Abstract. To identify the long-term trend of particle size variation, we analyzed aerosol optical depth (AOD, $\tau$) separated as dust ($\tau_D$) and coarse-($\tau_{PC}$) and fine-pollution particles ($\tau_{PF}$) depending on emission sources and size. Ångström Exponent values are also identified separately as total and fine-mode particles ($\alpha_T$ and $\alpha_{PF}$). We checked these trends in various ways: 1) first-order linear regression analysis of the annual average values, 2) percent variation using the slope of linear regression method, and 3) a reliability analysis using the Mann-Kendall (MK) test. We selected 17 AERONET sun/sky radiometer sites classified into six regions, i.e., Europe, North Africa, the Middle East, India, Southeast Asia, and Northeast Asia. $\tau$ decreased in Europe and Asian regions and increased in the Middle East, India, and North Africa. Values of $\tau_{PC}$ and $\tau_{PF}$ show that aerosol loading caused by non-dust aerosols decreased in Europe and Asia and increased in India. In particular, $\tau_{PF}$ considerably decreased in Europe and Northeast Asia (95 % confidential levels in MK-test), and $\tau_{PC}$ decreased in Northeast Asia (Z-values for Seoul and Osaka are -2.95 and -2.31, respectively). The change in $\tau_{PC}$ reflects the reduction of primary emissions from plants and other anthropogenic sources as the result of regulations by air policies. Values of $\alpha_T$ decreased by -3.3 to -30.5 % in Europe, North Africa, and the Middle East, which means the mean size of aerosol particles increased. Particle size on average became smaller over India and Asian regions considered in our study. We find that $\alpha_T$ increased by 1.3 to 13.1 %. In particular, $\alpha_{PF}$ increased in most areas, showing the probability that the average particle size of fine-mode aerosols became smaller in recent years.

Key words: aerosol optical depth, Ångström exponent, annual variation, fine-mode aerosol, AERONET
1. Introduction

Atmospheric aerosols are associated with air pollution and public health (Ramanathan et al., 2007; Ramanathan and Carmichael, 2008; Ipcc, 2019). In particular, small aerosol particles are damaging human health (WHO, 2016; Schraufnagel et al., 2019). The International Agency for Research on Cancer (IARC) classifies aerosol particles as a class 1 carcinogen (Loomis et al., 2013). The World Health Organization (WHO) is focusing on the number concentration of ultra-fine particles (WHO, 2021). Because of the hazard of particulate matter (PM), governments worldwide are continuously monitoring and controlling the mass concentration of PM (Collaud Coen et al., 2013; Li et al., 2014; Li et al., 2015; Mehta et al., 2018; Yang et al., 2018; Pozzer et al., 2019; Chirasophon and Pochanart, 2020; Liu et al., 2020). Particle size distribution however cannot be inferred from mass concentration observations (Lee et al., 2010; Burton et al., 2014). To understand the change in air pollution caused by PM and its adverse health effects, we need to identify the variations in size of small particles as well as mass concentration.

According to their sources, ambient atmospheric aerosols can be divided into natural and anthropogenic ones. Anthropogenic aerosols are emitted from industry activities, population growth, and combustion activities. Aerosols are also classified as fine- and coarse-mode particles depending on their size. Coarse-mode particles are related to primary emissions like industrial activities and biomass burning. This type of particle is highly correlated with the change of mass concentration (Han et al., 2015; Hatakeyama, 2017). Fine-mode particles are mainly considered as secondary aerosols formed by gaseous precursors, oxidants, and/or changes of meteorological conditions (Kitamori et al., 2009; Cheng and Li, 2010; Xue et al., 2014; Mesquita et al., 2016; Tan et al., 2017; Xu et al., 2017; Kong et al., 2018; Kudo et al., 2018; Wang et al., 2019). This particle type is closely related to visibility and adverse effects on human health.

Liu et al., 2020 stated that secondary aerosols such as PM$_{2.5}$ still cause haze as the result of high pollution levels, despite the fact that aerosol mass concentration levels have decreased in Beijing in recent years. Many studies show that aerosol mass concentration and aerosol optical depth (AOD, $\tau$) have decreased globally in recent years (Li et al., 2014; Li et al., 2015; Mehta et al., 2018; Pozzer et al., 2019; Cherian and Quaas, 2020; Liu et al., 2020; Dehkhoda et al., 2020). However, these changes vary by region. These parameters provide little information on the optical properties and size distribution of the pollution particles. Plus, we have difficulty confirming the change of fine-mode particles using changes of mass concentration.

