ can be estimated by assuming that the interconversion of NO to NO₂ reaches a photostationary steady-state (PSS), in which production and loss of NO₂ are to a good approximation equal.

The PSS assumption for [NO₂] in the following mechanism (reactions R23 to R29) leads to Eq. 1

$$[\text{HO}_2 + \text{RO}_2]_{\text{PSS}} = \frac{k_{\text{NO}+\text{O}_3}}{k_{\text{NO}+(\text{HO}_2+\text{RO}_2)}} \left(\frac{j_{\text{NO}_2}[\text{NO}_2]}{k_{\text{NO}+\text{O}_3}[\text{NO}]} - [\text{O}_3] \right) \quad (\text{Eq.1})$$

110 where j_{NO_2} is the photolysis frequency of NO₂; $k_{\text{NO}+\text{O}_3}$ ($1.9 \times 10^{-14} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ at 298K and 1 atm.) is the rate coefficient of the reaction of NO with O₃ and $k_{\text{NO}+(\text{HO}_2+\text{RO}_2)}$ is usually estimated for the most abundant peroxy radicals HO₂ and CH₃O₂ by assuming a 1:1 HO₂ to CH₃O₂ ratio and averaging the $k_{\text{NO}+\text{HO}_2}$ ($8.2 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ at 298K and 1 atm.) and $k_{\text{NO}+\text{CH}_3\text{O}_2}$ ($7.7 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ at 298K and 1 atm.) rate coefficients for the reaction with NO. As noted by Parrish et al. (1986), the PSS assumption for NO₂ requires conditions with sufficient and stable solar irradiation, ensuring stable NO₂ photolysis rates (j_{NO_2}).

115 The radical calculation made on the assumption of the NO₂ steady state is very sensitive to the accuracy of the NO₂ to NO ratio and the O₃ measurements. The comparison of $[\text{HO}_2 + \text{RO}_2]_{\text{PSS}}$ calculated using Eq.1 with ground-based (e.g., Ridley et al., 1992; Cantrell et al., 1997; Carpenter et al., 1998; Volz-Thomas et al., 2003), and airborne measurements, has shown in the past different degrees of agreement. The underestimations and overestimations found in air masses with different chemical compositions are not well understood. For the case of airborne measurements, the NO₂ steady state calculation generally overestimates the measured peroxy radicals (Cantrell et al., 2003a, 2003b). The differences observed could not be attributed to systematic changes in NO, 120 altitude, water vapour and temperature, although these variables are often correlated. The NO to NO₂ ratio calculated from NO measured using in-situ technique and NO₂ measured using remote sensing (more detail about the measurement techniques is given in Table 1) used in this study is considered to have a sufficiently large error. So, the NO₂ steady state approach is not accurate enough to calculate $[\text{HO}_2+\text{RO}_2]$ for the measurements considered in this study.

125 Ground-based (Mihelcic et al., 2003; Kanaya et al., 2007, 2012; Elshorbany et al., 2012; Lu et al., 2012, 2013; Tan et al., 2017, 2018; Whalley et al., 2018, 2021; Lew et al., 2020) and airborne (Crawford et al., 1999; Tan et al., 2001; Cantrell et al., 2003b) measurements have also been compared with model simulations of HO₂ and RO₂. The discrepancies encountered depend upon the chemical composition of the air mass and the chemical mechanisms and constraints used in the model simulations. Recently, Tan et al., 2019 and Whalley et al., 2021 reported experimental radical budget calculations using PSS assumption for OH, HO₂ and RO₂ together with the published reaction rate coefficients of the reactions (R1 to R26), which control OH, HO₂ and RO₂ in the 130 lower troposphere, and the ground-based measurements of all relevant reactants and photolysis frequencies. In this study, a similar approach has been used, i.e., the sum of HO₂ and RO₂ is assumed to be in PSS, to calculate the amount of peroxy radicals in the air masses measured on-board of the **H**igh **A**ltitude **L**ong range (HALO) research aircraft over Europe during the first campaign of the EMeRGe (**E**ffect of **M**egacities on the transport and transformation of pollutants on the **R**egional to **G**lobal scales) project. The available on-board measurements of RO₂^{*} are defined as the total sum of OH, RO and peroxy radicals (i.e., $\text{RO}_2^* = \text{OH} + \sum \text{RO}$

135 + HO₂ + ∑RO₂, where RO₂ are the organic peroxy radicals producing NO₂ in their reaction with NO). As the amount of OH and RO is much smaller, RO₂^{*} to a good approximation is the sum of HO₂ and those RO₂ radicals that react with NO to produce NO₂. For the calculation, RO₂^{*} is assumed to be in PSS, and an analytical expression is developed with a manageable degree of complexity to estimate the concentration and mixing ratios of RO₂^{*}. The simultaneous on-board measurements of trace gases and photolysis frequencies are used to constrain the estimate of the RO₂^{*} concentration.

140 In contrast to other experimental deployments, the concentrations and/or mixing ratios of the majority of the key species involved in reactions R1 to R26 were continuously measured on-board HALO during the EMeRGe campaign. This enables the use of a large number of measurements to constrain the PSS calculation of RO₂^{*}. Consequently, this data set provides an excellent opportunity to gain deeper insight into the source and sink reactions of RO₂^{*} and the applicability of the PSS assumption for the different pollution regimes and related weather conditions in the free troposphere.

145 2. EMeRGe field campaign in Europe

The overarching objective of the EMeRGe project is to test and improve the current understanding of the photochemical and heterogeneous processing of pollution outflows from major population centres (MPCs) and their impact on the atmosphere. Two intensive observational periods (IOP) were carried out to investigate selected European and Asian MPC outflows. The European IOP took place from 10 to 28 July 2017 (<http://www.iup.uni-bremen.de/emerge/home/home.html>). An extensive set of in-situ and remote-sensing airborne measurements of trace gases and aerosol particles were made on-board the HALO aircraft (see www.halo-spp.de) along flight tracks in the lower layers of the troposphere from northwest Europe to the Mediterranean region.

155 During EMeRGe in Europe, HALO made a total of 53 flight hours distributed over seven flights to investigate the chemical composition of the outflows from the target MPCs: London, Paris, Benelux/ Ruhr metropolitan area, Po Valley, and urban agglomerations such as Rome, Madrid, and Barcelona. The flight tracks are shown in Fig. 1. All measurement flights started from the aircraft hangar at the DLR in Oberpfaffenhofen, southwest of Munich, Germany. To achieve the scientific goals, 60 % of the flights flew at altitudes below 3000 m. Vertical profiles of trace constituents were typically made by keeping the HALO altitude constant at different flight levels upwind and downwind of the target MPCs. The flights are named E-EU-FN, where E stands for EMeRGe, EU for Europe, and FN is the two-digit flight number. More details about the EMeRGe IOP in Europe and the set of instruments deployed on-board the HALO aircraft are described elsewhere (Andrés Hernández et al., 2022).

Figure 1: The research flight tracks made by HALO during the EMERGE-Europe campaign on 11, 13, 17, 20, 24, 26 and 28 July 2017 (E-EU-03 to E-EU-09, respectively, colour coded). MPC target areas are colour coded by shading, and the targeted locations/regions are marked with red stars, M: Madrid, B: Barcelona, P: Paris, L: London; BNL: BeNeLux; Ru: Ruhr area; PV: Po Valley, R: Rome. The location of the aircraft hangar at the DLR in Oberpfaffenhofen, Germany (OP) is indicated by a yellow star.

3. PerCEAS and other instruments on-board HALO during EMERGE

The RO_2^* measurements on-board the HALO research aircraft during EMERGE were made using the Peroxy Radical Chemical Enhancement and Absorption Spectrometer (PerCEAS). PerCEAS combines the Peroxy Radical Chemical Amplification (PerCA) and Cavity Ring-Down Spectroscopy (CRDS) techniques in a dual-channel instrument. Each channel has a separate chemical reactor and detector, which operate alternatively in both background and amplification modes to account for the rapid background variations during airborne measurements. In both modes NO is continuously added to the air sampled at the reactor, while CO is only added in the amplification mode to initiate the chain conversion of RO_2^* into NO_2 . In the amplification mode, the sum of the NO_2 produced from ambient RO_2^* through the chain reaction, the ambient NO_2 , the NO_2 produced from the ambient $\text{O}_3 - \text{NO}$ reagent gas reaction and the NO_2 produced in the inlet from any other sources (e.g., thermal decomposition of PAN) is measured. In the background mode, the sum of the ambient NO_2 , the NO_2 produced from the ambient $\text{O}_3 - \text{NO}$ reagent gas reaction and NO_2 produced in the inlet from any other sources is measured. The RO_2^* is retrieved by dividing the difference in NO_2 concentration (ΔNO_2) between amplification and background mode by the conversion efficiency of RO_2^* to NO_2 , which is referred to as eCL (effective chain length). The PerCEAS instrument and its specifications have been described in detail elsewhere (Horstjann et al., 2014, George et al., 2020).

The two chemical reactors for sampling the ambient air are part of the DUAL channel Airborne peroxy radical Chemical Amplifier (DUALER) inlet installed inside a pylon located on the outside of the HALO fuselage. During the EMERGE campaign in Europe, a reagent gas mixing ratio of 30 ppmv NO ($[\text{NO}] = 1.46 \times 10^{14}$ molecules cm^{-3} at 296 K, 200 mbar) and of 9 % CO ($[\text{CO}] = 4.4 \times 10^{17}$ molecules cm^{-3} at 296 K, 200 mbar) were added to the sample flow for the chemical conversion of RO_2^* to NO_2 . The DUALER inlet was operated at an internal pressure of 200 mbar to achieve stable chemical conversion. The HO_2 and RO_2 detection

185 sensitivity depends on the rates of loss of HO₂ and RO₂ by the reactions R19 and R22. The latter depend on the concentration of
the reagent gas NO added and the reactions rate coefficients, where k₂₂ is larger than k₁₉. The average eCL for a 1:1 HO₂ to CH₃O₂
mixture under the DUALER conditions during the campaign in Europe was determined to be 50 ± 8 from laboratory calibrations,
where the error is the ±1σ standard deviation estimated from the reproducibility of the experimental determinations. Likewise, the
ratio $\alpha = \text{eCL}_{\text{CH}_3\text{O}_2} / \text{eCL}_{\text{HO}_2}$ was determined to be 65% for the measurement conditions (George et al., 2020). The values obtained
190 from calibrations before and after the campaign agreed within their experimental errors.

Although the DUALER pressure is kept constant below the ambient pressure, variations in dynamical pressure > 10 mbar during
the flight change the residence time and induce turbulences inside the inlet (Kartal et al., 2010; George et al., 2020). These may
lead to different physical losses of radicals before amplification and affect the eCL. In the measurements presented in this study,
variations in dynamical pressure of this magnitude were only encountered during flight level changes of the aircraft. When used
195 during the analysis, these data sets are either excluded or flagged (P_flag). The effect of the ambient air humidity on eCL (Mihele
and Hastie, 1998; Mihele et al., 1999; Reichert et al., 2003) has been accounted for by a calibration procedure reported in George
et al. (2020). The [H₂O] in the DUALER inlet was lower than 1 × 10¹⁷ molecules cm⁻³ for 60 % of measurements during EMERGE
in Europe, for which the eCL_{wet} = 76 % of eCL_{dry}. At the highest humidity observed during the campaign, i.e., [H₂O]_{inlet} = 2 × 10¹⁷
molecules cm⁻³, the eCL_{wet} is 55 % of eCL_{dry} (see Fig. S1 in the supplementary information).

