14 **Abstract.** Emissions of ammonia (NH<sub>3</sub>) to the atmosphere impact human health, climate, and ecosystems through their  
15 critical contributions to secondary aerosol formation. Estimation of NH<sub>3</sub> emissions is associated with large uncertainties  
16 because of inadequate knowledge about agricultural sources. Here, we use satellite observations from the Infrared  
17 Atmospheric Sounding Interferometer (IASI) and simulations from the GEOS-Chem model to constrain global NH<sub>3</sub>  
18 emissions over the period of 2008-2018. We update the prior NH<sub>3</sub> emission fluxes with the ratio between biases in simulated  
19 NH<sub>3</sub> concentrations and effective NH<sub>3</sub> lifetimes against the loss of the NH<sub>x</sub> family. In contrast to about a factor of two  
20 discrepancies between top-down and bottom-up emissions found in previous studies, our method results in a global land NH<sub>3</sub>  
21 emission of 78 (70-92) Tg a<sup>-1</sup>, ~30 % higher than the bottom-up estimates. Regionally, we find that the bottom-up inventory  
22 underestimates NH<sub>3</sub> emissions over South America and tropical Africa by 60-70 %, indicating under-representation of  
23 agricultural sources in these regions. We find a good agreement within 10 % between bottom-up and top-down estimates  
24 over the U.S., Europe, and eastern China. Our results also show significant increases in NH<sub>3</sub> emissions over India (13 %  
25 decade<sup>-1</sup>), tropical Africa (33 % decade<sup>-1</sup>), and South America (18 % decade<sup>-1</sup>) during our study period, consistent with the  
26 intensifying agricultural activities in these regions in the past decade. We find that inclusion of sulfur dioxide (SO<sub>2</sub>) column  
27 observed by satellite is crucial for more accurate inference of NH<sub>3</sub> emission trends over important source regions such as  
28 India and China where SO<sub>2</sub> emissions have changed rapidly in recent years.

## 29 **1 Introduction**

30 Emissions of ammonia (NH<sub>3</sub>) to the atmosphere have critical implications for human health, climate, and ecosystems. As the  
31 main alkaline gas, NH<sub>3</sub> reacts with acidic products from precursors such as nitrogen oxides (NO<sub>x</sub>) and sulfur dioxide (SO<sub>2</sub>)  
32 to form fine particulate matter, which is a well-documented risk factor for human health, causing great welfare loss globally

33 ([Erisman 2021](#); [Gu et al., 2021](#)). Particulate matter also affects the Earth's radiative balance by directly scattering incoming  
34 radiation ([Ma et al., 2012](#)) and indirectly as cloud condensation nuclei ([Höpfner et al., 2019](#)). Additionally, both gas-phase  
35 ammonia ( $\text{NH}_3$ ) and aerosol-phase ammonium ( $\text{NH}_4^+$ ) can deposit onto the surface of land and water through dry and wet  
36 processes, and are associated with soil acidification ([Zhao et al., 2009](#)), ecosystem eutrophication ([Dirnböck et al., 2013](#)),  
37 biodiversity loss ([Stevens et al., 2010](#)), and cropland nitrogen uptake ([Liu et al., 2013](#)).

38  $\text{NH}_3$  is emitted from a variety of anthropogenic and natural sources, including agriculture, industry, fossil fuel combustion,  
39 biomass burning, natural soils, ocean, and wild animals ([Behera et al., 2013](#)). Among these, agricultural activities, mainly  
40 livestock manure management and mineral fertilizer application, are the most important  $\text{NH}_3$  sources, which account for  
41 ~70% of the total  $\text{NH}_3$  emissions globally ([Bouwman et al., 1997](#); [Sutton et al., 2013](#)).  $\text{NH}_3$  emissions can be estimated with  
42 a bottom-up approach based on information of emission activities and emission factors ([Hoesly et al., 2018](#); [Crippa et al.,](#)  
43 [2021](#)). However, bottom-up estimates of  $\text{NH}_3$  emissions are generally thought to be uncertain, relative to other pollutants that  
44 are mainly from fossil fuel combustion sources (e.g.,  $\text{NO}_x$ , CO). One of the challenges is that the intensity of agricultural  
45  $\text{NH}_3$  emissions, emission factors, either from livestock or fertilizer, depends strongly on management and farming practices,  
46 but this information is usually not widely available ([Zhang et al., 2017](#)). Furthermore, microbial activities that are  
47 responsible for agricultural  $\text{NH}_3$  emissions are highly variable and has a complex dependence on environmental conditions,  
48 which is often inadequately captured by bottom-up approaches ([Behera et al., 2013](#); [Vira et al., 2021](#)). In many cases,  
49 emission factors used in bottom-up modelling are based on local studies that are not representative for the diversity of  
50 conditions and are not dependent on meteorological parameters.

51 Top-down analyses of atmospheric observations (e.g.,  $\text{NH}_3$  concentrations or  $\text{NH}_4^+$  depositional fluxes) provide an alternative  
52 constraint on  $\text{NH}_3$  emissions. For example, observations of  $\text{NH}_3$  concentrations and  $\text{NH}_4^+$  deposition fluxes from surface  
53 networks can be used to infer regional  $\text{NH}_3$  emission fluxes (e.g., [Paulot et al., 2014](#)). However, surface sites are often  
54 sparse, especially in developing continents such as Africa and South America, limiting our capability to constrain  $\text{NH}_3$   
55 emissions globally. The advent of satellite observations makes it possible to investigate long-term spatially resolved  $\text{NH}_3$   
56 emissions from national, continental, to global scales. Van Damme et al. ([2018](#)) reported large  $\text{NH}_3$  point sources across the  
57 globe that are detected by the Infrared Atmospheric Sounding Interferometer (IASI) instrument but missing in the bottom-up  
58 inventories. Studies have also applied satellite data (e.g., IASI and Cross-track Infrared Sounder (CrIS)) to study  $\text{NH}_3$   
59 emissions from important source regions, including the U.S. ([Cao et al., 2020](#); [Chen et al., 2021b](#)), China ([Zhang et al.,](#)  
60 [2018](#)), and Europe ([Marais et al., 2021](#); [van der Graaf et al., 2021](#)). These regional studies show 20 % to 50 % differences  
61 between top-down and bottom-up estimates of  $\text{NH}_3$  emissions.

62 Compared to regional analyses, long-term global analyses of  $\text{NH}_3$  emissions based on satellite observations are relatively  
63 scarce (e.g., [Evangelou et al., 2021](#)). This is partly because of the computational challenges arising from a full-fledged  
64 inversion for a long period of time and over large spatial extents. In a recent study, Evangelou et al. ([2021](#)) proposed a fast  
65 top-down method, in which  $\text{NH}_3$  emissions are computed as the ratio between  $\text{NH}_3$  column observations and  $\text{NH}_3$  lifetime.  
66 This method relies on  $\text{NH}_3$  lifetime diagnosed from a chemical transport model (CTM) and assumes a local mass balance.

67 Their analysis found a global NH<sub>3</sub> emission of around 180 Tg a<sup>-1</sup>, which is roughly triple the widely used bottom-up  
68 estimates (e.g., 62 Tg a<sup>-1</sup> by the Community Emission Data System, CEDS). This large upward adjustment, if true, would  
69 have huge implications for global reactive nitrogen cycles and indicate that our current understanding of global NH<sub>3</sub>  
70 emissions is seriously flawed.