This research developed a method to separate $\tau$ as dust and coarse-/fine-mode pollution particles using size distribution and the linear depolarization ratio ($\delta_p$). This method was applied to the long-term observation data of the Aerosol Robotic Network (AERONET) sun/sky radiometer (Dubovik et al., 2002; Omar et al., 2005; Levy et al., 2007; Mielonen et al., 2009; Lee et al., 2010; Russell et al., 2010) to determine aerosol types. We also analyzed the proportion of fine mode in the total aerosols, particle size characteristics change, and regional characteristics (Dubovik et al., 2002; Noh et al., 2011; Boselli et al., 2012).
2. Methodology

2.1. Study sites

We selected AERONET Sun/sky radiometer sites that meet the following criteria: First, the sites have acquired data continuously for more than nine years since 2001, making them suitable for studying the long-term trend of $\tau$. Second, the depolarization ratio is essential to calculate dust ratio, so we have limitations in using data in American and European sites. Third, the selected observation sites need to be representative of regional characteristics. Eventually, we chose 17 AERONET sites to identify the annual change of regional aerosol particle characteristics. These sites are distributed across six regions, i.e., Europe, North Africa, Middle East, India, Southeast Asia, and Northeast Asia (Figure 1). The stations Venice (Italy, 45.31° N, 12.51° E), Thessaloniki (Greece, 40.63° N, 22.96° E) are located in Europe. We also add Erdemli (Turkey, Institute of Marine Science-Erdemli, 36.56° N, 34.26° E) to the European site as Turkey is bordering the eastern Mediterranean Sea. There are four sites in Africa. Tamanrasset (Algeria, 22.79° N, 5.53° E) and the Cape Verde (16.73° N, 22.94° W) stations are located in the dust emission belt that stretches from North Africa westward out into the Atlantic Ocean. Cinzana (Mali, 13.28° N, 5.93° W) is located in the northwest part of the Sahel zone and is mainly affected by Saharan dust outbreaks. Ilorin (Nigeria, 8.48° N, 4.67° E) is located at the upper tip of the Guinea savannah zone in the sub-Sahel. This station is mainly influenced by Saharan dust and biomass burning aerosol (Balarabe et al., 2016). There are two measurement sites in the Middle East, i.e., Sede Boker (Israel, 30.86° N, 34.78° E) and Mezaira (the United Arab Emirates, 23.10° N, 53.75° E). The regions in India, i.e., Kanpur (26.51° N, 80.23° E) and Ballia (Gandhi_College, 25.87° N, 84.13° E) are in Uttar Pradesh which is a state in northern India. These sites are influenced mainly by large-scale anthropogenic emission sources (biomass burning, fossil-fuel combustion, and industrial activities) and mineral dust transported from western India (Ram et al., 2010). Two Southeast Asia sites, Chiang Mai (18.77° N, 98.97° E) and Bangkok (Silpakorn University, 13.82° N, 100.04° E) are located in northern and central Thailand and have the characteristics of an urban environment. Four sites, Beijing (China, 39.98° N, 116.38° E), Seoul (Korea, 37.46° N, 126.95° E), Osaka (Japan, 34.65° N, 135.59° E), and Taipei (Taiwan, 25.02° N, 121.54° E) are representative regions in Northeast Asia. Beijing is known as the region with the highest concentration of pollution particles worldwide (Li et al., 2014). Seoul is downwind of westerly winds from Beijing and thus often affected by long-range transport of pollution particles from China. Seoul also has a high concentration of locally produced pollution particles. Osaka is a coastal city that produces less anthropogenic pollution than China and Korea. The effect of long-range transport of pollution on Taipei is relatively low. Northeast Asia and Indian areas are the regions with high levels of aerosol emissions globally; so, we need to observe aerosol properties intensely. All 17 sites provide us with version 3 level 2.0 data for a minimum of 9 years. The total number of observation days per year is shown in Supplementary Table S1.
2.2. AOD separation into dust, coarse- and fine-mode pollution using depolarization ratio

WHO recommended type classification of PM like black carbon or elemental carbon (BC/EC), ultrafine particles (UFP), and particles originating from sand and dust storms (SDS) to manage control of emission of aerosols effectively (WHO, 2021). Although not explicitly classified based on WHO guidelines, we divided aerosol types as dust, fine- and coarse-mode particles depending on depolarization ratio and particle size data.

Dubovik et al., 2006 introduced kernel look-up tables that describe mixtures of spheroid particles. These kernel look-up tables are used to infer the depolarization ratio ($\delta_p$) of mineral dust observed with AERONET sun/sky radiometer. Details of the AERONET inversion algorithm are given by Dubovik et al., 2006 and Noh et al., 2017. The dust ratio ($R_D$) was used to estimate the contributions of dust and anthropogenic pollution/biomass burning particles to the total aerosol optical depth ($\tau_T$) of mixed aerosol plumes under the assumption that both types of aerosol particles are externally mixed (Shimizu et al., 2004; Tesche et al., 2009; Noh, 2014). $R_D$ was retrieved from the linear particle depolarization ratio ($\delta_p$). Noh et al., 2017 have shown that the $\delta_p$ derived from Sun/sky radiometer observations at 1020 nm and the lidar-derived $\delta_p$ at 532 nm show a comparably high correlation. For that reason, we used the $\delta_p$ at 1020 nm to retrieve the dust ratio ($R_D$). Shimizu et al., 2004 and Tesche et al., 2009 suggested a $R_D$ retrieval method on the basis of

$$R_D = \frac{(\delta_p - \delta_2)(1 + \delta_1)}{(\delta_1 - \delta_2)(1 + \delta_p)} \quad (1)$$