200 In addition to the measurement of RO₂* from PerCEAS, other in-situ and remote-sensing measurements and basic aircraft data
from HALO are used in this study. Details of the corresponding instruments are summarised in Table 1. The remote sensing
instruments used on HALO during EMERGE were the mini-Differential Optical Absorption (minDOAS) and the Heidelberg
Airborne Imaging DOAS Instrument (HAIDI). The miniDOAS observes the atmosphere using six telescopes: two being optimised
for the ultraviolet, two for the visible, and two for the near infrared. Three telescopes observe in nadir viewing and three in limb
205 viewing. The three limb scanning telescopes point to the starboard side perpendicular to the aircraft fuselage axis. They are rotated
to compensate for roll relative to the horizon. A variant of the DOAS retrieval technique uses least square fitting of the measured
and radiative transfer modelled absorption along the line of sight to retrieve the differential Slant Column Density (dSCD) of the
target gas and a scaling reference gas. The latter is the dimer of molecular oxygen (O₄). As the vertical profile of the concentrations
of O₂ and thus O₄ are known then the mixing ratios of the target gas at the flight altitude is obtained from the target gas and O₄
210 dSCDs (for more details see Stutz et al., 2017; Hüneke et al., 2017; Kluge et al., 2020; Rotermund et al., 2021). The HAIDI nadir
observations are used to retrieve dSCDs below the aircraft. The dSCDs from HAIDI are then converted to mixing ratios using
knowledge of the aircraft altitude and the corresponding geometric Air Mass Factor (AMF), calculated by a radiative transfer
model under a well-mixed NO₂ layer assumption. As a result of this assumption, the calculated mixing ratios for HAIDI target
gases are lower limits and similar to the actual values while flying within and close to a well-mixed boundary layer. In spite of the
215 differences in sampling volume and temporal and spatial resolution between the in-situ and remote sensing measurement
techniques, the concentration of the gas HCHO measured by both techniques were in good agreement and the concentrations of
the NO₂ (remote sensing) and NO_y (in situ) were consistent (for more details see Schumann, 2020).

4. Results and discussion

4.1. Airborne RO_2^* measurements during EMERGE in Europe

RO_2^* mixing ratios up to 120 pptv were measured during the campaign, as shown in Fig. 2. Typically, the highest RO_2^* mixing ratios were observed below 3000 m over Southern Europe.

230

Figure 2: RO_2^* measured during EMERGe-Europe: a) as a function of longitude and latitude, b) as a function of latitude and altitude.

235

The origin and thus the composition of the air sampled during the seven flights over Europe were different and heterogeneous. Typically, the air masses measured were influenced by emissions from MPCs and their surroundings, and sometimes by biomass burning transported over short or long distances. The concentration and mixing ratio of RO_2^* rather depends on the insolation and the chemical composition of the air probed, particularly on the abundance of RO_2^* precursors, than on the origin of the air masses. Since RO_2^* are controlled by fast chemical and photochemical processes, the air mass origin and trajectory are not used in the calculation of RO_2^* concentrations and mixing ratios but are of interest as the source of RO_2^* precursors. Thus, the RO_2^* variability and its production rates provide valuable insight into the photochemical activity of the air masses probed.

240

Changes in RO_2^* as a function of latitude and altitude, as shown in Fig. 2, confirm the heterogeneity of the photochemical activity in the air masses probed. Figure 3 shows the RO_2^* vertical profiles averaged for the EMERGe flights over Europe in 500 m altitude bins. The error bars are standard errors (i.e., $\pm 1\sigma$ standard deviation of each bin). The vertical profiles may be biased as the higher altitudes have fewer measurements than those below 3000 m, as mentioned in section 2. The vertical profiles are a composite from averaging flights with legs carried out at different longitude and latitudes, and are only shown to summarise the variability in the composition of the air masses measured during the campaign.

245

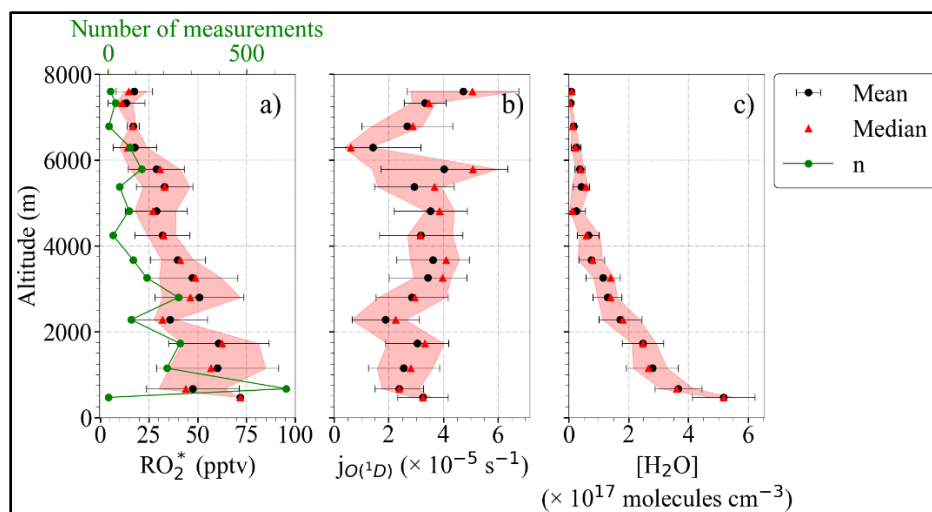

Figure 3: Composite average vertical profiles of a) RO_2^* , b) $j_{O(^1D)}$ and c) $[H_2O]$ observations. The measurements are binned over 500 m altitude. The error bars are the $\pm 1\sigma$ standard deviation of each bin. Median values (red triangles) the interquartile 25-75% range (red-shaded area) and the number of individual measurements, n , for each bin (in green) are additionally plotted.

250 Most of the EMeRGe measurements below 2000 m were carried out in the outflow of MPCs, which are expected to contain significant amounts of RO₂^{*} precursors. HALO flew at the lowest altitudes during flight legs over the English Channel, the Mediterranean and the North Sea. The H₂O concentration in the air masses decreases steadily with altitude as expected. The higher relative variability in H₂O observed at 3000 m and the increase at 5000 m is associated with measurements under stormy conditions, often over the Alps.

255 4.2. RO₂^{*} production rates

The rate of production of RO₂^{*} from the reactions R1 to R13 is given by:

$$P_{RO_2^*} = 2j_{O_D^1}[O_3] \frac{k_{O_D^1+H_2O}[H_2O]}{k_{O_D^1+H_2O}[H_2O]+k_{O_D^1+O_2}[O_2]+k_{O_D^1+N_2}[N_2]} + j_{HONO}[HONO] + 2j_{H_2O_2}[H_2O_2] + 2\sum_i j_i [OVOC_i] + \sum k_{O_3+alkenes_k}[O_3][alkenes_k]\gamma_k \quad (\text{Eq. 2})$$

where OVOC stands for oxygenated volatile organic compounds and γ is the effective RO₂^{*} yield from ozonolysis of alkenes.

260 In this study, Eq. 2 has been applied to the measurements taken within the EMeRGe campaign in Europe. There were no H₂O₂ measurements available for EMeRGe. However, the results reported by Tan et al. (2001), indicate that the rate of OH production from the H₂O₂ photolysis is not significant except when NO_x is low. To be more precise, for conditions having NO < 50 ppt, the partitioning of HO_x is strongly shifted to HO₂. HO₂ then predominantly reacts with itself or RO₂ to form peroxides, which can in turn photolyse. For conditions with NO > 50 pptv the rates of reactions of HO_x with NO_x are faster than those of HO₂ with HO₂ and RO₂. As the NO mixing ratio was higher than 50 pptv in 75 % of the air masses probed in Europe, the rate of the photolysis of H₂O₂ was as a first approximation assumed not to be significant source of OH for the EMeRGe dataset considered in this study.

270 Formaldehyde (HCHO), acetaldehyde (CH₃CHO), acetone, (CH₃C(O)CH₃), and glyoxal (CHOCHO) were the OVOCs measured in EMeRGe forming directly radicals through photolysis. They are produced in the photolysis and oxidation of VOCs and are likely the most abundant and reactive OVOCs present. In this study they were assumed to be the dominant VOCs in the air masses probed.

There were no measurements of alkenes provided in EMeRGe. Consequently, the ozonolysis term in Eq. 2 was not included in the analysis.

The above assumptions lead to Eq. 3, which calculates the RO₂^{*} production rate (P_{RO₂^{*}}) for the EMeRGe measurements as follows:

$$P_{RO_2^*} = 2j_{O(^1D)}[O_3] \frac{k_{O_D^1+H_2O}[H_2O]}{k_{O_D^1+H_2O}[H_2O]+k_{O_D^1+O_2}[O_2]+k_{O_D^1+N_2}[N_2]} + j_{HONO}[HONO] + 2j_{HCHO}[HCHO] + 2j_{CH_3CHO}[CH_3CHO] + 2j_{CH_3C(O)CH_3}[CH_3C(O)CH_3] + 2j_{CHOCHO}[CHOCHO] \quad (\text{Eq.3})$$

280 The production rate of RO₂^{*} molecules can be expressed in units of mixing ratio of RO₂^{*} by dividing with the air concentration at each altitude, calculated from the pressure and temperature measurements (for the vertical profile and the latitudinal distribution of P_{RO₂^{*}} see Fig. S2 and S3 in the supplementary information). Figure 4 shows the composite averaged vertical profile of all measured RO₂^{*} mixing ratios colour-coded with the calculated P_{RO₂^{*}}. For the sake of representativeness and comparability, the number of measurements in each altitude bin is shown in Fig. 4b. The higher RO₂^{*} mixing ratios observed below 4000 m are typically associated with P_{RO₂^{*}} ≥ 0.4 pptv s⁻¹. Above 4000 m both P_{RO₂^{*}} and RO₂^{*} start to decrease with altitude, as expected. This

is related to the decrease in H₂O and other radical precursor concentrations with altitude, as detailed in Fig. 5 and Fig. 6. In previous airborne campaigns at various parts of the world, RO₂^{*} vertical distributions showed a local maximum between 1500 and 4000 m, as reported by Tan et al. (2001), Cantrell et al. (2003a, 2003b), and Andrés-Hernández et al. (2009). In the present work, this local maximum is more evident for measurements with P_{RO₂^{*}} ≥ 0.5 pptv s⁻¹.