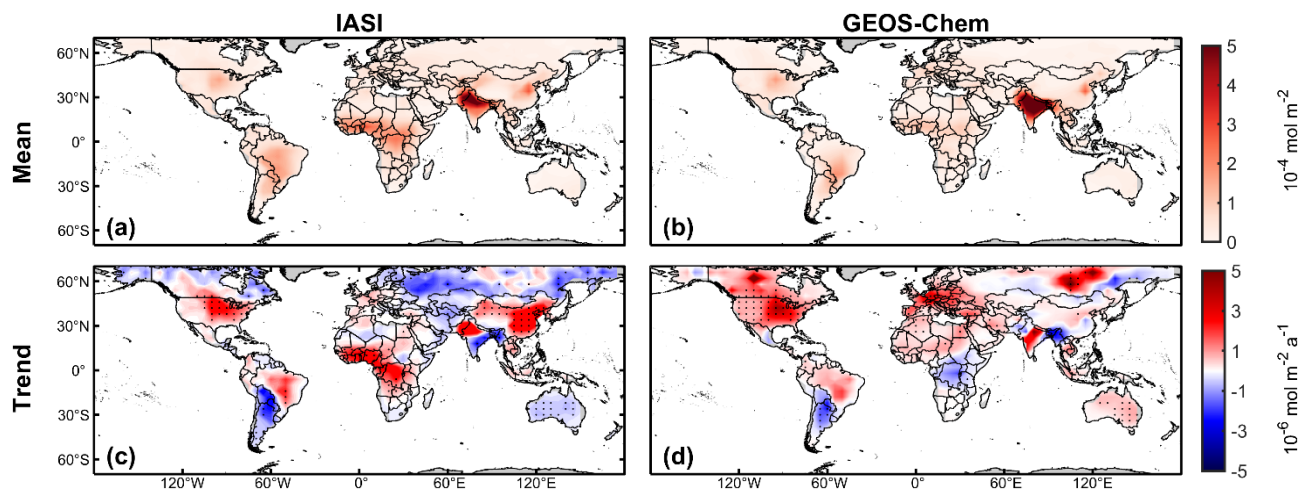

71 In this paper, we examine if the large discrepancy between the bottom-up and top-down estimates is due to the methodology.  
72 We refine the fast top-down approach by improving NH<sub>3</sub> lifetime diagnosis and partially accounting for the transport  
73 contributions. We develop a series of data filtering procedures to exclude results that are not sufficiently constrained by  
74 observations or affected by large deviations from the assumption of the fast top-down method. We apply the updated method  
75 to IASI observations to derive the global distribution of NH<sub>3</sub> emissions fluxes from 2008 to 2018, and examine the impact of  
76 the improved method on global NH<sub>3</sub> emission inferences.

## 77 **2 Methods**

### 78 **2.1 IASI observations**

79 We use 2008-2018 reanalyzed daily NH<sub>3</sub> total column retrievals (ANNI-NH<sub>3</sub>-v3R) from the IASI on board Metop-A. The  
80 IASI instrument measures the infrared radiation (645–2760 cm<sup>-1</sup>) from Earth's surface and the atmosphere with a circular 12  
81 km footprint at nadir (Clerbaux et al., 2009; Van Damme et al., 2017). The retrieval algorithm calculates the hyperspectral  
82 range index from IASI spectra measurements (Van Damme et al. 2014) and converts it to the NH<sub>3</sub> total column density via  
83 an artificial neural network (Whitburn et al., 2016; Franco et al., 2018). The retrieval uses consistent meteorological data  
84 from the ERA5 reanalysis, so it is suitable for the analyses of inter-annual variability and long-term trends (Hersbach et al.,  
85 2020). The ANNI-NH<sub>3</sub>-v3R product, has been validated against in situ measurements and is shown to have a good regional  
86 correlation (Guo et al., 2021; Van Damme et al., 2021). The dataset has been used in previous studies to estimate NH<sub>3</sub>  
87 emissions globally (e.g., Evangeliou et al., 2021) and regionally (e.g., Chen et al., 2021b; Marais et al., 2021).

88 Here we only use morning NH<sub>3</sub> data (around 9:30 local solar time) though IASI provides global coverage twice daily,  
89 because of the better precision of morning observations resulting from favourable thermal contrast conditions (Clarisse et al.  
90 2010). We filter out data with a cloud fraction greater than 10 % (Van Damme et al., 2018) and a skin temperature below  
91 263 K (Van Damme et al., 2014). The skin temperature dataset is from ERA5 (Hersbach et al., 2020). To compare with  
92 simulated NH<sub>3</sub> columns (see **Sect. 2.2**), we regrid and average monthly IASI NH<sub>3</sub> observations over land on the GEOS-  
93 Chem 4° × 5° grid (**Fig. 1a**). To reduce uncertainty from sparse sampling, we further exclude grid cells with the number of  
94 successful retrievals less than 800 in a month. We also test the choices of the threshold for 400 and 1200 per month in the  
95 sensitivity calculations (**Table 1**, line 5-6). This criterion affects mainly high latitudes during wintertime, where snow  
96 surfaces make it unfavourable for infrared measurements (**Fig. S1**).

97

98

99 **Figure 1.** Spatial distribution of (a, c) IASI and (b, d) GEOS-Chem NH<sub>3</sub> column concentrations. (a, b) Mean and (c, d) linear trends within  
 100 the 70°N-70°S during 2008-2018. Dots in (c) and (d) indicate that linear trends are significant at the 95 % confidence levels. Linear trends  
 101 are computed from the time series of annual averages.

## 102 2.2 GEOS-Chem simulations

103 We use the GEOS-Chem CTM v12.9.3 (10.5281/zenodo.3974569) to simulate global NH<sub>3</sub> concentrations. The GEOS-Chem  
 104 model, driven by the MERRA-2 reanalyzed meteorology (Gelaro et al., 2017), simulates the tropospheric ozone-NO<sub>x</sub>-  
 105 VOCs-aerosol chemistry at 4° × 5° resolution with 47 vertical layers (30 layers in the troposphere) (Bey et al., 2001; Park et  
 106 al., 2004). The thermodynamic equilibrium between gas phase NH<sub>3</sub> and aerosol phase NH<sub>4</sub><sup>+</sup> is explicitly simulated by the  
 107 ISORROPIA-II module in GEOS-Chem (Fountoukis & Nenes, 2007). The model also simulates the wet and dry deposition  
 108 of NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup>, the terminal sinks of atmospheric NH<sub>x</sub> (≡ NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>). Dry deposition is represented with a resistances-  
 109 in-series scheme (Wesely, 2007) and wet deposition includes scavenging in convective updrafts and in- and below-cloud  
 110 scavenging from large-scale precipitation (Wang et al., 2011; Amos et al., 2012). Anthropogenic emissions of simulated  
 111 chemicals including those of NH<sub>3</sub> are taken from a global emission inventory CEDS (Hoesly et al., 2018), overridden by  
 112 regional inventories in Canada (Air Pollutant Emission Inventory, APEI), the United States (2011 National Emissions  
 113 Inventory, NEI-2011), Asia (MIX-Asia v1.1) (Li et al., 2017), and Africa (DICE-Africa) (Eloise Marais and Christine  
 114 Wiedinmyer, 2016). Such compiled anthropogenic emissions only include incomplete information on inter-annual trends  
 115 because inventories are not all available throughout the whole period. Anthropogenic emissions are essentially invariant after  
 116 2013 in our setup (Fig. S2). The general lack of trends in SO<sub>2</sub> emissions in the simulation, if not accounted for, may cause  
 117 biases in inferred trends over regions such as India and China where SO<sub>2</sub> emissions have changed rapidly (Sun et al., 2018;  
 118 Qu et al., 2019; Chen et al., 2021a). Fire emissions are from Global Fire Emissions Database (GFED4) (van der Werf et al.,  
 119 2017), and biogenic VOC emissions are from the Model of Emissions of Gases and Aerosols from Nature (MEGAN)  
 120 (Guenther et al., 2012). Temporal (seasonal and inter-annual) variations in fire and biogenic emissions are resolved by the  
 121 inventories. Hereafter, we refer to NH<sub>3</sub> prior bottom-up emissions from this set of inventories as BUE1. For comparison, we

122 also use another set of bottom-up inventories which consist of EDGARv5.0 for anthropogenic emissions  
 123 (<https://data.jrc.ec.europa.eu/collection/edgar>, last access: 8 March 2022, [Crippa et al., 2020](#)), GFAS for fire emissions  
 124 (CAMS, <https://apps.ecmwf.int/datasets/data/cams-gfas/>, last access: 8 March 2022) (minor natural emissions are the same  
 125 as BUE1), which we denote as BUE2.