The parameters $\delta_1$ and $\delta_2$ denote the $\delta_p$ at 1020 nm of pure dust and non-dust particles, respectively, of an external mixture of aerosol particles. The values $\delta_1$ and $\delta_2$ can be empirically determined. We use 0.31 for $\delta_1$ in Europe, North Africa, the Middle East, and India. We use 0.30 for the Southeast and Northeast Asia regions, respectively. Those values were determined by the linear depolarization ratios of Saharan and Asian dust presented in previous research work (Freudenthaler et al., 2009; Burton et al., 2014; Shin et al., 2018). We used 0.02 as the minimum value for $\delta_2$. When $\delta_p$ was higher than $\delta_1$ or lower than $\delta_2$, $R_D$ was set to 1 or 0, respectively.

The coarse-mode fraction (CMF) of particles observed at 1020 nm is calculated from the ratio of the coarse-mode AOD to the total (coarse- and fine- mode) AOD. Thus, $R_D$ represents the proportion of AOD for pure dust particles in a mixed aerosol plume, while CMF denotes the ratio of coarse-mode particles to the total particle AOD. Besides, the fine-mode fraction (FMF) is calculated as (1-CMF).

The correlation coefficient ($R^2$) of the linear regression between CMF and RD varies from 0.21 to 0.84 for the different observation sites (Figure S1, supplementary material). Chiang Mai, Bangkok, and the Taipei sites show low $R^2$ values of 0.34, 0.21, and 0.33, respectively. Since those sites are not located in the main transport route of Asian dust, the influence of dust particles is comparably weak compared to the other sites. The tendency for $R_D$ to increase as CMF increases appears in all sites despite the weak correlation we find in our study.

Most of the dust particles are coarse-mode particles, which means that the value of CMF increases with $R_D$. CMF is higher than $R_D$ in most cases, which implies that these coarse-mode particles include dust and pollution particles generated by physical and chemical reactions, e.g., coagulation, condensation processes, and hygroscopic growth (Noh et al., 2017). The ratio of coarse-mode particles (CMP) denotes the proportion (number concentration) of
coarse-mode pollution particles to total particles. In here, dust particles are not considered. This ratio can be calculated by subtracting \( R_D \) from CMF at 1020 nm.

\[
CM_{1020} = CMF_{1020} - R_D
\]  

(2)

If \( R_D \) is higher than CMF, CMP is set to 0.

AOD of dust particles (\( \tau_D \)) at 1020 nm was calculated with equation (3) and the use of \( R_D \) and \( S_d \).

\[
\tau_{1020} = \tau_{1020} \times R_D \times \frac{S_{d,1020}}{S_{1020}}
\]

(3)

Here, 1020 denotes the wavelength at 1020 nm. The parameter \( S \) is the lidar ratio of the aerosol mixture. \( S \) can be calculated from the AERONET data products. The \( S_d \) is the lidar ratio of pure dust particles. It varies in dependence on the desert source. We take the value of 44 and 54 sr at 1020 nm for Asian dust and Saharan dust, respectively (Shin et al., 2018).

The AOD of coarse-mode particles (\( \tau_{PC} \)) observed at 1020 nm was calculated by equation (4). \( \tau_{PC} \) at 440, 675, and 870 nm was retrieved by equation (5), i.e.,

\[
\tau_{PC,1020} = \tau_{PC}(CMP)
\]

(4)

\[
\tau_{PC} = \tau_{PC,1020} \left( \frac{1020}{\lambda} \right)^{\alpha_{PC}}
\]

(5)

The term \( \alpha_{PC} \) is the Angström exponent of coarse-mode pollution. We used the value of 0.16 and 0.14 for Asian and Saharan dust, respectively (Shin et al., 2018).