285

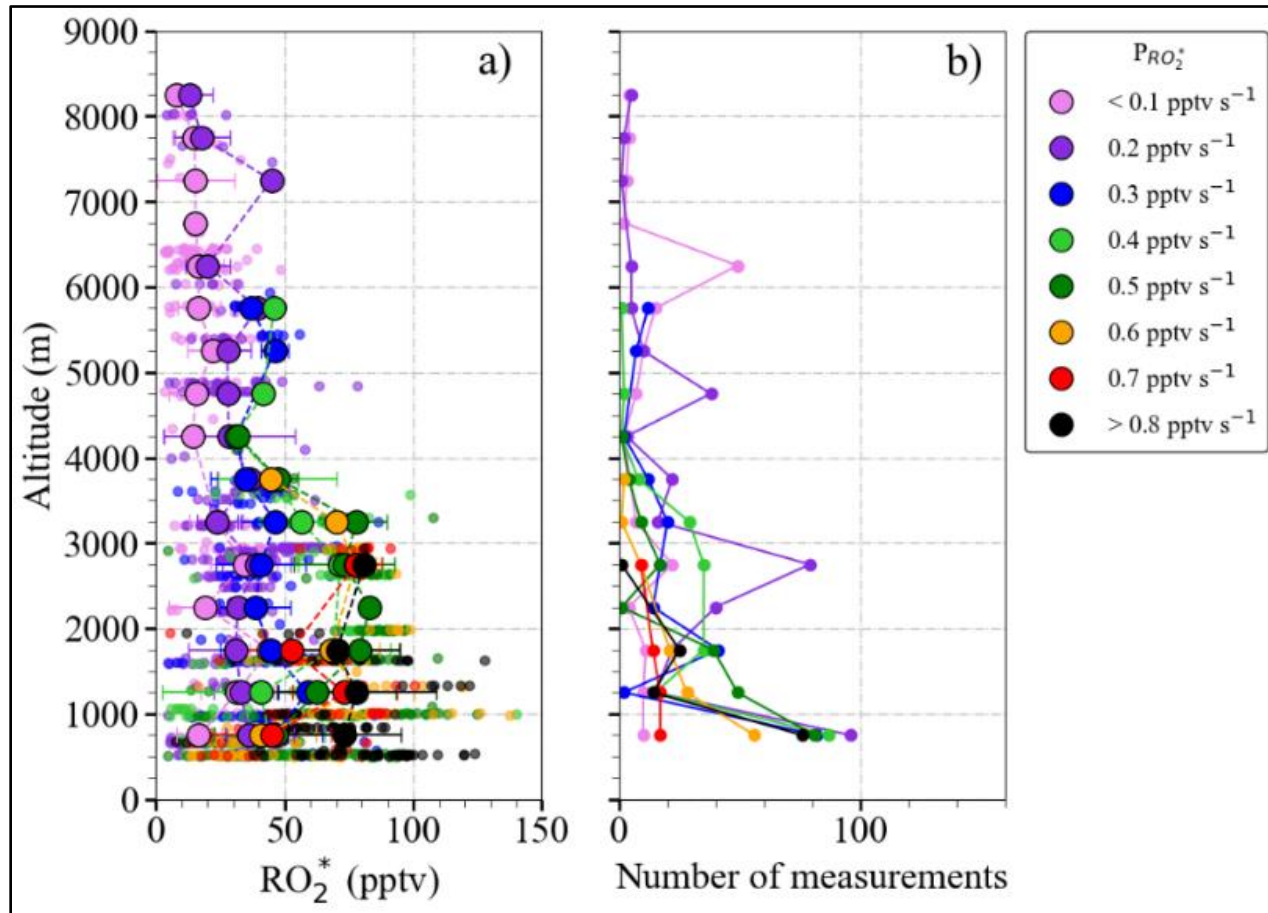

Figure 4: a) Composite averaged vertical distribution of measured RO₂^{*} colour-coded according to the value of P_{RO₂^{*}}, b) the number of measurements in each altitude bin. Small circles are 1-minute individual measurements binned with P_{RO₂^{*}} values in 0.1 pptv s⁻¹ intervals. Larger circles result from a further binning over 500 m altitude steps. All the production rates below 0.1 pptv s⁻¹ and above 0.8 pptv s⁻¹ are binned to 0.1 pptv s⁻¹ and 0.8 pptv s⁻¹, respectively. The error bars are the standard deviation for each altitude bin.

290

Figure 5 shows the fractional contribution of the production rate from each radical precursor reaction included in Eq. 3 as a function of altitude. The data are classified into three groups according to the rate of change of production of the RO₂^{*} mixing ratio P_{RO₂^{*}} < 0.07 pptv s⁻¹ (5a), 0.07 < P_{RO₂^{*}} < 0.8 pptv s⁻¹ (5b), and P_{RO₂^{*}} > 0.8 pptv s⁻¹ (5c) to show the lowest, most common, and highest ranges, respectively, encountered during the campaign. For 89 % of the measurements, 0.07 < P_{RO₂^{*}} < 0.8 pptv s⁻¹ applies, while the rest of the data are equally distributed in the other two P_{RO₂^{*}} ranges. The data in each group are always binned over 500 m when available.

295

Typically, the high amount of H₂O in the air masses probed leads to the reaction of O¹D with H₂O (reactions R1-R2a) being the highest RO₂^{*} radical production rate (≥ 50 %) below 4000 m. As the amount of H₂O reduces with altitude, the relative contribution from O₃ photolysis decreases. Above 4000 m, HCHO, HONO, and CHOCHO photolysis contributions range between 20 % to 40 %, 2.5 % to 30 %, and 5 % to 25 %, respectively. The HCHO contribution increases up to 80% during measurements above 6000 m. The contributions of CH₃CHO and CH₃C(O)CH₃ photolysis are, in contrast, practically negligible (< 5 %).

300

The vertical changes of the precursor mixing ratios and photolysis frequencies used to calculate $P_{RO_2^*}$ in Fig. 5 are shown in Fig. 6a to 6f. $P_{RO_2^*} < 0.07$ pptv s⁻¹ is associated with measurements under cloudy conditions, towards sunset where the photolysis frequencies are low, or at altitudes above 5000 m in air masses with a low amount of RO_2^* precursors. $P_{RO_2^*} > 0.8$ pptv s⁻¹ are found for air masses, measured below 2000 m in the outflow of MPCs over the sea, for conditions having sufficient insolation ($j_{O(^1D)} > 3 \times 10^{-5} S^{-1}$) and a high content of RO_2^* precursors (HCHO > 1000 pptv and HONO > 100 pptv). The increase in the photolysis frequencies as a function of altitude is concurrent with decreases in precursor concentrations. As a result, the $P_{RO_2^*}$ do not significantly vary with altitude in the air masses investigated.

In previous airborne campaigns, Tan et al. (2001) and Cantrell et al. (2003b) reported a reduction of the fractional contribution of the reaction of $O(^1D)$ with H_2O as the $P_{RO_2^*}$ value decreases. At very low $P_{RO_2^*}$ values (< 0.03 pptv s⁻¹), the sum of all other production terms exceeded the fraction from the $O(^1D) + H_2O$ term. For these conditions, H_2O_2 and VOCs photolysis dominated the $P_{RO_2^*}$. For the EMERGe data set in Europe, only 6 % of $P_{RO_2^*}$ are below 0.06 pptv s⁻¹.

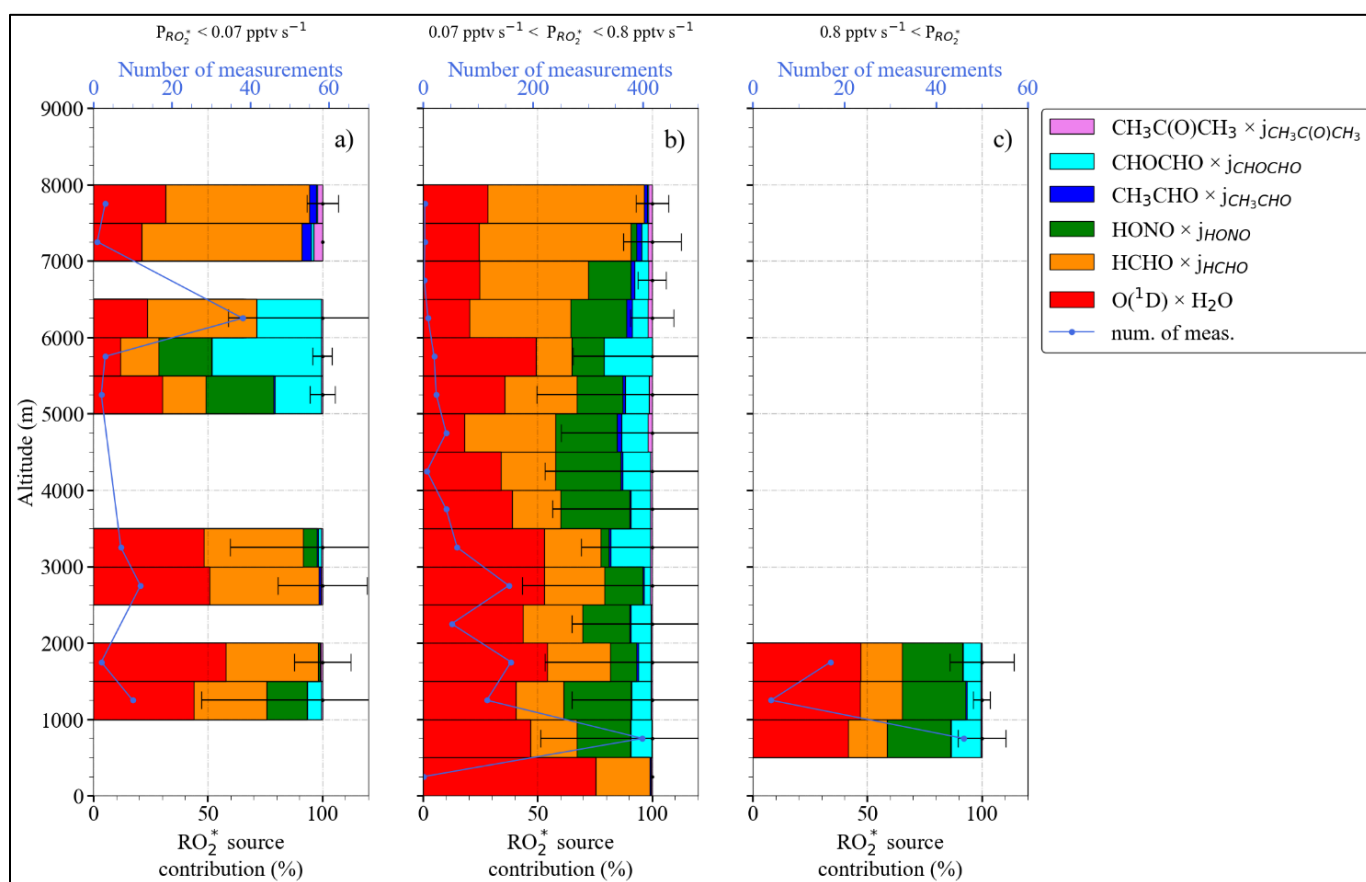

Figure 5: Total $P_{RO_2^*}$ and fractional precursor contributions estimated using Eq. 5 as a function of altitude, for: a) $P_{RO_2^*} < 0.07$ pptv s⁻¹, b) 0.07 pptv s⁻¹ < $P_{RO_2^*} < 0.8$ pptv s⁻¹, and c) $P_{RO_2^*} > 0.8$ pptv s⁻¹. Note the different scales in the number of measurements.