126 The GEOS-Chem simulation is conducted from 2008 to 2018 with an additional 1-month spin-up starting from December  
 127 2007. We sample the simulated  $\text{NH}_3$  and  $\text{NH}_4^+$  concentration fields between 9:00 to 10:00 local solar time, approximately the  
 128 IASI morning overpass time. To compare with the IASI  $\text{NH}_3$  columns, we integrate the vertical profiles of simulated  $\text{NH}_3$   
 129 concentrations by layer thickness. We note that the ANNI- $\text{NH}_3$ -v3R algorithm does not involve averaging kernels ([Whitburn](#)  
 130 [et al., 2016](#); [Van Damme et al., 2021](#)). [Van Damme et al. \(2018\)](#) reported the uncertainty in different vertical profiles of  
 131 individual  $\text{NH}_3$  measurements to be  $2\% \pm 24\%$  (global average). We also archive simulated depositional and transport rates  
 132 for  $\text{NH}_3$  and  $\text{NH}_4^+$ , which are used in emission fluxes estimation. In addition, we perform GEOS-Chem simulations in  
 133 selected years (2008, 2013, 2018) to examine the validation and consistency of our top-down  $\text{NH}_3$  emission estimates with  
 134 the ground-based measurements and IASI observations.

### 135 2.3 $\text{NH}_3$ emission fluxes estimation

136 We compute  $\text{NH}_3$  fluxes ( $\hat{E}_{\text{NH}_3}$ , in molecules  $\text{m}^{-2} \text{s}^{-1}$ ) in land grid cells for individual months from 2008 to 2018. We update  
 137 the prior model emission fluxes ( $E_{\text{NH}_3,\text{mod}}$ , in molecules  $\text{m}^{-2} \text{s}^{-1}$ ) with a correction term positively proportional to the  
 138 difference of observed ( $C_{\text{NH}_3,\text{obs}}$ , in molecules  $\text{m}^{-2}$ ) and simulated ( $C_{\text{NH}_3,\text{mod}}$ , in molecules  $\text{m}^{-2}$ ) monthly averaged  $\text{NH}_3$  total  
 139 column densities and inversely proportional to the lifetime of  $\text{NH}_3$  ( $\tau_{\text{NH}_3,\text{mod}}$ , in s):

$$140 \quad \hat{E}_{\text{NH}_3} = E_{\text{NH}_3,\text{mod}} + \frac{C_{\text{NH}_3,\text{obs}} - C_{\text{NH}_3,\text{mod}}}{\tau_{\text{NH}_3,\text{mod}}}, \quad (1)$$

141 where  $\tau_{\text{NH}_3,\text{mod}}$  is computed as the ratio of the simulated  $\text{NH}_3$  column and the sum of simulated loss rate of the  $\text{NH}_x$  family  
 142 ( $\text{NH}_x \equiv \text{NH}_3 + \text{NH}_4^+$ ) through the dry and wet depositions of  $\text{NH}_3$  ( $D_{\text{NH}_3,\text{mod}}$ , in molecules  $\text{m}^{-2} \text{s}^{-1}$ ) and  $\text{NH}_4^+$  ( $D_{\text{NH}_4^+,\text{mod}}$ , in  
 143 molecules  $\text{m}^{-2} \text{s}^{-1}$ ):

$$144 \quad \tau_{\text{NH}_3,\text{mod}} = \frac{C_{\text{NH}_3,\text{mod}}}{D_{\text{NH}_3,\text{mod}} + D_{\text{NH}_4^+,\text{mod}}}. \quad (2)$$

145 Here we calculate the lifetime of  $\text{NH}_3$  with the loss of the  $\text{NH}_x$  family rather than that of  $\text{NH}_3$ , because of the fast  
 146 thermodynamic equilibrium between gas-phase  $\text{NH}_3$  and aerosol/aqueous-phase  $\text{NH}_4^+$ , which implies that the conversion  
 147 from  $\text{NH}_3$  to  $\text{NH}_4^+$  is not a terminal loss for  $\text{NH}_3$  from the atmosphere. The  $\text{NH}_3$  lifetime may be underestimated over source  
 148 regions and overestimated over remote regions, if  $\text{NH}_3$  to  $\text{NH}_4^+$  conversions are treated as a terminal loss as in [Evangelou et](#)  
 149 [al. \(2021\)](#) rather than a partition within a chemical family ( $\text{NH}_x$ ) as in **Eq. (2)**.

150 In addition, our method linearizes the column-emission relationship at prior emissions as opposed to zero emissions in the  
 151 previous method (e.g., [Evangelou et al., 2021](#)). Here, the baseline  $\text{NH}_3$  column ( $C_{\text{NH}_3,\text{mod}}$ ) simulated by the GEOS-Chem

152 model explicitly accounts for the non-local contribution of transport, while the correction to prior emissions is done only  
 153 locally, that is, the difference between  $C_{\text{NH}_3,\text{obs}}$  and  $C_{\text{NH}_3,\text{mod}}$  is attributed only to errors in local emissions without  
 154 accounting for the sensitivity to emissions from other grid cells. This hybrid approach can partially include the non-local  
 155 contribution from transport but still keeps the computation tractable for a long-term study such as this study, striking a trade-  
 156 off between the computational efficiency of a local mass balance method (e.g., [Van Damme et al., 2018](#); [Evangelidou et al.,](#)  
 157 [2021](#)) and the accuracy of a full-fledged inversion, such as the 4D-Var method (e.g., [Cao et al., 2020](#); [Chen et al., 2021b](#)).  
 158 The errors arising from local correction of  $\text{NH}_3$  emissions are expected to be small in most cases, because the  $\text{NH}_3$  lifetime is  
 159 short relative to a typical transport time across a  $4^\circ \times 5^\circ$  grid cell on which emissions are estimated. To identify cases when  
 160 this error is not negligible, we apply a monthly  $\text{NH}_x$  budget analysis based on the GEOS-Chem simulation and exclude grid  
 161 cells from our analysis where transport dominates over local prior emissions or depositions in the monthly  $\text{NH}_x$  budget  
 162 (Transport/Emission>1 or Transport/Deposition>1) (**Fig. S3**).