We used equation (5) to calculate the AOD of the fine-mode pollution (\( \tau_{PF} \)) contribution

\[
\tau_{PF} = \tau_{\lambda} - \tau_{D} - \tau_{PC}
\]

(6)

2.3. Annual trend analysis via linear regression analysis and MK-test

To identify annual variation trends and regional properties, we calculated the change of \( \tau \) with three methods. First, we used linear regression analysis on the time series of annual average \( \tau \), and we checked the slope and percent variation from 2001 to 2018. Second, we used the linear regression equation \( y = a + bx \), where \( x \) is the time (year), and \( y \) is the annual average of \( \tau \). The slope \( b \) describes the change of \( \tau \); \( a \) is the intercept. The percent variation was calculated from the equation

\[
V(\%) = \left( \frac{a \bar{\tau}}{\bar{\tau}} \right) \times 100,
\]

(7)

where \( \bar{\tau} \) is the average of \( \tau \), \( N \) is the number of available data, and \( a \) is the slope obtained from the linear regression analysis. The \( p \)-value (probability value) is a scalar that describes how likely it is that the data occurred by random chance. The \( p \)-value should be small enough, depending on the level of confidence. We calculated all data and found a statistically significant trend.

We also applied the non-parametric Mann-Kendall (MK) statistical test (Mann, 1945; Kendall, 1975) and Sen’s slope values to find annual trend and variation (Salmi et al., 2002; Srivastava and Saran, 2017). The MK-test provides reliable information on the significance of monotonic trends of data in a time series. The magnitude of the trend can be explained by Sen’s slope test, which is a powerful method for investigating linear trends. There
are two hypotheses on the MK-test. Hypotheses are decided by the significance of the value of Z, which is related to the p-value. The following relationships are used:

H0: null hypothesis (no trend),

H1: alternative hypothesis (clear trend),

Critical value: |Z| < 1.96 Accept H0 (95% Confidence level),

|Z| < 1.65 Accept H0 (90% Confidence level),

otherwise, |Z| > 1.96 Accept H1 (95% Confidence level),

|Z| > 1.65 Accept H1 (90% Confidence level).

The sign of Z indicates an increase (+) or decrease (-). The Z value is generally accepted at a 95% confidence level, but the values and number of analysis elements are too small, so we used confidence levels up to 90% instead.

3. Results

3.1. Aerosol-type classification

In preparation for separating AOD according to dust-only and coarse- and fine-mode pollution AOD, we carried out an aerosol-type classification to understand the main aerosol types of each selected site. Shin et al., 2019 suggested a new aerosol type classification method. The authors proposed considering a) the contribution of mineral dust to the aerosol mixture based on a threshold value, denoted as $R_D$, which could be obtained from the depolarization ratio, in combination with b) the use of the single-scattering albedo (SSA). This latter parameter allows for identifying absorption properties of pollution/biomass burning aerosols and thus separating this aerosol type from mineral dust. In this study, we used seven aerosol types based on the values of $\delta_p$, respectively.

Aerosols were classified as pure dust (PD, $R_D > 0.89$), dust-dominated mixture (DDM, $0.53 \leq R_D \leq 0.89$), pollution-dominated mixture (PDM, $0.17 \leq R_D < 0.53$), and pollution particles ($R_D < 0.17$). Particles are classified on the basis of SSA as non-absorbing (NA, SSA>0.95), weakly-absorbing (WA, 0.90<SSA≤0.95), moderately absorbing (MA, 0.85≤SSA≤0.90), and strongly absorbing (SA, SSA<0.85) pollution; see Figure 3 of Shin et al., 2019.

Figure 2 shows the annual changes of major aerosol types at the 17 sites from 2001 to 2018. The results of our aerosol classification reflect the characteristics of the six regions well. In Europe, Southeast Asia, and Northeast Asia, pollution particles are the main type of aerosols. In the Middle East and North Africa, pure dust is dominant. The ratio of NA and WA is high but decreases in the order of Venice, Thessaloniki, and Erdemli. These regions have low values of PDM and DDM ratios, respectively. With regard to the North African region, the Sahara Desert obviously is the predominant source region. Naturally, PD is the predominant aerosol type. Ilorin in the Savannah region of Africa has a higher ratio of SA than other African regions as a result of biomass-burning aerosols. Sede Boker and Mezaira, which are located on the Arabian Peninsula, also show PD and DDM as the major aerosol types. The aerosol types of MA and WA can also be observed in Ilorin. The aerosol types MA and SA appear in
Sede Boker and Mezaira but are not as dominant as dust. Thus, anthropogenic pollutants at Ilorin are higher than in the other African regions investigated in our study. Logothetis et al., 2020 reported that coarse-mode absorbing aerosols are dominant in North Africa and the Arabian Peninsula because of dust transported from the Saharan and the Arabian deserts. However, fine-mode particles emitted from human activity in the Arabian Peninsula are also observed in autumn and winter.

The ratio of dust and pollution particles at Kanpur and Ballia in northern India are similar. Chiang Mai and Bangkok, located in the Indochina Peninsula, are affected mainly by human-made pollution aerosols. The contribution from dust is comparably low. We find 5 % for PDM at most. However, these two regions have differences in that the predominant aerosol types over Chiang Mai and Bangkok are SA and WA, respectively. The high value of SA at Chiang Mai is due to biomass burning aerosols emitted by agricultural burning and forest clearing activities during the dry season which lasts from November to April (Janjai et al., 2012). Bangkok has a low average SSA value of 0.90, but the SA ratio is lower than that of Chiang Mai because the impact of biomass burning is lower (Bridhikitti and Overcamp, 2011).