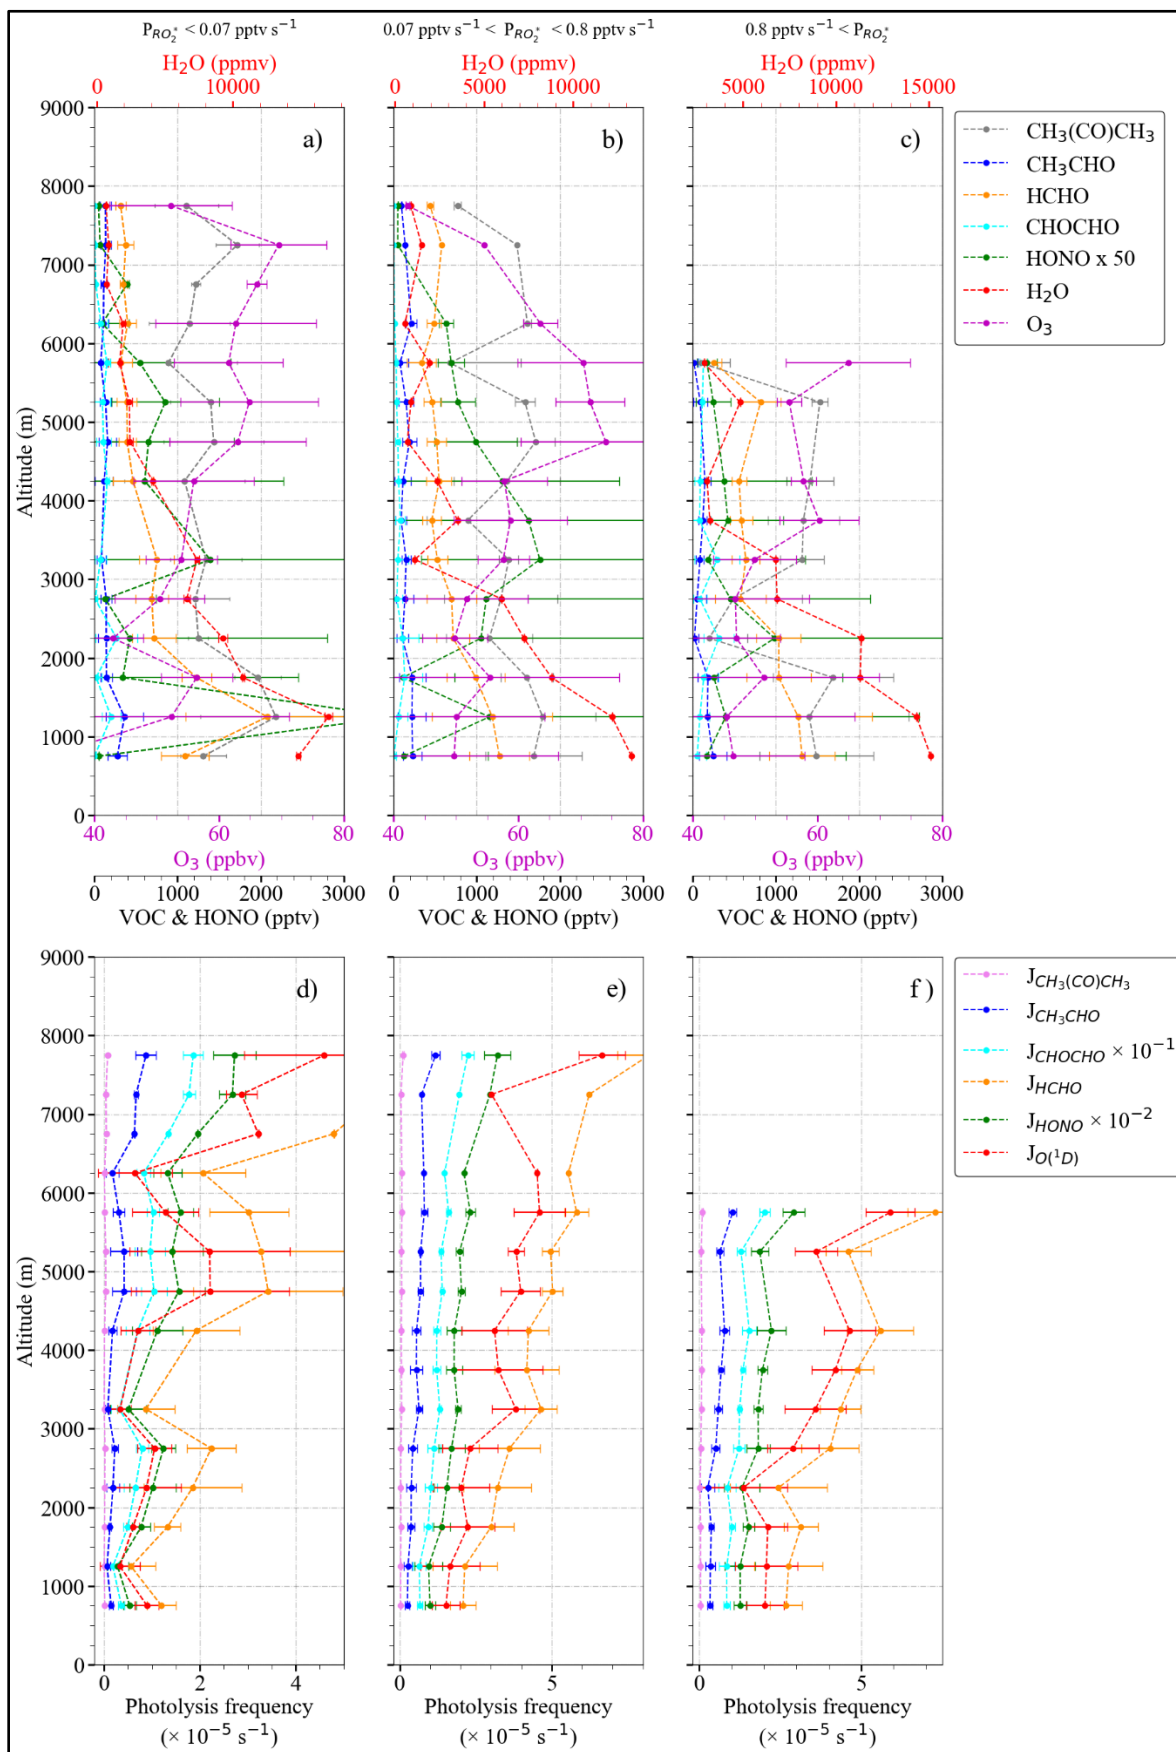

Figure 6: Vertical distribution and variation of a) to c) precursor mixing ratios; d) to f) photolysis frequencies for the P_{RO_2} bins as in Fig. 5. Note the different scales in the H_2O concentration

4.3. PSS estimation of the RO₂^{*} mixing ratios

Under most ambient conditions in the troposphere, the RO₂^{*} are short-lived, and the chemical lifetime of RO₂^{*} is much shorter than the chemical transport time into and out of an air mass being probed. Consequently, pseudo-steady-state conditions prevail, and the radical production and destruction rates are balanced:

325

$$P_{\text{RO}_2^*} = D_{\text{RO}_2^*} \quad (\text{Eq.4})$$

The reactions R5 to R7, R12, R16b, and R23 to R26 are interconversion reactions between OH, RO, HO₂ and RO₂ and do consequently occur without radical losses. Solving Eq. 4 leads to Eq. 5 if RO₂^{*} – RO₂^{*} reactions are assumed to be the dominant radical terminating processes.

330

$$2j_{\text{O}(\text{D})}[\text{O}_3] \frac{k_{\text{O}_\text{b} + \text{H}_2\text{O}} [\text{H}_2\text{O}]}{k_{\text{O}_\text{b} + \text{H}_2\text{O}} [\text{H}_2\text{O}] + k_{\text{O}_\text{b} + \text{O}_2} [\text{O}_2] + k_{\text{O}_\text{b} + \text{N}_2} [\text{N}_2]} + j_{\text{HONO}} [\text{HONO}] + 2j_{\text{HCHO}} [\text{HCHO}] + 2j_{\text{CH}_3\text{CHO}} [\text{CH}_3\text{CHO}] + 2j_{\text{CH}_3\text{C}(\text{O})\text{CH}_3} [\text{CH}_3\text{C}(\text{O})\text{CH}_3] + 2j_{\text{CHOCHO}} [\text{CHOCHO}] = k_{\text{RO}_2^* + \text{RO}_2^*} [\text{RO}_2^*]^2 \quad (\text{Eq. 5})$$

where j_{HCHO} , $j_{\text{CH}_3\text{CHO}}$, $j_{\text{CH}_3\text{C}(\text{O})\text{CH}_3}$, j_{CHOCHO} are respectively j_8 , j_9 , $j_{10a,b}$ and j_{11} , as in Table 1 in the supplementary information. and $k_{\text{RO}_2^* + \text{RO}_2^*}$ represents an effective RO₂^{*} self-reaction rate coefficient, comprising HO₂ – HO₂, HO₂ – RO₂ and RO₂ – RO₂ reaction rates.

335

Consequently, the RO₂^{*} concentrations are expected to correlate with the square root of the $P_{\text{RO}_2^*}$.

Figure 7 shows the relationship between the measured [RO₂^{*}] and the calculated $\sqrt[2]{P_{\text{RO}_2^*}}$. Generally, both [RO₂^{*}] and $\sqrt[2]{P_{\text{RO}_2^*}}$ increase with the photolysis frequency of O₃ ($j_{\text{O}(\text{D})}$). Measurements in which [RO₂^{*}] were less than 0.5×10^{12} molecules cm⁻³, $\sqrt[2]{P_{\text{RO}_2^*}}$ less than 1000 and with $j_{\text{O}(\text{D})} > 5 \times 10^{-5}$ were made above 6000 m, where the amount of RO₂^{*} precursors is low. The relatively weak correlation observed between [RO₂^{*}] and $\sqrt[2]{P_{\text{RO}_2^*}}$ indicates the necessity of other radical terminating processes and/or missing radical formation terms in the $P_{\text{RO}_2^*}$ calculation. Apart from this, the spread in the diagram confirms that the effective RO₂^{*} self-reaction rate $k_{\text{RO}_2^* + \text{RO}_2^*} [\text{RO}_2^*]^2$ varies widely in the air masses probed likely due to the effect of changes in HO₂ and ΣRO_2 concentrations in the individual loss reaction rate coefficients. Photochemical processing is expected to be enhanced over Southern Europe due to the prevailing conditions of high insolation and temperatures during the EMerGe flights, which might lead to the rapid production of RO₂^{*} from the photochemical oxidations of CO and VOCs. This is also reflected in the higher $P_{\text{RO}_2^*}$ and [RO₂^{*}] observed in Southern Europe as compared to those in Northern Europe (Fig. 7b).