163 Because rapid changes in  $\text{SO}_2$  emissions in eastern China and India, particularly after 2012, are not captured by our prior  
 164 simulation (**Fig. S2**), the estimation of  $\text{NH}_3$  emission trends using **Eq. (1)** may be biased over these regions. To address this  
 165 issue, we further modify **Eq. (1)** to include observed trends in  $\text{SO}_2$  column concentrations:

$$166 \quad \hat{E}_{\text{NH}_3,\text{SO}_2\text{-correct}} = E_{\text{NH}_3,\text{mod}} + \frac{C_{\text{NH}_3,\text{obs}} - C_{\text{NH}_3,\text{mod}} + 2\omega C_{\text{SO}_4^{2-},\text{mod}}}{\tau_{\text{NH}_3,\text{mod}}}, \quad (3)$$

167 where  $\omega$  (%) is the fractional changes of average  $\text{SO}_2$  columns relative to the baseline year (i.e., 2012) over China or India  
 168 and  $C_{\text{SO}_4^{2-},\text{mod}}$  (molecules  $\text{m}^{-2} \text{s}^{-1}$ ) is the simulated column densities of aerosol sulfate. Here, we specify a linear trend of -5 %  
 169  $\text{a}^{-1}$  for eastern China and 5 %  $\text{a}^{-1}$  for India between 2012 and 2018, based on values derived from the ozone monitoring  
 170 instrument (OMI) and Ozone Mapping and Profiler Suite (OMPS) observations ([Wang and Wang, 2020](#); [Liu et al., 2018](#)).  
 171 We also test the impact of the uncertainty in  $\omega$  on trend inferences over China and India. The factor 2 accounts for the fact  
 172 that two molecules of  $\text{NH}_3$  are required to neutralize one molecule of  $\text{H}_2\text{SO}_4$ . **Eq. (3)** only applies when  $\text{NH}_3$  is in excess, a  
 173 condition usually met in eastern China and India but not necessarily elsewhere ([Lachatre et al., 2019](#); [Acharja et al., 2022](#)).  
 174 Therefore, we only apply **Eq. (3)** to eastern China and India to understand the impact of changing  $\text{SO}_2$  emissions on the  
 175 inference of  $\text{NH}_3$  emission trends. To use  $\text{SO}_2$  observations systematically in  $\text{NH}_3$  emission estimations requires further  
 176 investigations.

## 177 **2.4 Uncertainty and sensitivity analysis**

178 We perform a series of perturbation and sensitivity experiments to assess the uncertainty of our estimates (**Table 1**. We  
 179 perturb  $C_{\text{NH}_3,\text{mod}}$  and  $\tau_{\text{NH}_3,\text{mod}}$  in **Eq. (1)**. The perturbations to  $\tau_{\text{NH}_3,\text{mod}}$  are set to be 50 % and 200 % (**Table 1**, Line 1-2).  
 180 The perturbation to  $C_{\text{NH}_3,\text{mod}}$  is set to be the standard deviation of monthly mean column concentrations ( $\sigma_{C,\text{obs}}$ ) (**Table 1**,  
 181 Line 3-4), which is given by:

182

$$\sigma_{C,obs} = \sqrt{\frac{\sum_{i=1}^{i=n} (\sigma_i \times \Omega_i)^2}{n-1}}, \quad (4)$$

183 where  $\Omega_i$  (in mol m<sup>-2</sup>) is the  $i^{\text{th}}$  NH<sub>3</sub> column measurement out of a total number of  $n$  observations in a grid cell during a  
 184 month and  $\sigma_i$  is the relative error. We then use  $\Omega \pm \sigma_{C,obs}$  to evaluate the effect of measurement errors in emission estimates  
 185 (**Table 1**, Line 3-4). We compute results with alternative data filtering parameters (**Table 1**, Line 5-8), including the  
 186 thresholds to exclude grid cells when the number of observations is too small (**Table 1**, line 5-6) and the local mass balance  
 187 assumption is potentially invalid (**Table 1**, Line 7-8). We also test if our trend inferences over China and India using Eq. (3)  
 188 is sensitive to uncertainty in observed trends in SO<sub>2</sub> concentrations ( $\omega$ ).

189 **Table 1.** Uncertainty and sensitivity analyses of top-down NH<sub>3</sub> emissions. Annual averaged NH<sub>3</sub> emissions are summed over global land  
 190 areas for 2008–2018.

	Parameter perturbed	Average emission (Tg a <sup>-1</sup> )
0	None <sup>a</sup> (TDE)	78
1	Halved NH <sub>3</sub> lifetime <sup>b</sup>	92
2	Doubled NH <sub>3</sub> lifetime <sup>c</sup>	70
3	Upper IASI column error	83
4	Lower IASI column error	72
5	Number of retrievals > 400 <sup>d</sup>	81
6	Number of retrievals > 1200 <sup>e</sup>	74
7	Transport/Emission < 0.2 <sup>f</sup>	72
8	Transport/Emission < 5 <sup>g</sup>	84

191 <sup>a</sup>Excluding a grid cell if retrieval number is less than 800 during a month, or transport dominates over emissions or  
 192 depositions in the simulated monthly NH<sub>3</sub> budget.

193 <sup>b-c</sup>The lifetime is 50 % and 200 % of values from Eq. (1), respectively.

194 <sup>d-e</sup>Monthly retrieval number threshold for including a grid cell is set to be 400 and 1200, respectively.

195 <sup>f-g</sup>Local budget ratio the threshold for including a grid cell is set to be 0.2 and 5, respectively.

## 196 3 Results and discussion

### 197 3.1 Observed and simulated NH<sub>3</sub> concentrations

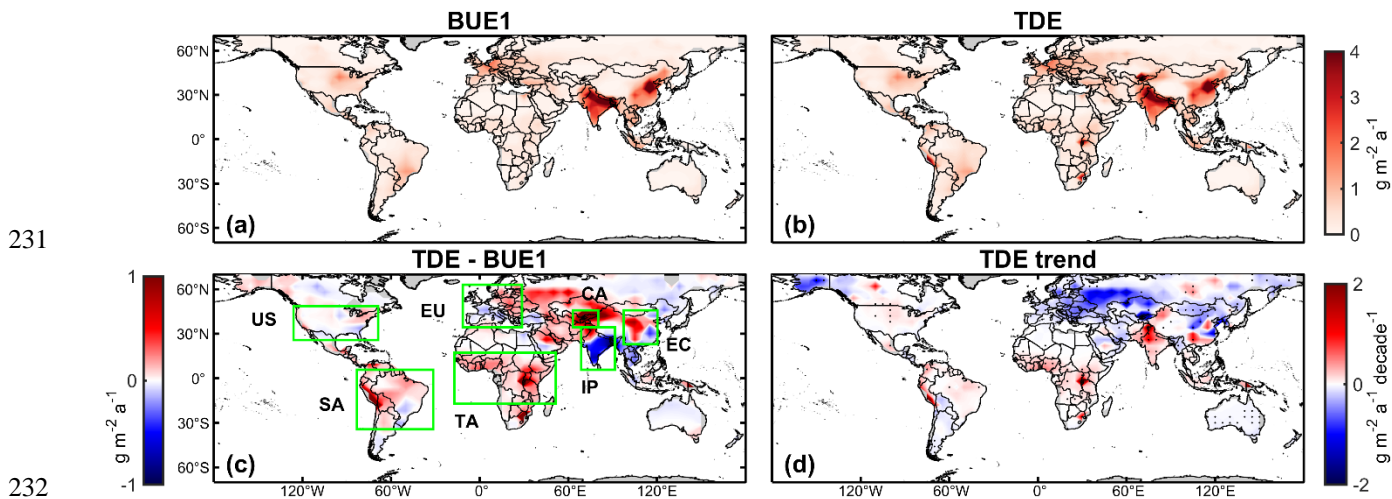

198 **Fig. 1a and 1b** plot observed and simulated NH<sub>3</sub> total column concentrations averaged over 2008-2018. The GEOS-Chem  
 199 simulation generally reproduces the global distribution of NH<sub>3</sub> concentrations observed by the IASI instrument. Good  
 200 agreements (i.e., difference < 10 %) are found in the U.S., Europe, and southern South America. Meanwhile, the GEOS-