The Northeast Asian region seems to be affected by both dust and pollution. Asian dust heavily affects the Northeast Asian region in spring, i.e., March, April, and May (Liu et al., 2019). The ratio of DDM and PDM is high in Beijing which is comparably close to the source regions of Asian dust. Seoul is located downwind of the emission regions. The impact of dust is relatively low in Osaka, which is relatively far from the source region. Besides, the Osaka site is not in the main transport pathway of dust. Shin et al., 2015 stated that dust might mix with pollution when the dust is transported near the surface for a long time. Taipei has the lowest dust effect because it is not located on the pathway of Asian dust.

### 3.2. Annual trend of dust, coarse- and fine-mode pollution AOD

One aim of our study is to learn more about how AOD may depend on aerosol particle size. Thus, we separated AOD into the contribution by dust-only ($\tau_D$), coarse-mode pollution ($\tau_{PC}$), and fine-mode pollution ($\tau_{PF}$). We used $R_D$, CMF, and the relationships of equations (1) to (6). Then, we investigated the change of annual mean values and the regional differences.

Before separating AODs according to aerosol types, we compared trends in the average values of $\tau_T$ for each region and site during 2001–2018 (supplementary Figure S2). The average value of $\tau_T$ at 440 nm was highest ($1.22 \pm 0.76$) in Beijing and was lowest (0.48 ± 0.12) in Thessaloniki. Regionally, Northeast Asia (1.22–0.58), Southeast Asia (0.93–0.76), and India (0.82–0.80) show high $\tau_T$ values. Europe (0.54–0.48) and the Middle East (0.56–0.49) show low values. The average $\tau_T$ value of North Africa except Ilorin (1.04 ± 0.48) tends to be at the lower end of values (Table 1).

The remarkable thing is the change of the annual averages of $\tau_T$. This change is summarized for each site in Table 2. Values of $\tau_T$ decreased every year in Northeast Asia and Europe. Notably, Beijing showed the most prominent decreasing trend of $\tau_T$. We find an average value of $-0.0138 \tau_{yr^{-1}}$. The Chiang Mai and Bangkok sites in Southeast Asia showed a decrease of $\tau_T$, too. We find average values of $-0.0039 \tau_{yr^{-1}}$ and $0.0012 \tau_{yr^{-1}}$.
at these two sites, respectively. However, this decrease of $\tau_T$ showed considerable change depending on the years considered in our study. We find, for example, that $\tau_T$ was slightly higher from 2008 to 2016 ($0.00117 \text{ yr}^{-1}$ for Chiang Mai and 0.0107 $\text{yr}^{-1}$ for Bangkok) and then sharply decreased in 2017 (Figure S2(e)).

The Middle East, India, and North Africa except Cinzana showed an increase of $\tau_T$ with time. As shown in Table 2, the rate of annual change of $\tau_T$ at Ballia and Kanpur showed a clear tendency to increase. We find 0.0048 $\tau_{\text{yr}}^{-1}$ and 0.0069 $\tau_{\text{yr}}^{-1}$, respectively. In most North Africa and the Middle East regions, the change rate of $\tau_T$ (-0.006 to 0.0020 $\tau_{\text{yr}}^{-1}$) is lower than other regions; however, $\tau_T$ of Tamanrasset sites increased as $0.0108 \tau_{\text{yr}}^{-1}$ because of $\tau_D$. It is supported by the results from El-Metwally et al., 2020. The authors conclude that Tamanrasset is the site most affected by dust from the downwind Saharan sources in the Saharan/Arabian region.

Other studies also confirmed this trend of regional $\tau_T$ change. Balarabe et al., 2016 reported that, based on AERONET data, there were no remarkable AOD trends for the period from 1998 to 2013 over Ilorin, Nigeria. Maghrabi and Alotaibi, 2018 reported a significant increase of approximately 0.119 of the annual mean AOD at 500 nm measured by AERONET sunphotometer in the central Arabian Peninsula from 1999 to 2015. Klingmüller et al., 2016 also stated that AOD increased in Saudi Arabia between 2001 and 2012. (Pilahome et al., 2020) reported an increase of AOD at 550 nm across Thailand based on analyzing MODIS (Moderate Resolution Imaging Spectroradiometer) data for the years 2006 to 2016. In addition, the change in the concentration of particulate matter, expressed by AOD, was attributed to different aerosol types. The authors identified the following aerosol types in decreasing order of importance: biomass burning, anthropogenic pollution, and soil emission. Meteorological conditions played a significant role, too (Bridhikitti and Overcamp, 2011; Wang et al., 2015; Yin et al., 2019; Chirasophon and Pochanart, 2020).