345

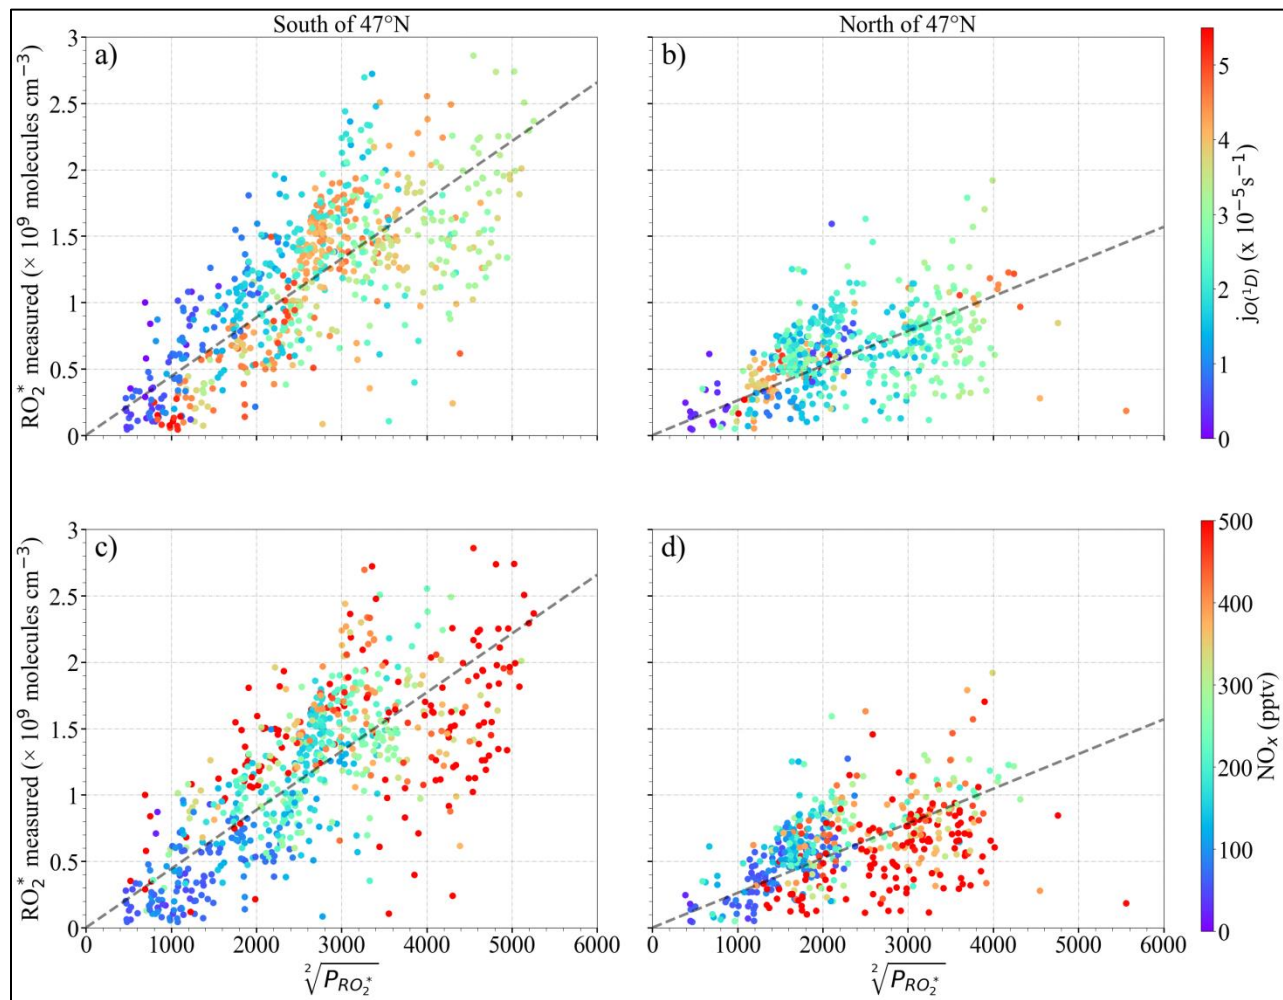

Figure 7: Measured $[\text{RO}_2^*]$ versus calculated $\sqrt{P_{\text{RO}_2^*}}$ colour-coded for values of a) $j_{\text{O}(^1\text{D})}$ and b) latitude.

350 The correlation between $[\text{RO}_2^*]$ and $\sqrt{P_{\text{RO}_2^*}}$ improves when the measurements south and north of 47°N are separately analysed (Fig. 8). For a given $[\text{RO}_2^*]$, the $P_{\text{RO}_2^*}$ calculated is higher for the measurements north of 47°N than south of 47°N . The lowest $[\text{RO}_2^*]$ to $\sqrt{P_{\text{RO}_2^*}}$ ratios are associated with higher NO_x ($\text{NO} + \text{NO}_2$), especially north of 47°N , indicating the urban character and higher amounts of the RO_2^* precursors of the air probed (Fig. 8d). Please note that these results are only valid for the data set acquired over Europe during EMeRGe flights and do not yield a relationship between $[\text{RO}_2^*]$ and $\sqrt{P_{\text{RO}_2^*}}$, which is generally applicable under all conditions for these two latitude windows.

355

Figure 8: Measured $[RO_2^*]$ vs $\sqrt{P_{RO_2^*}}$ for the following latitudes: a) and c) south of $47^\circ N$; b) and d) north of $47^\circ N$. Note that a) and b) are colour-coded with $j_{O(^1D)}$; c) and d) are colour-coded by NO_x mixing ratio. The dashed lines indicate the linear fit for visual support.

360

The relationship between RO_2^* and $P_{RO_2^*}$ is further investigated to identify the dominant RO_2^* loss process in the air masses considered in this study. As stated in section 3, HO_2 and RO_2 are not speciated but retrieved as RO_2^* by the PerCEAS instrument. Because not all peroxy radicals are detected equally by the instrument, the comparison of measured and calculated RO_2^* values is complicated. To investigate this the changes in the HO_2 to the total RO_2^* ratios have been taken into consideration by δ , i.e., $[HO_2] = \delta[RO_2^*]$ and $[CH_3O_2] = (1 - \delta)[RO_2^*]$, in the analysis. As a first approach, RO_2 is assumed to consist only of CH_3O_2 to reduce the complexity of the calculations by considering only CH_3O_2 reaction rate constants. The reaction channel R25b is not considered in the calculation since the yield of this channel is $< 5\%$ (Burkholder et al., 2020) for $CH_3O_2 + NO$ reaction. Moreover, in a previous study the ratio $\alpha = eCL_{CH_3O_2}/eCL_{HO_2}$ was determined to be 65% for the measurement conditions (George et al., 2020).

365

The Eq. 5 is additionally extended to include RO_2^* effective yields from VOC oxidation and radical losses through HONO, HNO_3 :

$$(2j_{11}[O_3]\beta + j_3[HONO])(1 - \rho) + 2j_8[HCHO] + 2j_9[CH_3CHO] + 2(j_{10a} + j_{10b})[CH_3C(O)CH_3] + 2j_{11}[CHOCHO] = \delta[RO_2^*](k_{23}[NO] + k_{24}[O_3])\rho + 2k_{15}\delta(1 - \delta)[RO_2^*]^2 + 2k_{16a}((1 - \delta)[RO_2^*])^2 + 2k_{14}(\delta[RO_2^*])^2 \quad (\text{Eq. 6})$$

370

where β is the effective yield of OH in the reaction of $O(^1D)$ with H_2O given by:

$$\beta = \left(\frac{k_{2a}[\text{H}_2\text{O}]}{k_{2a}[\text{H}_2\text{O}] + k_{2b}[\text{O}_2] + k_{2c}[\text{N}_2]} \right),$$

On the left-hand side of Eq. 6, $1-\rho$ accounts for the effective yield of HO_2+RO_2 through the radical initiation reactions R2a and R3 and reactions R5 to R7 and reaction R12. As the calculation is constrained with on-board measurements, only the reactions of measured VOCs were considered in reaction R12. Similarly, on the right-hand side of Eq. 6, ρ accounts for the radical termination through the OH + NO, OH + NO₂, and OH + HONO reactions (reactions R19 to R21) relative to the radical undergoing OH to peroxy radical conversion.

Consequently, ρ is given by:

$$\rho = \frac{(k_{19}[\text{NO}] + k_{20}[\text{NO}_2] + k_{21}[\text{HONO}])}{(k_5[\text{O}_3] + k_6[\text{CO}] + k_7[\text{CH}_4] + k_{12a}[\text{HCHO}] + k_{12b}[\text{CH}_3\text{CHO}] + k_{12c}[\text{CH}_3\text{C}(\text{O})\text{CH}_3] + k_{12d}[\text{CH}_3\text{OH}] + k_{12e}[\text{CHOCHO}] + k_{17}[\text{HO}_2] + k_{19}[\text{NO}] + k_{20}[\text{NO}_2] + k_{21}[\text{HONO}])}$$

Measurements of CH₄, HCHO, CH₃CHO, CHOCHO, CH₃OH, and CH₃C(O)CH₃ on-board HALO are available and implemented in Eq. 6. These comprise the most abundant and reactive OVOCs and are considered to be a representative surrogate for the VOCs that act as RO₂^{*} precursors through oxidation and photolysis. During the EMeRGe campaign in Europe, $k_{12a} \times \text{HCHO}$ and $k_{12b} \times \text{CH}_3\text{CHO}$ have the highest contribution to the $1 - \rho$ from all the OVOC measured. Their impact on the RO₂^{*} budget is found to be similar because their respective concentrations compensate the difference in the rate coefficients of their reactions with OH ($k_{12a} = 8.5 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and $k_{12b} = 1.5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 298K and 1 atm.). Despite its high mixing ratios measured, CH₃C(O)CH₃ is less important in the $1 - \rho$ term. This is because the rate coefficient $k(T)_{12c}$ is significantly slower than k_{12a} and k_{12b} (see Table S1 in the supplement). Similarly, the contribution of CHOCHO and CH₃OH is an order of magnitude lower than that of HCHO and CH₃CHO.

Concerning the term $\delta[\text{RO}_2^*](k_{23}[\text{NO}] + k_{24}[\text{O}_3])\rho$ on the right hand side of Eq.6, the HO₂ reaction with O₃ has a negligible effect as k_{24} is almost four orders of magnitude smaller than k_{23} and the NO concentrations remained about three orders of magnitude smaller than the O₃ measured during the campaign.

The impact of the methylglyoxal (CH₃C(O)C(O)H) photolysis was also investigated by using the CH₃C(O)C(O)H^{*} measurements provided by the miniDOAS instrument. The CH₃C(O)C(O)H^{*} measured is the sum of CH₃C(O)C(O)H, and a fraction of other substituted dicarbonyls (mainly 2,3-butanedione, C₃H₆O₂), with similar visible absorption spectra. For the calculation, CH₃C(O)C(O)H was assumed to be half of CH₃C(O)C(O)H^{*} as recommended by Zarzana et al. (2017) and Kluge et al. (2020). The RO₂^{*} calculated by including CH₃C(O)C(O)H photolysis systematically overestimated the measurements. As the adequacy of the recommended factor of 0.5 varies with the actual air mass composition, CH₃C(O)C(O)H was not included in the calculations.

Figure 9 shows the fractional contribution of the destruction rate ($D_{\text{RO}_2^*}$) calculated for a 1:1 mixture of HO₂ and CH₃O₂ using the reactions included in Eq. 6 as a function of altitude. The data are classified into three groups according to the rate of destruction of RO₂^{*} mixing ratio $D_{\text{RO}_2^*} < 0.01 \text{ pptv s}^{-1}$ (a), $0.01 < D_{\text{RO}_2^*} < 0.9 \text{ pptv s}^{-1}$ (b), and $D_{\text{RO}_2^*} > 0.9 \text{ pptv s}^{-1}$ (c) to show the lowest, most common, and highest ranges, respectively, encountered during the EMeRGe campaign. For 90 % of the measurements, $0.01 < D_{\text{RO}_2^*} < 0.9 \text{ pptv s}^{-1}$ applies, while the rest of the data are equally distributed in the other two $D_{\text{RO}_2^*}$ ranges. The data in each group are always binned over 500 m when available.

As can be seen in Fig. 9, the $\pm 1\sigma$ standard deviation of the obtained bins is very high. In spite of this, the HO₂ – CH₃O₂ and HO₂ – HO₂ reactions seem to dominate the radical destruction processes in the air masses probed. Their combined contribution is > 70

% in all the cases except in the 1000 m bin of $D_{RO_2^*} > 0.9$ pptv s^{-1} . Other significant radical losses occur through the HONO and HNO_3 formation. The contribution of the $CH_3O_2 + CH_3O_2$ reaction to the total RO_2^* destruction rate is $< 5\%$.