201 Chem model underestimates  $\text{NH}_3$  concentrations in eastern China, northern South America, and tropical Africa by 20-120 %,  
202 and overestimates in southern India by around 50 %, indicating biases in  $\text{NH}_3$  emissions over these regions.  
203 **Fig. 1c and 1d** show 2008-2018 linear trends in  $\text{NH}_3$  column concentrations derived from the IASI observations and the  
204 GEOS-Chem simulations. The linear trends are computed based on the time series of annual averages. The IASI trends  
205 shown in Fig. 1c are in general consistent with a recent analysis by Van Damme et al. (2021). IASI observes a positive  $\text{NH}_3$   
206 concentration trend of  $2.9 \% \text{ a}^{-1}$  over the U.S., and this trend is well captured by GEOS-Chem. Similarly, the observation and  
207 the simulation agree on a dipole pattern in South America (i.e., positive trend in Brazil and negative trend in Argentina).  
208 Because anthropogenic emissions over this region are set to be invariant in our simulation (**Fig. S2**), this agreement suggests  
209 that these trends are due to meteorological conditions and/or fire emissions, rather than changes in anthropogenic emissions.  
210 The satellite also observes significant positive trends in  $\text{NH}_3$  concentrations over China ( $5.2 \% \text{ a}^{-1}$ ) and tropical Africa ( $2.0 \% \text{ a}^{-1}$ ),  
211 but these trends are not reproduced in the simulation ( $0.3 \% \text{ a}^{-1}$  for China and  $0.2 \% \text{ a}^{-1}$  for tropical Africa). These  
212 simulation-observation differences can not only reflect discrepancies in the trends of anthropogenic  $\text{NH}_3$  emissions, but also  
213 be attributed to uncaptured changes in  $\text{SO}_2$  and/or  $\text{NO}_x$  emissions in these regions. We also find that a positive  $\text{NH}_3$   
214 concentration trend over Europe appears in the simulation ( $3.0 \% \text{ a}^{-1}$ ) but is much weaker ( $1.0 \% \text{ a}^{-1}$ ) in the observation,  
215 suggesting decreasing emissions after 2013. Satellite data shows positive  $\text{NH}_3$  concentration trends in north-western India  
216 but negative trends in in south-eastern India which are not reproduced by the simulation, though these trends over India are  
217 mostly insignificant (at the 95 % confidence level) except for a few grid cells in the Southeast. Strong GEOS-Chem trends in  
218 eastern Canada and Siberia result from large wildfires that occurred in the latter part of the study period. IASI trends in  
219 northern boreal regions are less robust because of noisy and sparse measurements over high latitudes (**Fig. S1** and **Fig. S3**)

### 220 **3.2 $\text{NH}_3$ emissions inferred from IASI observations**

221 **Fig. 2** shows the spatial distributions of  $\text{NH}_3$  emission fluxes and their 2008–2018 linear trends inferred from IASI  
222 observations using the method described in **Sect. 2.3**. **Fig. 3** plots annual time series aggregated for seven selected regions.  
223 The top-down emission (TDE) estimates suggest upward adjustments in  $\text{NH}_3$  emissions over South America (SA) by 62 %,  
224 tropical Africa (TA) by 69 %, and Central Asia (CA) by 327 %, relative to the prior inventory (BUE1), but downward  
225 adjustments in  $\text{NH}_3$  emissions by 14 % in India Peninsula (IP) and by 33 % in Canada. After accounting for the contributions  
226 from natural emissions including fires, we find that most of these biases in  $\text{NH}_3$  emissions can be attributed to anthropogenic  
227 sources, except for Canada where the underestimation appears to relate to fire emissions. This result reflects a general  
228 inadequate representation of agricultural and industrial emissions from developing continents in current global emission  
229 inventories. The TDE finds good agreements with the BUE1 (difference within 10 %) over the U.S., Europe (EU), eastern  
230 China (EC) and Australia.

233 **Figure 2.** Spatial distribution of  $\text{NH}_3$  emission fluxes during 2008-2018. (a) Bottom-up emissions (BUE1), (b) top-down emissions (TDE)  
 234 inferred from IASI observations, (c) difference between TDE and BUE1 estimates and (d) emission trends derived from TDE estimates.  
 235 Green boxes denote seven regions analyzed in Sect. 3.2. Top-down emission fluxes are computed with Eq. (1) except for IP and EC where  
 236 Eq. (3) is applied. Linear trends are computed from the time series of annual averages. Dots in (d) represent significant linear trends at the  
 237 95 % confidence level.

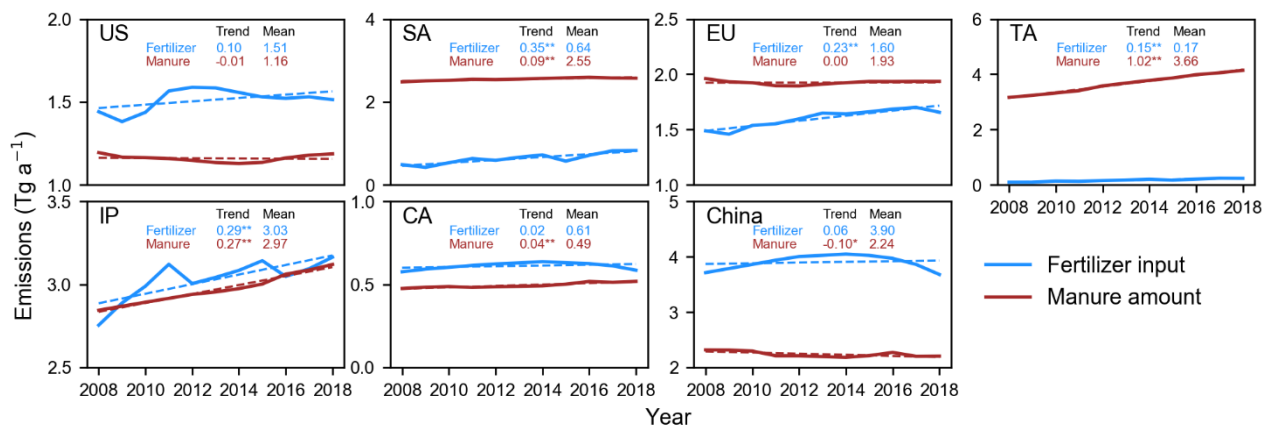

238 In addition to the adjustments in average emissions, the TDE also detects changes in  $\text{NH}_3$  emissions during the period of  
 239 2008-2018, as expressed in linear trends computed from annual time series. We find significant positive emission trends in  
 240 SA ( $1.7 \text{ Tg a}^{-1} \text{ decade}^{-1}$  or  $18 \% \text{ decade}^{-1}$ ) and TA ( $2.8 \text{ Tg a}^{-1} \text{ decade}^{-1}$  or  $33 \% \text{ decade}^{-1}$ ) (**Fig. 3**). The large positive trends in  
 241 TA are found around Lake Natron, consistent with Clarisse et al. (2019) (Fig. 2d). These increases in  $\text{NH}_3$  emissions are  
 242 concurrent with intensifying agricultural activities in these regions (Warner et al., 2017; E. Hickman et al., 2020), except for  
 243 a 2010 peak over SA, which coincides with fires in savanna and evergreen forests there (Chen et al., 2013). Comparison with  
 244 data from the Food and Agriculture Organization of the United Nations (FAO) (<http://www.fao.org/faostat>, last access: 7  
 245 May 2022) suggests that the increase in SA is driven primarily by growing application of synthetic fertilizer ( $55 \% \text{ decade}^{-1}$ ),  
 246 whereas the increase in TA is consistent with increasing manure amount ( $28 \% \text{ decade}^{-1}$ ) from a growing livestock  
 247 population (E. Hickman et al., 2021) (**Fig. 4**).