The annual mean of dust-only AOD ($\tau_D$) was high in North Africa, naturally, because dust is a major aerosol type in that part of the world. We find low values of $\tau_D$ in Southeast Asia, see Figure 2. In the India and Northeast Asia region except for Beijing, the annual change of $\tau_D$ tended to decrease from -0.004 to -0.002 $\tau_{\text{yr}}^{-1}$ (Table 2). In case of Beijing, $\tau_D$ increased by 36.3% (0.0011 $\tau_{\text{yr}}^{-1}$). In Europe, Middle East Asia, and North Africa, the annual rate of change increased from 0.002 to 0.0133 $\tau_{\text{yr}}^{-1}$. The exception is Ilorin, where we find -0.3% ($-0.0001 \tau_{\text{yr}}^{-1}$).

We assume that non-dust AOD values describe anthropogenic emissions and local biomass burning. Anthropogenic emissions mainly belong to the fine-mode fraction of the particle size distribution; therefore, denote their contribution to AOD as $\tau_{PF}$. In contrast, locally emitted particles from biomass burning belong to the coarse-mode fraction of pollution. We denote this part of AOD as $\tau_{PC}$.

The annual average values of $\tau_{PC}$ slightly increased in Europe, North Africa, and India, and decreased in the Middle East and Northeast Asia. We find values between -0.0015 and 0.0004 $\tau_{\text{yr}}^{-1}$. These numbers show that we need to consider percent variations to compare the rate of change by region, because the rate of change depends on the initial value. Especially, it is difficult to confirm the evident change of $\tau_{PC}$ in Europe and India. The percent variation in Thessaloniki and Ballia was 11.9% and 10.5%, respectively.
The annual average value of $\tau_{PF}$ also varied by region. The mean changes of $\tau_{PF}$ (at 440 nm) for the observation site in India show a clear tendency towards increasing values. We find 0.0055 $\tau_{PF} yr^{-1}$ for Ballia and 0.0019 $\tau_{PF} yr^{-1}$ for Kanpur. In the other regions, except for Erdemli (Europe), Ilorin, Tamanrasset (North Africa), and Sede Boker (Middle East), the changes of mean $\tau_{PF}$ tended to decrease significantly compared to $\tau_D$ and $\tau_{PC}$. We find values between -0.0011 to -0.0142 $\tau_{PF} yr^{-1}$. The stations at Erdemli, Ilorin, Tamanrasset, and Sede Boker showed a slight increase of $\tau_{PF}$, i.e., 0.0005, 0.0024, 0.0001, and 0.0008 $\tau_{PF} yr^{-1}$, respectively.

In the next step, we analyzed changes of $\tau$ (increase and decrease) in terms of aerosol types. We used in our analysis the percent variation of $\tau_T$, $\tau_D$, $\tau_{PC}$, and $\tau_{PF}$ (see Equation 7), respectively. We find a decline of $\tau_T$ and $\tau_{PF}$ in Europe. We find comparably high confidence levels of 95% (based on MK test) for the stations in Thessaloniki and Venice, see Table 3. In addition, the slope of $\tau_D$ in Thessaloniki and Venice (using the linear-regression method) was 0.0037 $\tau_D yr^{-1}$ and 0.0012 $\tau_D yr^{-1}$, but the percent variation was as high as 112.29% (Thessaloniki) and 125.22% (Venice).

$\tau_T$ decreased for the Asian stations, in a similar fashion to the sites in Europe. However, this change of $\tau_T$ was different for the Southeast and Northeast Asian stations if we take account of the aerosol types.

With respect to Southeast Asia, the decrease of $\tau_T$ seems to be mainly caused by a decrease in emissions of fine-mode particles. In Northeast Asia, changes in $\tau$ showed different characteristics according to region. The MK-test shows 95% confidence level for the trends observed for $\tau_T$ (Beijing and Osaka), $\tau_D$ (Osaka), $\tau_{PC}$ (Seoul and Osaka), and $\tau_{PF}$ (Beijing and Osaka).

Non-dust coarse-mode particles are mainly emitted from sources related to anthropogenic activities, e.g., traffic and plants. Regulations on emissions of air pollution thus may be responsible for the lower concentrations of this type of coarse-mode particles (Bridhikti and Overcamp, 2011; Mehta et al., 2018).

In the case of Beijing, which is affected by high levels of air pollution, $\tau_D$ increased by 36.2% (0.0011 $\tau_D yr^{-1}$). The non-dust part of AOD, and particularly the AOD related to fine-mode particles ($\tau_{PF}$), seemed to decrease by -38.1% (-0.0142 $\tau_{PF} yr^{-1}$). Thus, taking account of all three components, we find that the decrease of fine-mode pollution mainly causes a decrease in total AOD. This result is similar to results reported in previous research (Li et al., 2015). The authors show that black carbon in China decreased due to the strict policy of reduction of pollution emissions. Li et al. (2015) furthermore stated that dust aerosol concentrations had increased between 2002 and 2006 but then remained constant between 2008 and 2013.