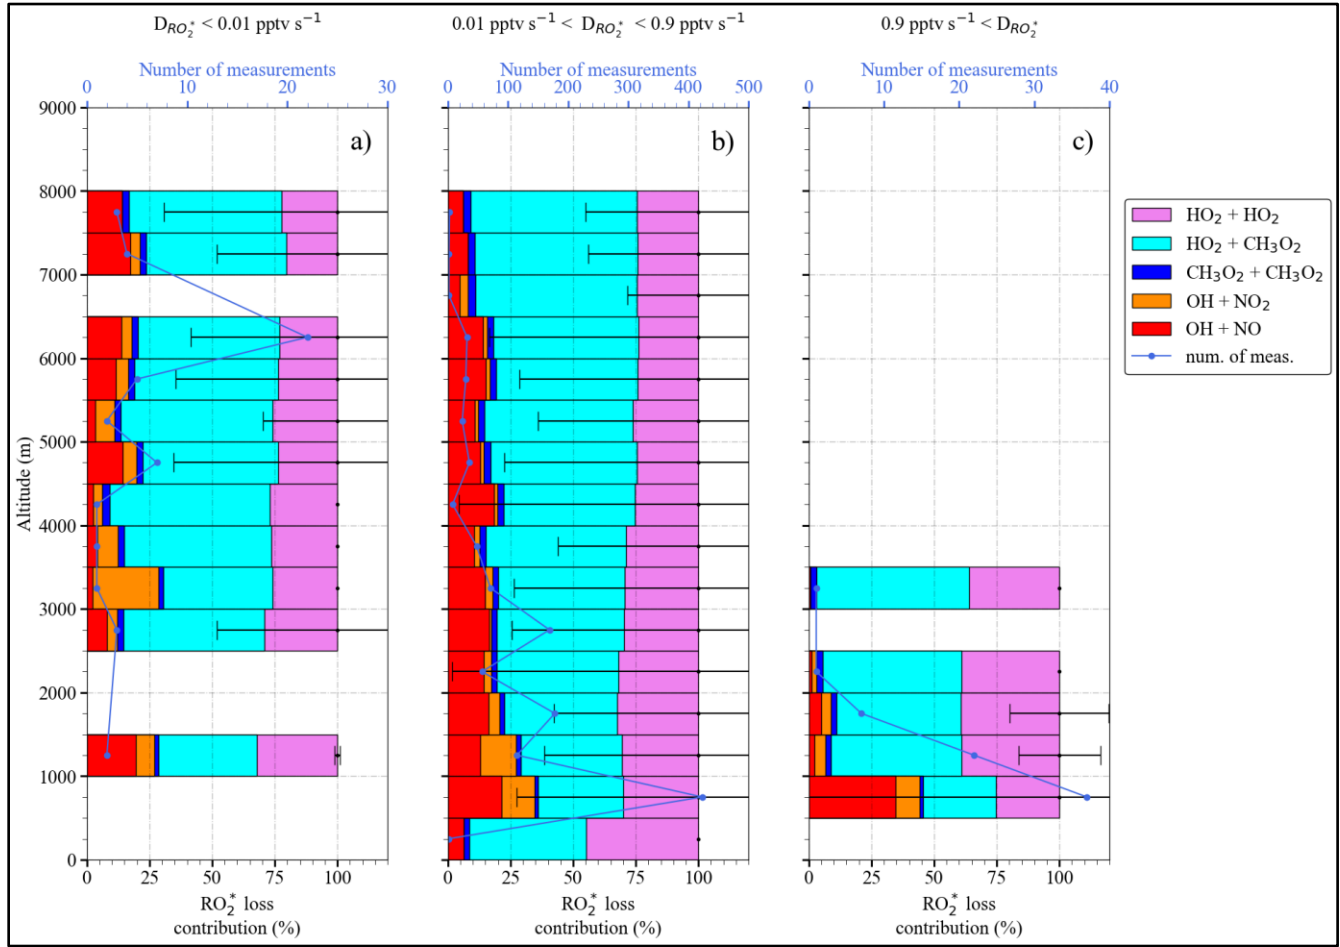

Figure 9: RO_2^* destruction rate $D_{RO_2^*}$ and fractional contributions from loss reactions in Eq.6 as a function of altitude, for: a) $D_{RO_2^*} < 0.01$ pptv s^{-1} , b) 0.01 pptv $s^{-1} < D_{RO_2^*} < 0.9$ pptv s^{-1} , and c) $D_{RO_2^*} > 0.9$ pptv s^{-1} . Note the different scales in the number of measurements.

Since Eq. 6, is quadratic in $[RO_2^*]$ it can be solved for $[RO_2^*]_c$ where c stands for calculated, as:

$$[RO_2^*]_c = \frac{-(-L_{RO_2^*}) - \sqrt{L_{RO_2^*}^2 - 4(-2k_{RO_2^*})P_{RO_2^*}}}{2(-2k_{RO_2^*})} \quad (\text{Eq. 7})$$

where

$$k_{RO_2^*} = (k_{16a}(1 - \delta)^2 + k_{15}\delta(1 - \delta) + k_{14}\delta^2)$$

$$L_{RO_2^*} = (\delta(k_{23}[NO] + k_{24}[O_3])\rho)$$

$$P_{RO_2^*g} = (2j_1[O_3]\beta + j_3[HONO])(1 - \rho) + 2j_8[HCHO] + 2j_9[CH_3CHO] + 2(j_{10a} + j_{10b})[CH_3C(O)CH_3] + 2j_{11}[CHOCHO]$$

where $k_{RO_2^*}$ is a weighed rate coefficient of RO_2^* self-reactions for a 1:1 mixture of HO_2 and CH_3O_2 , $L_{RO_2^*}$ comprises the formation of HONO and HNO_3 and $P_{RO_2^*g}$ is the gross production of RO_2^* .

The second solution of the quadratic equation gives negative values for $[RO_2^*]_c$, therefore is assumed to have no physical meaning. A more detailed derivation of Eq. 6 and Eq. 7 are given in the supplementary information.

Figure 10 shows the measured RO_2^* (hereinafter referred to as RO_2^{*m}) mixing ratio versus the calculated RO_2^*c mixing ratio using Eq. 7. RO_2^{*m} and RO_2^*c are the measured and calculated RO_2^* respectively for $\delta = 1$, i.e., $\text{RO}_2^* = \text{HO}_2$ and $\delta = 0.5$, i.e., $\text{HO}_2 = \text{RO}_2$. The eCL corresponding to $\delta = 1$ and $\delta = 0.5$ used for the RO_2^{*m} retrievals were determined in laboratory experiments, as reported by George et al. (2020). The small circles represent 1-minute RO_2^{*m} , whereas the large circles are the mean of the RO_2^{*m} binned over 10 pptv RO_2^*c intervals. The RO_2^* data are colour-coded with the on-board NO measurements. The linear regression slopes are around 0.7 ($R^2 = 0.96$), indicating an overall 25 – 30 % overestimation of the RO_2^{*m} . The y-axis intercept is below the instrumental detection limit for most measurement conditions. Table 2: Linear regression parameters from RO_2^{*m} versus RO_2^*c using Eq.7 from Fig.10.

Formula used to calculate RO_2^*	δ	slope	y-intercept (pptv)	R^2
Eq. 7	1.00	0.71	5	0.96
	0.50	0.74	6	0.97

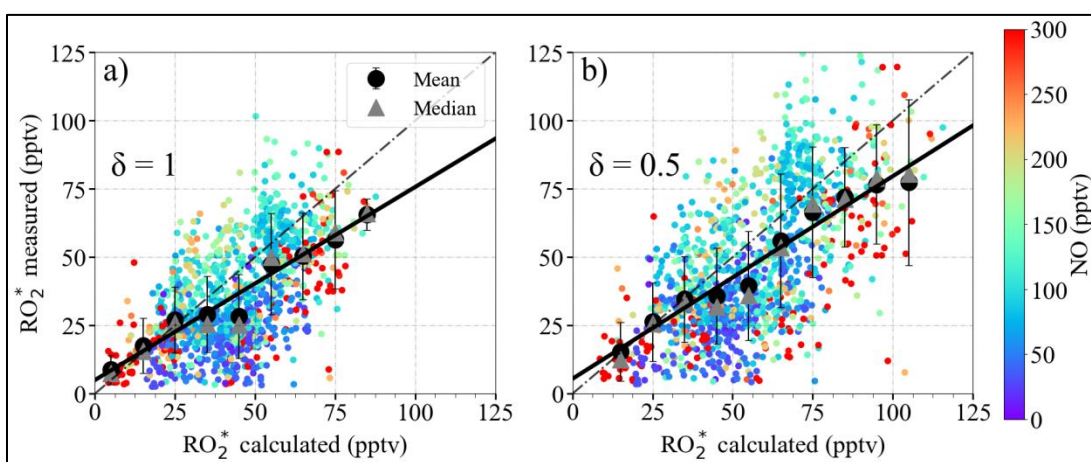

Figure 10: RO_2^{*m} versus RO_2^*c using Eq. 7 for a) $\delta = 1$ and b) $\delta = 0.5$. The data are colour-coded with the measured NO mixing ratios. The 1-minute (small circles), the mean of the binned RO_2^{*m} over 10 pptv RO_2^*c intervals (large circles), and the median of each bin (grey triangles) are shown. The error bars indicate $\pm 1\sigma$ standard deviation of each bin. The linear regression for the binned values (solid line) and the 1:1 relation (dashed line) are also depicted for reference.

Figure 11 shows the vertical profiles of RO_2^{*m} and RO_2^*c mixing ratios calculated for $\delta = 0.5$, averaged for the EMERGE flights over Europe in 500 m altitude bins. RO_2^*c seems to overestimate RO_2^{*m} for altitudes above 4000 m. As mentioned in Sect. 4.1, the vertical profiles are a composite from averaging flights with legs carried out at different longitude and latitudes. Therefore, the differences between RO_2^{*m} and RO_2^*c have been studied in more detail respect to the composition of the individual air masses (see the RO_2^{*m} and RO_2^*c mixing ratios as a function of latitude and altitude in Fig. S4 in the supplementary information).

440

Figure 11: Vertical distribution of the mean $RO_2^* m$ and mean $RO_2^* c$ using Eq. 7 for $\delta = 0.5$ for the EMerGe data set in Europe. The measurements are binned over 500 m altitude. The error bars are the $\pm 1\sigma$ standard deviation of each bin. Median values (red and green triangles) the interquartile 25-75% range (red and blue shaded areas) and the number of individual measurements, n , for each bin (in green) are additionally plotted.

445

Figure 12 shows the data for $\delta = 0.5$ colour-coded with NO , NO_x , the sum of $HCHO$, CH_3CHO , $CHOCHO$, CH_3OH , and $CH_3C(O)CH_3$ (from now on referred to as $\Sigma VOCs$), as a surrogate for the amount of OVOCs acting as RO_2^* precursors, and the $\Sigma VOCs$ to NO ratio. The largest differences between $RO_2^* m$ and $RO_2^* c$ are observed for the bins around 50 pptv. The $RO_2^* c$ overestimate the $RO_2^* m$ mostly for $RO_2^* m < 25$ pptv observed above ≈ 4000 m. These air masses are characterised by $NO < 50$ pptv, $\Sigma VOCs$ typically below 4 ppbv, high $\Sigma VOCs/NO$ ratios (> 50), and low insolation conditions, i.e., $j_{O(^1D)} < 2 \times 10^{-5} s^{-1}$ (see

450

Fig. S5 in the supplementary information). Under these insolation conditions, the radical production rate is expected to be low, and the $RO_2^* - RO_2^*$ reactions are expected to dominate the RO_2^* loss processes. As OH and H_2O_2 were not measured during the EMerGe campaign in Europe, Eq. 7 does not include the loss reactions R17 and R18, which might be significant under such conditions (Tan et al., 2001) and explain the overestimation of $RO_2^* m$. This is also the case for the overestimations observed below 40 pptv $RO_2^* m$ at other altitudes, where $NO < 50$ pptv but the $\Sigma VOCs/NO$ ratios remain low. The overestimation may therefore be

455

independent of the $\Sigma VOCs/NO$ ratios. For $NO \leq 50$ pptv, $NO_2 \leq 100$ pptv, $RO_2^* \leq 40$ pptv and $HCHO \leq 1$ ppbv, the rate of reaction R17, which forms H_2O and O_2 from OH and HO_2 , is about 4 times faster than the rate of the OH oxidation reaction of the dominant OVOCs (reaction R12) considered in this study or the rate of formation of $HONO$ (reaction R19).

RO₂^{*}_m is both underestimated and overestimated for ΣVOCs mixing ratios greater than 7 ppbv. The composition of these air masses is very different, as reflected by the ΣVOCs/NO ratios. This implies that Eq. 7 does not capture the peroxy radical yields adequately from the measured VOCs and OVOC in these cases. The differences between RO₂^{*}_m and RO₂^{*}_c may be explained in part by a) changes in OH yields due to additional VOC oxidation processes, which are not in Eq. 7 and/or b) RO₂^{*} production from the photolysis of carbonyls, which were not measured and/or c) RO₂^{*} production from the ozonolysis of alkenes or unidentified biogenic terpene emissions and/or d) overestimation of the loss processes.