248 Our results infer large but variable trends over northern high latitudes (e.g., negative trends in Alaska, central Russia, and  
 249 eastern Europe, but positive trends in Canada) (**Fig. 2d**). Because of large uncertainties associated with high-latitude  
 250 observations and emission optimization, these trends are less robust but can be partly attributed to variations in fire activities.  
 251 Decreases in Russia and eastern Europe are related to wildfire of boreal forests in early part of the study period (2008-2011)  
 252 (Keywood et al., 2012; Warner et al., 2017), while emission increases in Canada is due to wildfire in the late part of the  
 253 period (2013-2016 and 2017) (Pavlovic et al., 2016), as also shown in the prior fire inventory (GFED4) (**Fig. S4**). We also  
 254 infer negative trends ( $-43 \% \text{ decade}^{-1}$ ) in Australia, which are statistically significant, but the absolute magnitude of these  
 255 trends is small ( $-0.03 \text{ g m}^{-2} \text{ a}^{-1} \text{ decade}^{-1}$  in **Fig. 2d**). The TDE estimation does not find significant trends in  $\text{NH}_3$  total  
 256 emissions over the US and Central Asia.

257

258 **Figure 3.** Annual  $\text{NH}_3$  emissions for seven selected regions during 2008-2018. Shadings represent the upper and lower bounds derived  
 259 from uncertainty analyses (see Sect. 2.4). Average annual emissions ( $\text{Tg a}^{-1}$ ), absolute linear trends ( $\text{Tg a}^{-1} \text{decade}^{-1}$ ) and relative trends (%  
 260  $\text{decade}^{-1}$ ) for 2008-2018 are inset. The asterisk symbols '\*\*' and '\*\*\*' represent that linear trends are significant at the 95 % and 99 %  
 261 confidence level, respectively. Red dashed lines represent top-down  $\text{NH}_3$  emission estimates over IP and EC during 2013-2018, based on  
 262 Eq. (3) that accounts for observed trends of  $\text{SO}_2$  (denoted as "SO<sub>2</sub>-corrected"). Statistics for this estimate are also inset. The prior  
 263 inventory (BUE1) implemented in our simulation only partially account for inter-annual changes from bottom-up information (i.e., Fig. 4).

264

265 **Figure 4.** Synthetic fertilizer and livestock manure amount based on FAO reports (<http://www.fao.org/faostat>) during 2008-2018. To  
 266 roughly compare the contribution from the two sectors, we convert FAO reported statistics to  $\text{NH}_3$  emissions ( $\text{Tg a}^{-1}$ ) by applying fixed  
 267 emission factors of 13 % for manure N contents (Ma et al., 2020) and 17 % for synthetic fertilizer N contents (Riddick et al., 2016). Values  
 268 of means ( $\text{Tg a}^{-1}$ ) and linear trends ( $\text{Tg a}^{-1} \text{decade}^{-1}$ ) are inset. Scales differ between panels.

### 269 3.3 Impact of changing $\text{SO}_2$ emissions on $\text{NH}_3$ emission trends over eastern China and India

270 Based on  $\text{NH}_3$  column measurements (Eq. (1)), we also find a decadal increase of 61 %  $\text{decade}^{-1}$  ( $6.6 \text{Tg a}^{-1} \text{decade}^{-1}$ ) in  $\text{NH}_3$   
 271 emissions over eastern China (Fig. 3). This increase is especially large after 2013 and is driven mainly by increases of IASI  
 272  $\text{NH}_3$  column concentration in eastern China (Fig. 1c). This large post-2013 increase is inconsistent with flat or even  
 273 declining fertilizer input and manure amount (Fig. 4). On the other hand, we find no appreciable emission trend in IP (Fig.

274 **3**), which appears to agree with relatively stable IASI NH<sub>3</sub> concentrations over the period (**Fig. 1c**) but is not supported by  
275 increases in fertilizer applications and manure amount shown in the FAO report (**Fig. 4**).

276 An assumption underlying **Eq. (1)** is that the model simulation captures the partition between gas-phase NH<sub>3</sub> and aerosol-  
277 phase NH<sub>4</sub><sup>+</sup>. In addition to alkaline NH<sub>3</sub>, the partition is also determined by the abundance of acids (e.g., H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub>).  
278 Inaccurate emissions of their precursors (e.g., SO<sub>2</sub> and NO<sub>2</sub>) in the model simulation, in particular over regions with  
279 excessive NH<sub>3</sub>, can lead to biases in simulating the NH<sub>3</sub>-NH<sub>4</sub><sup>+</sup> partition. It is well known that SO<sub>2</sub> emissions in China have  
280 decreased rapidly after 2013 because of stringent air pollution control measures (Sun et al., 2018; Zhai et al., 2021), while  
281 SO<sub>2</sub> emissions from India have been increasing (Qu et al., 2019). But these regional trends are not captured in our prior  
282 simulation because our simulation does not have annual-varying emission inventories for these regions (**Fig. S2**).

283 We find that the discrepancies between top-down (**Eq. 1**) and bottom-up estimates of emission trends over EC and IP can be  
284 largely reconciled by including observed SO<sub>2</sub> column concentrations in the top-down calculation (**Eq. (3)**). By accounting  
285 for OMI and OMPS observed SO<sub>2</sub> trends (Wang and Wang, 2020), we derive an overall decreasing trend in NH<sub>3</sub> emissions  
286 in EC between 2013 and 2018 ( $-2.2 \pm 2.3 \text{ Tg a}^{-1} \text{ decade}^{-1}$ ,  $-28 \pm 32 \text{ \% decade}^{-1}$ ) (uncertainty derived by perturbing  $\omega$  by 1%  
287 a<sup>-1</sup>, same for the India results below). This result suggests that observed increases in NH<sub>3</sub> columns over China are largely  
288 explained by decreases in SO<sub>2</sub> emissions (**Fig. 1** and **Fig. 3**), consistent with previous studies (Fu et al., 2017; Liu et al.,  
289 2018; Lachatre et al., 2019; Chen et al., 2021a). Bottom-up inventories (e.g., MEIC v1.3, EDGAR v5.0) also report stable or  
290 declining NH<sub>3</sub> emissions from China during the period (Li et al., 2017; Crippa et al., 2020). Meanwhile, the revised method  
291 (**Eq. (3)**) finds a positive post-2013 trend ( $3.3 \pm 0.3 \text{ Tg a}^{-1} \text{ decade}^{-1}$ ,  $30 \pm 3 \text{ \% yr}^{-1}$ ) in NH<sub>3</sub> emissions over India. Compared  
292 with our original estimate using **Eq. (1)**, NH<sub>3</sub> emission trends derived with **Eq. (3)** (i.e., decrease in China and increase in  
293 India after 2013) is more consistent with the bottom-up information of fertilizer input and manure management (**Fig. 4**). This  
294 result demonstrates the potential of assimilating both NH<sub>3</sub> and SO<sub>2</sub> satellite observations in constraining NH<sub>3</sub> emissions,  
295 which should be further explored in the future.