The annual change of $\tau_T$ for the stations in North Africa increased during (0.0006–0.0108 $\tau_D yr^{-1}$) over ten more years. The exception is the station at Ciznana. The properties of the variations seem to be different for the different regions. The percent variation of the $\tau_T$increase at Tamanrasset is quite obviously related to a change of $\tau_D$. The Cape Verde and Ilorin stations showed a slightly increasing trend, most likely caused by a change of coarse- and fine-mode particles. Ciznana is the only site of all North African stations where we find a decrease of $\tau_T$. This decrease seems to be driven by a decrease in $\tau_{PF}$.

The $\tau_D$ in the Middle East increased, which resulted in an increase of total optical depth. In the case of India, the change of $\tau_T$ is related to a decrease in $\tau_D$ and an increase in $\tau_{PC}$ and $\tau_{PF}$. The increase in $\tau_{PC}$ and $\tau_{PF}$ may
be associated with new policies related to aerosol emissions in the Indian regions considered in this study (Khan et al., 2019; Yin et al., 2019).

A comprehensive graph of the annual average, the overall increase, and the percent variation associated with total, dust-only, and coarse- and fine-mode pollution AOD is presented in Figure 3.

3.2. Ångström Exponent and FMF: Annual Trends

Our analysis shows regional differences in aerosol type and size changes which can be inferred from annual mean values of AOD, see Table 2. In addition to this result, we examined the change of particle size distribution, especially that of fine-mode particles, more closely by using the Ångström exponent of total ($\alpha_T$) and fine-mode particles ($\alpha_{PF}$) and the FMF (fine-mode fraction). The changes of $\alpha_T$ and $\alpha_{PF}$ also can be seen in supplementary Figures S6 and S7. The value of $\alpha_{PF}$ indicates the presence of anthropogenic pollution particles. FMF describes the fraction of fine-mode particles compared to all particles in the atmospheric column observed by the sun photometer (Table 2). Figure 4 shows the comprehensive results of the average value, the increasing rate, and the percent variation of $\alpha_T$ and $\alpha_{PF}$.

The $\alpha_T$ in Europe, North Africa, and the Middle East regions except Ilorin decreased during the research period we analyzed. We find negative values ranging from -3.3% to -30.5%. FMF decreased by -3.7% to -21.1%. These trends show that the particles on average became larger. This result is similar to the main findings discussed in the previous section, where we showed that $\tau_D$ and $\tau_{PC}$ increased and $\tau_{PF}$ decreased. These changes are associated with increased levels of dust particle concentration and reduced levels of fine-mode particles due to climate change (Bridhikitti and Overcamp, 2011; Krasnov et al., 2014; Klingmüller et al., 2016) and environmental regulations (Li et al., 2015; Mehta et al., 2018; Pozzer et al., 2019; Chirasophon and Pochanart, 2020). The Ilorin site in Nigeria is different from the other North African regions. Ilorin is located in the transition zone between the humid tropical area (South Africa) and the semi-arid area (North Africa) (Ogunjobi et al., 2008; Falaiye et al., 2015). This site also exhibits an increase in anthropogenic emissions caused by the rapid increase of population and economic growth (Balarabe et al., 2016).

Additionally, we checked if changes of $\alpha_{PF}$ corroborate our assumption that characteristics of the size distribution of the fine-mode particles also changed. The values of $\alpha_{PF}$ in Europe, North Africa, and the Middle East except Erdemli (Turkey) and Mezaira (UAE) show positive trends, i.e., 0.0015 $yr^{-1}$ to 0.0101 $yr^{-1}$. These increases indicate that the size of the fine-mode particles became smaller.

The annual mean of $\alpha_T$ at Ballia and Kanpur increased in 0.0050 $yr^{-1}$ (4.9%) and 0.0024 $yr^{-1}$ (4.1%), respectively. These increases indicate that particle size became smaller. The increase of the FMF value corroborates this result. The values of $\alpha_{PF}$ showed a positive trend at the Kanpur site, which means that fine-mode particles became smaller over the course of several years. The negative values of $\alpha_{PF}$ in Ballia might be caused by the comparably few data points available for the first few years of observations (Supplementary Table S1). Kanpur is a highly polluted city in the Indo-Gangetic region (Chakraborty et al., 2015; Chen et al., 2016) which may explain in large part the high concentration of small particles in this region.
In Southeast Asia, the values of $\alpha_T$ increased. We find $0.0105 \, \text{yr}^{-1}$ (6.7%) at Chiang Mai and $0.0119 \, \text{yr}^{-1}$ (8.0%) in Bangkok. $\alpha_{PF}$ showed a more increasing trend compared to $\alpha_T$ as $0.0163 \, \text{yr}^{-1}$ (9.0%) and $0.0175 \, \text{yr}^{-1}$ (10.0%) at Chiang Mai and Bangkok, respectively. On the contrary, FMF showed a negative trend as $-0.0022$ (-0.9%) at Chiang Mai and $-0.0002$ (-0.1%) at Bangkok.