In addition, Eq. 7 does not consider the loss of RO₂ through the organic nitrate formation (reaction R25b) which results in an underestimation of radical loss in the presence of RO₂ with higher organic group. Tan et al., 2019 reported changing the yields for organic nitrate formation channel in reaction R25 from 5% to 20% has a small but notable influence on their experimental budget analysis. Similarly, the RO₂ loss through organic nitrate formation which are not included in Eq. 7 might explain the RO₂^{*}_m overestimations for ΣVOC < 2ppb and ΣVOCs/NO < 20, and for NO > 200 pptv.

Figure 12: RO₂^{*}_m versus RO₂^{*}_c using Eq. 7 for δ = 0.5 colour-coded with the measured a) NO mixing ratio, b) NO_x mixing ratio, c) ΣVOCs mixing ratio, where ΣVOCs = HCHO + CH₃CHO + (CHO)₂ + CH₃OH + CH₃C(O)CH₃, and d) ΣVOCs/NO ratio. The 1-minute (small circles), the mean of the binned RO₂^{*}_m over 10 pptv RO₂^{*}_c intervals (large circles), and the median of each bin (triangles) are shown. The error bars represent the ± 1σ standard deviation of each bin. The linear regression for the binned values (solid line) and the 1:1 relationship (dashed line) are plotted for reference.

475 Although considered small, the spatial and temporal differences in the in-situ measurements of the key trace gases (O_3 , NO , H_2O , CO , CH_4 , VOCs) as compared to those of the remote sensing observations (NO_2 and HONO) used in Eq. 7 may also contribute to the overall spread observed in Fig. 12. Although the temporal evolution and the amount of the trace gases measured using in-situ and remote sensing instruments agree reasonably well, as shown for HCHO in Fig. 13, the remote sensing instruments have, in general, larger air sampling volumes compared to that of in-situ instruments. This may occasionally lead to significant differences
 480 depending on the location of the pollutant layers with respect to HALO. In addition, PTR-MS measurements of HCHO might include interferences from molecular fragments of other compounds in the sample air (Inomata et al., 2008). Further details about the accuracy and comparability of the instrumentation on-board during the campaign can be found elsewhere (Schumann, 2020).

485 Figure 13: An example of the time series of the measured HCHO mixing ratios retrieved from the remote sensing (HAIDI in blue and miniDOAS in green) and in-situ (HKMS in red) instruments during the E-EU-04 flight on 14.07.2017. The shaded region shows $\pm 1\sigma$ uncertainties of the HKMS and miniDOAS instruments. The flight altitude is depicted in black.

In summary, apart from the inaccuracies in the reaction rate coefficients, the differences between $RO_2^*_m$ and $RO_2^*_c$ might be caused by a combined effect of the limitations of the analytical expression to simulate complex non-linear chemistry and the measurement uncertainties arising from the spatial heterogeneity of the plume for the remote sensing instruments. Consequently, the
 490 quantification of limiting factors in Eq. 7 require the analysis of the pollution events encountered along the flights individually.

The ratio of $RO_2^*_m$ to $RO_2^*_c$ ($RO_2^*_m/RO_2^*_c$) has been used to assess the applicability of Eq. 7 for the calculation of RO_2^* in the air masses probed. In Fig. 14, the data are colour-coded with respect to $RO_2^*_m/RO_2^*_c$, H_2O , $\Sigma VOCs$, and NO_x . The air masses probed at altitudes above 2000 m are close to the PSS assumptions used to develop Eq. 7, and consequently, the $RO_2^*_m/RO_2^*_c$ remains \leq
 495 1. In contrast, $RO_2^*_m/RO_2^*_c$ is at its highest value below 2000 m, reaching up to 3. At these altitudes, most of the flights in Europe were carried out in pollution plumes, in which both the amount of NO_x and RO_2^* precursors are high. The analytical expression does not capture the RO_2^* variations resulting from fast non-linear photochemistry present in these pollution plumes. This is the case for the measurements made between $42^\circ N$ and $46^\circ N$ in the outflow of Po Valley and Rome. $\Sigma VOCs > 7$ ppbv and NO_x mixing ratios > 500 pptv indicate high radical precursor loading and relatively fresh emissions. The $RO_2^*_m/RO_2^*_c$ is also > 2 in the measurements over the English Channel (between $50^\circ N$ and $52^\circ N$) with $\Sigma VOCs$ and NO_x mixing ratio > 7 ppbv and 1000 pptv,
 500 respectively.

Figure 14: Plots of a) the ratio of $RO_2^* m$ to $RO_2^* c$ ($RO_2^* m/RO_2^* c$) assuming that $\delta = 0.5$; b) H_2O ; c) $\sum VOCs$; d) NO_x as a function of latitude and altitude for the EMeRGe measurements in Europe.

The applicability of Eq. 7 for calculating the in-flight measurements of RO_2^* along the track of the E-EU-03 flight on 11 July 2017 was studied in more detail. The E-EU-03 flight investigated the outflow of selected MPCs in Italy (i.e., Po Valley and Rome). Consequently, the flight track was routed along the western coast of Italy and included vertical profiling over the Tyrrhenian Sea upwind of Rome (see Fig. S6 in the supplementary information). As indicated by $j_{O(^1D)}$, in Fig. 15, cloudless conditions dominated throughout the flight track. The $RO_2^* c$ agree reasonably well with $RO_2^* m$ throughout this period except in the pollution plume measured from 12:05 to 12:25 UTC. In this plume, CO, NO, NO_2 , HONO, NO_y , and HCHO were 100 ppbv, 180 pptv, 150 pptv, 120 pptv, 1ppbv and 2 ppbv, respectively. The $RO_2^* m$ are approximately 20 % underestimated by $RO_2^* c$ during this period. Backward trajectories calculated using FLEXTRA indicate the transport of pollution through the Mediterranean mixed with dust plumes originating from Tunisia. The NO mixing ratios observed indicate the proximity to emission sources.

The measurements of VOCs used in Eq. 7 may not be representative of the actual complex VOC composition in the plume measured from 12:05 to 12:25 UTC. Consequently, the RO_2 to HO_2 ratio, the branching ratios and effective rate coefficients for $RO_2^* - RO_2^*$ reactions might not be well represented in Eq. 7. Taking CH_3O_2 as a surrogate for all RO_2 might lead to uncertainties

in the RO_2^* calculations in the presence of OVOCs with larger organic chains. On the experimental side, changes in the HO_2 to RO_2 ratio affect the accuracy of the PerCEAS retrieval of the total sum of radicals. As noted in section 3, in this study $RO_2^* = HO_2 + 0.65 \times RO_2$, and the eCL is determined for a 1:1 mixture of $HO_2:CH_3O_2$, i.e. $\delta = 0.5$ is used for the RO_2^* retrieval. However, the HO_2 to CH_3O_2 ratio is not expected to remain constant in all the air masses probed. For a 3:1 ratio of $HO_2:RO_2$, the $RO_2^*_m$ would decrease by 10 %. Similarly, a $HO_2:RO_2$ ratio of 1:3 would lead to an increase of 10 % in the reported $RO_2^*_m$. This uncertainty is well below the in-flight uncertainty of the PerCEAS instrument indicated by the error bars in Fig. 14 (George et al., 2020), and cannot account for the overall underestimation. However, it might reduce the differences observed between $RO_2^*_m$ and $RO_2^*_c$ in particular cases. A complete explanation of the variability of RO_2^* in the pollution plumes measured within the campaign in Europe is beyond the scope of this analysis and requires an investigation by high-resolution chemical models.

Figure 15: Temporal variation of $RO_2^*_m$ and $RO_2^*_c$, selected radical precursors and $j_{O(^1D)}$ along the E-EU-03 flight track: a) $RO_2^*_m$, $RO_2^*_c$ mixing ratios. The flight altitude is indicated in black. The P_flag indicates RO_2^* measurements affected by dynamical pressure variation in the inlet; b) O_3 , CO, HCHO mixing ratios, and $j_{O(^1D)}$; c) NO, NO_2 , NO_y , and HONO mixing ratios.

4.4. Comparison of results with other studies

4.4.1 RO₂^{*} production rate

Cantrell et al. (2003b) proposed that the production of RO₂^{*}, P_{RO₂^{*}}, is equal to the sum of two terms representing RO₂^{*} – RO₂^{*} reactions and the RO₂^{*} – NO_x reactions in the troposphere. As a result of this assumption, these authors describe the relationship between HO₂, RO₂, P_{RO₂^{*}} and NO_x as:

$$P_{RO_2^*} = k_{RR} [HO_2 + RO_2]^2 + k_{RN} [HO_2 + RO_2] [NO_x] \quad (\text{Eq. 9})$$

where k_{RR} and k_{RN} refer to effective rate coefficients for RO₂^{*} – RO₂^{*} and RO₂^{*} – NO_x reactions, and are calculated as fit parameters. Solving Eq. 9 for [HO₂ + RO₂]² leads to:

$$[HO_2 + RO_2] = \sqrt[2]{A + B^2} - B \quad (\text{Eq. 10})$$

where $A = \frac{P_{RO_2^*}}{k_{RR}}$ and $B = \frac{k_{RN}[NO_x]}{2 k_{RR}}$. For low NO_x and/or high P_{RO₂^{*}}, B becomes negligible compared to A. Then [HO₂ + RO₂] approaches $\sqrt[2]{A}$ and is independent of NO_x. For high NO_x and /or low P_{RO₂^{*}}, [HO₂ + RO₂] approaches zero.

The RO₂^{*}_m and RO₂^{*}_c for the EMERGe observations in Europe, binned in 0.1 pptv s⁻¹ P_{RO₂^{*}} intervals, were fitted according to the procedure of Cantrell et al. (2003b) and the results are shown in Fig. 16. The obtained fit parameters for Fig. 16a and Fig. 16b are k_{RR} = 7 × 10⁻⁵; k_{RN} = 9 × 10⁻⁶. The RO₂^{*} calculated by Eq. 7 appears to be close to the linear function of the NO_x measured. Similar to the results of the study of Cantrell et al. (2003b), a decrease of RO₂^{*} with NO_x is identified for NO_x > 1000 pptv. RO₂^{*}_c does not show the decrease with increase in NO_x for P_{RO₂^{*}} ≥ 0.7 pptv s⁻¹. This might be explained by the under estimation of radical losses through organic nitrate formation in Eq. 7 as explained in section 4.3.

Despite the low agreement of the fitted lines with the RO₂^{*}_m, a decrease of the RO₂^{*}_m as a function of NO_x is still observed. The disagreement between the RO₂^{*}_m and the curves estimated using Eq. 10 implies that the simplified Eq. 9 from Cantrell et al. (2003b), is insufficient to adequately describe the chemical and physical processes occurring in the air masses probed. Part of the disagreement might arise from missing terms in the P_{RO₂^{*}} calculated using Eq. 3 or inaccuracies related to the NO to NO₂ ratio in the air mass, which are more evident at higher P_{RO₂^{*}}. As expected, the ratio of calculated [RO₂^{*}_c] to $\sqrt[2]{P_{RO_2^*}}$ has a negative linear dependence on the measured [NO_x] (see Fig. 16c). The comparable relationship of $\frac{RO_{2m}^*}{\sqrt[2]{P_{RO_2^*}}}$ to [NO_x] is not linear for NO_x < 100 pptv approximately (see Fig. 16d). This indicates that the simplified approach of Cantrell et al. (2003b) is not applicable to the more complex non-linear processes involved in the air masses investigated within EMERGe.