### 296 **3.4 Global total NH<sub>3</sub> emissions**

297 Integrating over land areas globally, our IASI-based TDE estimates of NH<sub>3</sub> is 78 (70-92) Tg a<sup>-1</sup> (range of estimates from  
298 uncertainty analysis, see **Table 1**) (**Fig. 5**). This result is about 20-40 % higher than bottom-up inventories (BUE1, 62 Tg a<sup>-1</sup>  
299 and BUE2, 56 Tg a<sup>-1</sup>). In contrast, a previous study by Evangeliou et al. (2021) also based on the IASI data estimated a much  
300 higher global NH<sub>3</sub> emission of 180 Tg a<sup>-1</sup> (**Fig. 5**). One cause of the difference between the two IASI-based estimates is in  
301 diagnosis of NH<sub>3</sub> lifetime from CTM. Evangeliou et al. (2021) treats conversion from NH<sub>3</sub> to NH<sub>4</sub><sup>+</sup> as a terminal loss and  
302 diagnoses NH<sub>3</sub> lifetime averaged  $11.6 \pm 0.6 \text{ h}$  globally from a CTM, which is close to a constant NH<sub>3</sub> lifetime (12 h)  
303 assumed in Van Damme et al. (2018). In this study, we account for the fact that fast thermodynamic equilibrium can  
304 establish between NH<sub>3</sub> and NH<sub>4</sub><sup>+</sup> so that NH<sub>3</sub> can only be terminally lost through the deposition of the NH<sub>x</sub> family (**Eq. (2)**),  
305 which yields a global averaged NH<sub>3</sub> lifetime of  $21.2 \pm 3.8 \text{ h}$  (**Fig. 6**). This longer NH<sub>3</sub> lifetime implies a higher sensitivity of  
306 NH<sub>3</sub> column density to NH<sub>3</sub> emissions, leading to a lower estimate for global NH<sub>3</sub> emissions. In addition, instead of locally

307 scaling observed  $\text{NH}_3$  column by lifetime (Van Damme et al., 2018; Evangeliou et al., 2021; Marais et al., 2021), our method  
 308 (Eq. (1)) partially accounts for the non-local contribution from transport by including prior  $\text{NH}_3$  columns from a full 3-D  
 309 simulation and using their difference from observed  $\text{NH}_3$  columns to correct prior emissions, which prevents derivation of  
 310 large  $\text{NH}_3$  emissions in remote regions where observed  $\text{NH}_3$  concentrations are driven mainly by transport. Our data filtering  
 311 strategy (Sect 2.1 and 2.2) is also crucial to avoid spurious top-down results when satellite coverage is poor and the local  
 312 mass balance assumption does not hold.

313

314 **Figure 5.** Comparison of our top-down  $\text{NH}_3$  emission estimates (TDE) with other top-down (Fixed 12h and Evangeliou et al. (2021)) and  
 315 bottom-up (BUE1 and BUE2) results during 2008-2018. The red line and red bar represent central estimates of the TDE, and the blue  
 316 shaded area and the blue error bar indicate the uncertainty evaluated by our study (Sect. 2.4).

317

318 **Figure 6.** Spatial distribution of  $\text{NH}_3$  lifetime (h) diagnosed from GEOS-Chem (Eq. (2)) within the  $70^\circ\text{N}$ - $70^\circ\text{S}$  during 2008-2018.

319 **Fig. 6** shows the spatial variation in  $\text{NH}_3$  lifetime diagnosed from the GEOS-Chem simulation. Short  $\text{NH}_3$  lifetimes ( $< 10$  h)  
 320 are found mainly in northern high latitudes. Short lifetime in eastern China is due to high wet  $\text{NH}_4^+$  deposition velocity,  
 321 although some regional studies suggested an overestimation of deposition fluxes by the model especially in forest areas (e.g.,  
 322 Yangtze River basin) (Zhao et al., 2017; Xu et al., 2018). Very long  $\text{NH}_3$  lifetime ( $> 100$  h) occurs over Sahara and  
 323 Australia, where dry conditions result in slow wet deposition.

### 324 3.5 Uncertainty evaluation

325 We derive the uncertainty of top-down estimates from the perturbation tests in **Table 1**. **Fig. 7** shows the global spatial  
326 distribution of annual average uncertainties of  $\text{NH}_3$  emissions derived from the ensemble of these perturbation tests.  
327 Absolute uncertainties are expressed as half of the ensemble ranges, and relative uncertainties are computed by normalizing  
328 absolute uncertainties by ensemble averages. We find that both absolute and relative uncertainties are large in Central Asia  
329 and Tropical Africa, indicating that these source regions are not well constrained by observations. In comparison,  
330 observations have some constraints over important source regions of eastern China and northern India, which have small  
331 relative uncertainties ( $< 20\%$ ) but still appreciable absolute uncertainties ( $> 0.4 \text{ g a}^{-1} \text{ m}^{-2}$ ). Uncertainties are small ( $< 20\%$   
332 and/or  $< 0.2 \text{ g a}^{-1} \text{ m}^{-2}$ ) in Europe and the U.S.

334 **Figure 7.** Spatial distribution of TDE (a) relative and (b) absolute uncertainty during 2008-2018. Absolute uncertainties are derived as half  
335 of the perturbation ensemble range (**Table 1**) and relative uncertainties are computed by normalizing absolute uncertainties with ensemble  
336 averages.

337 Our fast top-down method (Eq. (1) and Eq. (3)) relies on simplification of  $\text{NH}_3$  chemical and physical processes. Therefore,  
338 it is not guaranteed that a simulation driven by TDE will generate results in improved agreement with IASI observations. We  
339 evaluate the consistency of our results using full GEOS-Chem simulations in the selected years of 2008, 2013, and 2018.  
340 Results are shown in **Fig. S5** (fractional bias, FB) and **Table S1** (number of valid grid cells,  $R^2$ , and root mean square error).  
341 The GEOS-Chem simulations driven by the prior emissions (BUE1) tends to underestimate  $\text{NH}_3$  column density (mean FB  
342  $\sim 30\%$ ), while that driven by our TDE estimates achieves lower biases (mean FB  $\sim 10\%$ ), demonstrating the consistency of  
343 our TDE results with IASI observations.

### 344 3.6 Comparison to independent surface networks

345 We also compare simulated surface  $\text{NH}_3$  concentrations with independent ground-based measurements, including (1)  
346 biweekly averaged  $\text{NH}_3$  concentrations in North America (AMoN, <https://nadp.slh.wisc.edu/networks/ammonia-monitoring-network/>, last access: 3 June 2022), (2) half-hourly/daily/weekly averaged  $\text{NH}_3$  concentrations in (EMEP, <http://ebas-data.nilu.no/>, last access: 3 June 2022), and (3) monthly averaged  $\text{NH}_3$  concentrations in south-eastern Asia (EANET, <https://www.eanet.asia/>, last access: 3 June 2022). AMoN measures  $\text{NH}_3$  concentrations by passive devices (simple  
349 diffusion-type sampler), while EMEP and EANET use both active and passive sampler systems among different sites (multi-  
350 type samplers). For comparison, we convert the observed  $\text{NH}_3$  concentrations in  $\mu\text{g m}^{-3}$  to ppbv using a factor of 1.44  
351

352 (assume 25 °C temperature and 1 atmosphere pressure) and average observations monthly over the GEOS-Chem 4° × 5°  
 353 grid. **Fig. 8** shows the comparison by season. Only small adjustments are inferred by our satellite-based estimations in these  
 354 regions (i.e., North America, Europe, and South-eastern Asia). Thus, TDE and BUE1 show similar performance against  
 355 these ground measurements. Although the simulation can capture the site-to-site variations reasonably well, simulated  
 356 surface values are in general biased low compared to observations. This low bias is also reported in the evaluation of  
 357 previous IASI-based estimates (e.g., Evangeliou et al, 2021; Chen et al., 2021b). Further investigations are needed to  
 358 understand the reasons for this bias.