Considering that the major aerosols in Southeast Asia are biomass burning aerosol and anthropogenic aerosol composed of fine-mode aerosol, it is estimated that the particle size of these two types is continuously decreasing (Chirasophon et al., 2020; Bridhikitti et al., 2011; Khan et al., 2019; Yin et al., 2019).

The values of $\alpha_T$ in Northeast Asia have a bit of difference to 1.3–13.3% depending on stations. For example, Seoul and Taipei had highly positive increases of $\alpha_T$. That positive increases could be related to reducing the dust concentration, which would lead to a significant decrease of $\tau_{PC}$ compared to that of $\tau_{PF}$. For Beijing, the $\alpha_T$ slightly increased compared to the other sites. Our data show that $\tau_D$ increased. In addition, the decrease of $\tau_{PC}$ was more significant than the decrease of $\tau_{PF}$. Thus, we come to the conclusion that the increase of $\alpha_T$ most likely was caused by a change in the atmosphere's dust load.

The $\alpha_{PF}$ values in the Asian region increased by 2.3% to 13.1% ($0.0024$ to $0.0175 \, \text{yr}^{-1}$) over the observation periods considered in our study. The data indicate that fine-mode particle size became smaller over the years and that this change might also be related to changes in the chemical composition of the pollution particles. Joo et al., 2021 reported that extinction efficiencies in Korea increased although the PM$_{2.5}$ mass concentration decreased. This result suggests that even though the PM$_{2.5}$ concentration decreased compared to the past, either particle size of PM$_{2.5}$ became smaller or the number of particles with high scattering efficiency increased. Uno et al., 2020 stated that the chemical composition of aerosols in East Asia changed significantly. With regard to regions downwind of China, sulfate (accumulation mode) concentrations decreased significantly, and nitrate (accumulation–coarse mode) concentrations increased (Plaza et al., 2011). These results show that there clearly is a need to conduct more long-term studies on the relationship between aerosol mass and optical density, size distribution, and chemical composition.

### 4. Summary and Conclusion

We analyzed trends in regional AOD based on separating aerosols into dust and coarse- and fine-mode pollution particles for 17 AERONET observation sites. Mainly, we focused on the change in AOD and Ångström exponents of fine-mode pollution particles ($\tau_{PF}$ and $\alpha_{PF}$). The following key results were obtained:

- The change characteristics of $\tau_D$, $\tau_{PC}$, and $\tau_{PF}$ are different for each region. In Europe and Asia, the decrease in $\tau\alpha$ was remarkable due to effects caused by new air policies. The $\tau_D$ increased near the Sahara region.
- The $\tau_{PF}$ mainly decreased in Europe and Southeast Asia, whereas $\tau_{PC}$ decreased in the Middle East and Northeast Asia. $\tau_{PC}$ and $\tau_{PF}$ are related to non-dust AOD. Thus, we assume that changes related to the practical policymaking have on air pollution emissions.
- The mean size of particle size distribution became larger in Europe, the Middle East, and North Africa because of emissions of dust particles. On the other hand, the mean particle size became smaller in India and Southeast Asia. We assume that this reduction of particle size is primarily related to the change in the concentration of fine-mode particles.

- The changes of $\alpha_{PF}$ show that the size of fine-mode particles emitted from anthropogenic pollution most likely became smaller compared to particle size in past times in the regions we investigated here. We believed that the size change of fine-mode particles might be related to secondary aerosols, and it can cause adverse effects on visibility and human health.

Particle size and characteristics are essential to understanding air pollution and visibility and have changed over the past decade or more, but few studies about those properties. Therefore, we need more studies paying attention to changes in the size and quantity of fine-mode pollution particles to reflect air pollution policy.

**Author contributions**

JS1 (J. Shin) and JS2 (J. Sim) analyzed data; ND, SJ, TK, GK collected resources; SS and DS advised the methodology and curated data; YN supervised all the research; JS1 wrote the manuscript draft; DM, MT, and YN wrote review and editing;

Table 3. MK-test results in terms of number of data points (n), Z-value, p-value, and Sen’s slope (S) of $\tau_{440}$ nm according to aerosol type. The Z-value follows the standard normal distribution and explains the significance of the trend. The p-value decides on the significance of the hypothesis (from highly likely to highly unlikely) depending on the significance level. S is Sen’s slope estimator and means the degree of increase or decrease in trend. (* denotes clear trend with 95% confidence level, $|z| > 1.96$)