Figure 16: a) $RO_2^*{}_c$ binned into $P_{RO_2^*}$ intervals of 0.1 pptv s^{-1} versus binned NO_x ; b) $RO_2^*{}_m$ binned into $P_{RO_2^*}$ intervals of 0.1 pptv s^{-1} versus binned NO_x ; c) ratio of $[RO_2^*]_c$ to $\sqrt{P_{RO_2^*}}$ versus NO_x ; and d) $[RO_2^*]_m$ to $\sqrt{P_{RO_2^*}}$ ratio versus NO_x . The data in the a) and b) panels are assigned different colours, as a function of the radical production rate interval. The NO_x observations are binned into 50 equidistant intervals on a logarithmic scale. The solid lines in panels a) and b) are the least square fits, obtained using Eq. 9. In panels c) and d) the ratio of $[RO_2^*]_c$ to $\sqrt{P_{RO_2^*}}$ and $[RO_2^*]_m$ to $\sqrt{P_{RO_2^*}}$ are binned into 50 NO_x intervals equidistant on the logarithmic scale from 10 to 10000 pptv. Error bars indicate the $\pm 1\sigma$ standard deviation for the distribution in each bin.

4.4.2 O_3 production rate

The O_3 production rate (P_{O_3}) is calculated from the EMERGE Europe dataset using the reaction of RO_2^* with NO in a similar manner to that used in previous studies of photochemical processes in urban environments (e.g. Kleinman et al., 1995; Volz-Thomas et al., 2003; Mihelcic et al., 2003; Cantrell et al., 2003b; and references herein).

$$P_{O_3} = k_{RO_2^*+NO}[RO_2^*][NO] \quad (\text{Eq. 11})$$

where $k_{RO_2^*+NO}$ is taken as the average of k_{HO_2+NO} and $k_{CH_3O_2+NO}$.

Figure 17 shows the mean P_{O_3} calculated using Eq. 11 from the $RO_2^*{}_m$ and $RO_2^*{}_c$ as a function of NO. The measurements are binned into 50 NO mixing ratio bins. The bin size increases with NO to keep the points equidistant on the logarithmic scale. The calculated P_{O_3} for the $RO_2^*{}_m$ and $RO_2^*{}_c$ agree well within the standard deviation of the bins.

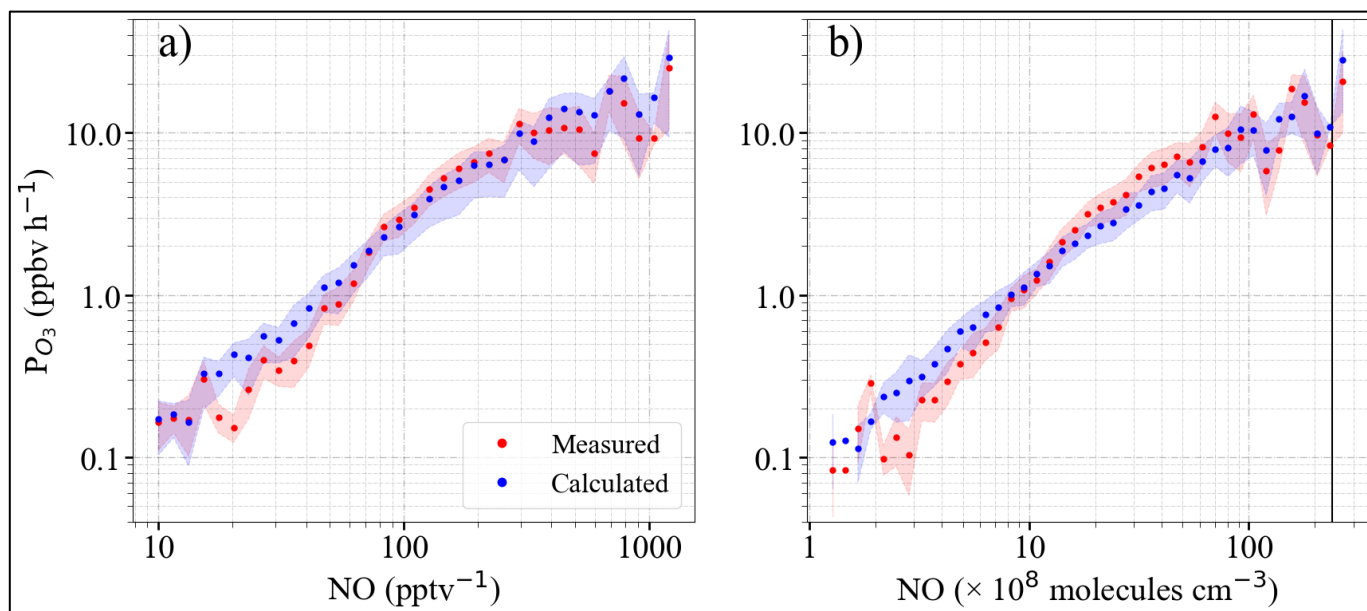

Figure 17: Calculated O_3 production rate (P_{O_3}) determined using $RO_2^*_m$ (red dots) and $RO_2^*_c$ (blue dots) as a function of: a) NO mixing ratio; b) NO number density. The 1-minute measurements are binned into 50 bins of NO equidistant on the logarithmic scale for panel a) from 10 to 10000 pptv and for panel b) from 5×10^7 to 3.5×10^{10} molecules cm^{-3} respectively. The shaded area shows the $\pm 1\sigma$ standard deviation of each bin. To facilitate comparison with ground-based measurements, the black line plotted in panel b) is the number density corresponding to 1 ppbv NO at 1000 mbar and 25°C.

Similar P_{O_3} values have been reported for ground-based measurements in polluted areas such as Wangdu (Tan et al., 2017) and Beijing (Whalley et al., 2021) and similar ranges of peroxy radicals and NO mixing ratios. In previous work, Whalley et al. (2018) calculated P_{O_3} to be about an order of magnitude lower than that found in this study from observations in central London for about an order of magnitude lower amount of $HO_2 + RO_2$. For $NO > 1$ ppbv, the P_{O_3} estimated from the measurement of HO_2 and RO_2 , or from the assumptions of an HO_2 to RO_2 ratio were underestimated by the models in other studies in the urban atmosphere (e.g. Martinez et al., 2003; Ren et al., 2003; Kanaya et al., 2008; Mao et al., 2010; Kanaya et al., 2012; Ren et al., 2013; Brune et al., 2016; Griffith et al., 2016). This behaviour is generally attributed to an underestimate of large RO_2 concentrations, which likely undergo multiple bimolecular reactions with NO before forming an HO_2 radical.

During the EMERGE campaign in Europe, the NO mixing ratios were < 1 ppbv (approximately $< 3 \times 10^{10}$ molecules cm^{-3}). The ozone production rates obtained for both $RO_2^*_m$ and $RO_2^*_c$ are in reasonable agreement with other modelling studies in urban environments where the mixing ratio of NO is < 1 ppbv (Tan et al., 2017; Whalley et al., 2021)

5. Summary and conclusions

This study exploits the airborne measurements of various atmospheric constituents on-board the HALO research aircraft over Europe in summer 2017 to investigate radical photochemistry in the probed airmasses. RO_2^* are calculated by assuming a photostationary steady-state (PSS) of RO_2^* and compared with the actual measurements. The calculation is constrained by the simultaneous airborne measurements of radical precursors, photolysis frequencies and reactants of RO_2^* such as NO_x and O_3 . The calculated radical production rates $P_{RO_2^*}$ do not significantly vary with altitude in the air masses investigated as the increase in the photolysis frequencies as a function of altitude is concurrent with decreases in precursor concentrations.

The significance and the importance of selected initiating and terminating processes in the RO_2^* chemistry are investigated by gradually increasing the complexity of the analytical expression. The agreement of the calculations with the measurements over a wide range of chemical composition and insolation conditions improves when the analytical expression is extended to account for effective radical yields from VOC oxidation and radical losses through nitrates and nitrites formation. The RO_2^* measured is usually overestimated when NO is < 50 pptv in the air probed. This behavior might be explained by RO_2^* loss processes involving reactions with OH (e.g., the reaction of HO_2 with OH, but possibly to a lesser extent the three-body reaction of OH with itself to make H_2O_2). These reactions may become significant RO_2^* loss processes at low NO concentrations as measured during the campaign but are excluded from the analytical expression, which is constrained by on-board measurements. Similarly, the RO_2 loss through organic nitrate are also excluded from the analytical expression. These reactions may become significant RO_2^* loss processes in the presence of RO_2 with higher organic groups. This might explain some of the RO_2^* overestimations by the analytical expression observed for $\text{NO} > 200$ pptv.

The RO_2^* calculated under assumption of a photostationary state mostly underestimated the RO_2^* measured in polluted plumes of urban origin at altitudes below 2000 m. Changes in the HO_2 to RO_2 ratios in different plumes can account for the disagreement in particular cases. In pollution plumes with the sum of the OVOCs measured mixing ratios being higher than 7 ppbv approximately, the underestimation of the measurements can reach up to 80 %. In these plumes, the oxidation and/or photolysis of VOCs, which were not measured, and the ozonolysis of alkenes might be significant sources of RO_2^* , limiting the accuracy of the analytical expression. More information about peroxy radical speciation and VOC partitioning is required to better describe the fast photochemistry in these pollution plumes.

However, the analytical expression developed is robust enough to simulate the radical chemistry in most of the conditions in the free troposphere encountered during EMERGe in Europe. Speciated radical and VOC measurements in future campaigns would facilitate the estimation of radical loss reactions in air masses having $\text{NO} < 50$ pptv and improve radical production rates estimations in pollution plumes having a high amount of VOCs, where non-linear complex chemistry is involved. Comparing RO_2^* measurements with RO_2^* calculations from the analytical expression helps to identify different chemical and physical regimes, which can be used to constrain future model studies.

The calculated O_3 production rates for $\text{NO} < 1$ ppbv are in the same order of magnitude as those previously reported for urban environments. This indicates that the selected RO_2^* production and loss processes and observations of the radical precursors on-board are, to a good approximation, adequate for the estimation of the O_3 production in the measured airmasses in the free troposphere over Europe.

Disclaimer. Financial support. The study was funded in part by the German Research Foundation (Deutsche Forschungsgemeinschaft; DFG) HALO-SPP 1294, the University and the State of Bremen, IPA, DLR, Oberpfaffenhofen, Germany. The contributions from BS, FK, and KP were supported via the DFG grants PF 384/16, PF 384/17 and PF 384/19. KB was granted funding via the DFG grant PI 193/21-1 and acknowledges additional financial from the Heidelberg Graduate School for Physics. EF was supported via the DFG grant NE 2150/1-1 and acknowledges additional financial support from the Karlsruhe Institute of Technology. MG, YL, MDAH and JPB acknowledge financial support from the University of Bremen.

Acknowledgements

Author contribution:

635 MG, VN, and YL undertook the RO₂* measurements, flying as key scientists on-board HALO. VN led the deployment of PeRCEAS
in the HALO aircraft. MG led the analysis of the PeCEAS measurements and prepared the manuscript with contributions from all
co-authors. MDAH and JPB initiated the EMeRGe research project and consortium, acted as co-principal and principal
investigators, and participated in the measurement campaigns. They developed the overarching EMeRGe scientific objectives and
the required measurement portfolio, directed the EMeRGe research campaigns, and participated in the data analysis presented. AZ,
640 BB, BS, EF, FO, FK, HS, HZ, KB, KP, and TH have contributed by providing their measurements made on-board HALO during
the campaign and participated in the discussion of results.

Competing interests:

The authors declare that they have no conflict of interest.