359  
 360 **Figure 8.** Validation of simulated NH<sub>3</sub> concentrations driven by BUE1 and TDE against ground-based measurements from AMoN,  
 361 EMEP, EANET for selected years (2008, 2013 and 2018) in four seasons (January-March, JFM; April-June, AMJ; July-September, JAS;  
 362 October-December, OND). Scatterplots are plotted in log scale and average RMSE (ppb) and FB (%) for each season are inset. The  
 363 asterisk symbols \*\* and \*\*\* represent that differences between BUE1 and TDE are significant at the 95 % and 99 % confidence level.

## 364 4 Conclusions

365 This study quantifies global ammonia ( $\text{NH}_3$ ) fluxes monthly from 2008 to 2018 at  $4^\circ \times 5^\circ$  resolution, through a fast top-  
366 down method that incorporates IASI satellite observations and GEOS-Chem model simulations. The top-down method  
367 updates the prior  $\text{NH}_3$  emissions with a correction term positively proportional to the difference of the observed and  
368 simulated  $\text{NH}_3$  concentrations, and inversely proportional to the lifetime diagnosed from a CTM. This method revises  
369 previously proposed fast top-down methods in two aspects. First, we account for thermodynamic equilibrium within the  $\text{NH}_x$   
370 family in diagnosing  $\text{NH}_3$  lifetime, while previous studies either assume a globally constant lifetime or treat conversion from  
371  $\text{NH}_3$  to  $\text{NH}_4^+$  as a terminal sink. Second, our formulation linearizes the column-emission relationship at prior emissions as  
372 opposed to zero emissions in the previous method, which in general reduces errors from the local mass balance  
373 approximation. Another improvement is that we apply several data filtering procedures to exclude unreliable top-down  
374 results that are not sufficiently constrained by observations or affected by large deviations from the local mass balance  
375 assumption. The top-down method developed in this study is particularly useful for long-term global analysis of emission  
376 trends, because it largely accounts for the impact of meteorology through the CTM simulation and requires only small  
377 amount of computation relative to a full-fledged inversion.

378 We apply this improved fast top-down method to IASI  $\text{NH}_3$  column observations from 2008 to 2018. We find that the BUE1  
379 underestimates  $\text{NH}_3$  emission over South America (62 %) and tropical Africa (69 %), but overestimates over India (14 %)  
380 and Canada (33 %). The bottom-up inventory agrees with the top-down estimate over the U.S., Europe, and eastern China  
381 (i.e., within 10 %). Our analysis also shows significant increases in India (13 % decade<sup>-1</sup>), tropical Africa (33 % decade<sup>-1</sup>),  
382 and South America (18 % decade<sup>-1</sup>) during the study period, consistent with intensifying agricultural activities over these  
383 regions. An analysis of agricultural statistics suggests that the increase in tropical Africa is likely driven by growing  
384 livestock population and that in South America by increasing fertilizer usage.

385 We show that large increases in  $\text{NH}_3$  concentrations in eastern China is mainly driven by rapid decreases in  $\text{SO}_2$  emissions in  
386 recent years. By accounting for observed  $\text{SO}_2$  columns, we find that  $\text{NH}_3$  emissions from eastern China are significantly  
387 decreasing during 2008-2018 (-19 % decade<sup>-1</sup>), with a larger negative trend after 2013 (-28 % decade<sup>-1</sup>), as compared to a  
388 significant positive trend (61 % decade<sup>-1</sup>) derived from assimilating only  $\text{NH}_3$  data. Similarly, a lack of trend in observed  
389  $\text{NH}_3$  concentrations over India is due to concurrent increases in  $\text{SO}_2$  and  $\text{NH}_3$  emissions. After including observed  $\text{SO}_2$   
390 columns in the calculation, we estimate a 13 % increase in  $\text{NH}_3$  emissions over India, with a significant post-2013 positive  
391 trend (30 % decade<sup>-1</sup>). These results from assimilating both  $\text{NH}_3$  and  $\text{SO}_2$  data is more consistent with the agricultural  
392 statistics in China and India. The multi-satellite ( $\text{SO}_2$  and  $\text{NH}_3$ ) method is only applied in India and China in this study. To  
393 extend this idea globally requires development of formulations for varied sulfate-nitrate-ammonium aerosol regimes and  
394 needs to be addressed in a future study.

395 Our estimate for global total  $\text{NH}_3$  emission is 78 (70-92) Tg a<sup>-1</sup>, about 30 % higher than the BUE1 estimate. This contrasts  
396 with a much higher estimate (180 Tg a<sup>-1</sup>) derived from Evangeliou et al. (2021) also using IASI data. The discrepancy can be

397 primarily attributed to a longer NH<sub>3</sub> lifetime (i.e., global average 21 h) diagnosed in our method, which represents a greater  
398 sensitivity of NH<sub>3</sub> column to emissions, and a more conservative data filtering strategy, which removes potentially unreliable  
399 top-down results. Our diagnosis of NH<sub>3</sub> lifetime is an improvement over Evangeliou et al. (2021), by accounting for the  
400 thermodynamic equilibrium between gas phase NH<sub>3</sub> and aerosol phase NH<sub>4</sub><sup>+</sup> in our formula. We show with model  
401 simulations, our top-down estimate achieves better consistency with IASI observations, compared to the bottom-up emission  
402 inventory.

403

#### 404 *Data availability.*

405 The IASI L2 ammonia satellite observations are available at the AERIS data infrastructure (<https://iasi.aeris-data.fr/>). The  
406 ERA5 skin temperature and GFAS fire emission can be request through Copernicus Climate Data Store  
407 (<https://cds.climate.copernicus.eu/cdsapp#!/home>). Agricultural data are available through Food and Agriculture  
408 Organization of the United Nations (FAO) (<http://www.fao.org/faostat>). The GEOS-Chem model can be retrieved from  
409 10.5281/zenodo.3974569. All the other data and scripts used for the present publication are available under MIT license on  
410 GitHub: <https://github.com/bnulzq/NH3-emission.git>.

#### 411 *Author contributions.*

412 ZL and YZ designed the study. ZL performed the simulations and analyses and wrote and coordinated the paper. WC  
413 contributed to the model simulations for consistency evaluation. LC, MVD, and PFC developed the IASI-NH<sub>3</sub> satellite  
414 product. ZL and YZ wrote the paper with inputs from all authors.

#### 415 *Competing interests*

416 The contact author has declared that neither they nor their co-authors have any competing interests.

#### 417 *Acknowledgements.*

418 This study is supported by Westlake University. We thank the High-Performance Computing Center of Westlake University  
419 for the facility support and technical assistance. We acknowledge the AERIS data infrastructure <https://www.aeris-data.fr> for  
420 providing access to the IASI data. The IASI L1c data are received through the EUMETCast near real-time data distribution  
421 service. Research at ULB was supported by the Belgian State Federal Office for Scientific, Technical and Cultural Affairs  
422 (Prodex HIRS) and the Air Liquide Foundation (TAPIR project). LC is Research Associate supported by the Belgian F.R.S.-  
423 FNRS. Hersbach et al., (2020) was downloaded from the Copernicus Climate Change Service (C3S) Climate Data Store. The  
424 results contain modified Copernicus Climate Change Service information 2020. Neither the European Commission nor  
425 ECMWF is responsible for any use that may be made of the Copernicus information or data it contains. IASI is a joint  
426 mission of Eumetsat and the “Centre National d’Études Spatiales” (CNES, France). We acknowledge the constructive

427 comments and suggestions from Prof. Peter Hess from the Cornell University, Dr. Yi Wang from the University of Iowa, and  
428 Dr. Shixian Zhai from Harvard University. We also acknowledge Dr. Nikolaos Evangeliou from Norwegian Institute for Air  
429 Research for providing his NH<sub>3</sub> emission flux data and for discussions with ZL.
