1 **Abstract.** Evaluating the influence of anthropogenic emissions changes on air quality requires accounting for the influence of
2 meteorological variability. Statistical methods such as multiple linear regression (MLR) models with basic meteorological vari-
3 ables are often used to remove meteorological variability and estimate trends in measured pollutant concentrations attributable
4 to emissions changes. However, the ability of these widely-used statistical approaches to correct for meteorological variability
5 remains unknown, limiting their usefulness in the real-world policy evaluations. Here, we quantify the performance of MLR
6 and other quantitative methods using simulations from a chemical transport model, GEOS-Chem, as a synthetic dataset. Focus-
7 ing on the impacts of anthropogenic emissions changes in the US (2011 to 2017) and China (2013 to 2017) on PM_{2.5} and O₃,
8 we show that widely-used regression methods do not perform well in correcting for meteorological variability and identifying
9 long-term trends in ambient pollution related to changes in emissions. The estimation errors, characterized as the differences
10 between meteorology-corrected trends and emission-driven trends under constant meteorology scenarios, can be reduced by
11 30%-42% using a random forest model that incorporates both local and regional scale meteorological features. We further
12 design a correction method based on GEOS-Chem simulations with constant emission input and quantify the degree to which
13 anthropogenic emissions and meteorological influences are inseparable, due to their process-based interactions. We conclude
14 by providing recommendations for evaluating the impacts of anthropogenic emissions changes on air quality using statistical
15 approaches.

16 1 Introduction

17 Researchers and policy makers have long been interested in understanding the anthropogenic drivers of trends in observed air
18 pollutant concentrations in order to inform air quality policies. Declining trends in pollutant concentrations such as particulate
19 matter with diameter less than 2.5 microns ($PM_{2.5}$) have been observed in many countries that adopted policies to limit
20 anthropogenic emissions such as SO_2 and NO_x , including the US (McClure and Jaffe, 2018) and China (Zhang et al., 2019). As
21 information on anthropogenic emissions are often unavailable or very uncertain, researchers and policy makers often rely on the
22 trends in measured air pollutants to assess the effects of policies. Attributing trends in observed concentrations to anthropogenic
23 emissions changes requires correcting for the influence of changing meteorology, which has become increasingly important but
24 challenging in a changing climate (Saari et al., 2019). Numerous papers attempt to use statistical methods to separate impacts of
25 meteorology from emissions changes in evaluating trends in air quality, but the performance of these commonly-used statistical
26 approaches remains unassessed. Further, the impacts of meteorological variability may not even be distinguishable from air
27 quality trends driven by anthropogenic emission changes, due to their interactions; the magnitude of this interaction also
28 remains unquantified. In this paper, we devise a model-based experiment for evaluating the performance of different statistical
29 methods used for meteorological corrections. We focus on a case of identifying emissions-driven linear trends in measured
30 concentrations of $PM_{2.5}$ and ozone (O_3), when information on the anthropogenic emission is not available.

31 Measured pollutant concentrations are often used as the primary basis for evaluating air quality actions. For example, in
32 2013, China's central government established targets that aimed to reduce annual average $PM_{2.5}$ concentrations of three urban
33 clusters by 15% to 25% between 2012 and 2017 (State Council of the People's Republic of China, 2013). This later translated
34 into a stringent and binding target of a maximum annual mean $PM_{2.5}$ concentration of $60 \mu g/m^3$ in 2017 for Beijing, which was
35 ultimately reached (the 2017 concentration was $58.5 \mu g m^{-3}$) (Beijing Municipal Ecology and Environment Bureau, 2013).
36 However, several studies estimated that the concentration would have exceeded this target in Beijing were it not for meteoro-
37 logical conditions in winter 2017 that favored pollution reductions (Vu et al., 2019; Chen et al., 2019; Cheng et al., 2019).
38 The European Union and US Environmental Protection Agency (EPA) use a three-year average of the $PM_{2.5}$ concentration
39 to determine compliance with air quality standards (European Union, 2020; U.S. Environmental Protection Agency, 2019).
40 The US EPA has also proposed to use statistical approaches that aim to correct for the impacts of weather variability on O_3
41 concentrations in the designation processes (Wells et al., 2021).

42 Many studies use multiple linear regression (MLR) models with basic meteorological variables to correct for meteorological
43 variability in order to estimate the impacts of emissions changes on measured air quality (Otero et al., 2018; Zhai et al., 2019;
44 Li et al., 2018, 2020; Han et al., 2020; Chen et al., 2020). Zhai et al. (2019) and Li et al. (2020) use MLR models to estimate the

45 degree to which trends in $PM_{2.5}$ and O_3 from 2013 to 2019 in China were driven by anthropogenic emissions changes. They
46 first use MLR to predict the $PM_{2.5}$ and O_3 concentrations with meteorological variables, and then interpret the residuals of
47 the MLR model as signals resulting from emissions changes. A related approach is to combine MLR with techniques that can
48 decompose time series of observed concentrations into long-term, seasonal, and short-term components (e.g., Kolmogorov-
49 Zurbenko (KZ) filters (Zurbenko, 1994)). Ma et al. (2016) and Chen et al. (2019) use KZ filters to calculate the long-term
50 component of observed $PM_{2.5}$ and then apply MLR to separate the impacts of long-term meteorological changes on the
51 concentrations. Henneman et al. (2015) apply MLR to the short-term component (identified by KZ filters) of air pollutant
52 concentrations near Atlanta during 2000 to 2012, to separate the impact of short-term meteorological variability, and then
53 estimate the long-term trend in air quality.

54 Other statistical methods including non-linear regression or machine learning models have also been used to correct for
55 meteorological variability (Holland et al., 1998; Carslaw et al., 2007; Hayn et al., 2009; Vu et al., 2019). One popular method
56 is to use a generalized additive model (GAM) to estimate non-linear smooth functions of each meteorological variable within a
57 given smoothing function family with penalization on non-smoothness. The US EPA uses a GAM model of temperature, wind
58 direction and speed, humidity, pressure, stability, transport trajectories, and synoptic weather to perform weather corrections in
59 assessing long term trends in O_3 (Camalier et al., 2007). An increasing number of studies use machine learning models (Grange
60 et al., 2018; Vu et al., 2019; Zhang et al., 2020; Shi et al., 2021; Qu et al., 2020). Vu et al. (2019) use a random forest model
61 to predict pollutant concentrations in Beijing with time index and meteorological variables and then calculates the “weather-
62 normalized” concentration for each day with 1000 sets of meteorological fields drawn from the historical meteorological data.
63 They found that the decrease of $PM_{2.5}$ during 2013 to 2017 was largely driven by emissions reductions, although the magnitude
64 of reduction is smaller when correcting for meteorological variability.

65 Despite a large number of papers which apply various meteorology correction methods, very little is known about whether
66 these methods can effectively correct for meteorological variability and thus realistically estimate the counterfactual air quality
67 and reveal the underlying impacts of anthropogenic emissions changes. Most studies cite the prediction performance of their
68 statistical models (such as R^2 and/or mean squared errors) to justify their method choice and analysis. However, good pre-
69 diction performance does not guarantee the correct estimation of counterfactuals and causal effects (Runge et al., 2019). The
70 performance of these meteorology-corrected methods is unable to be assessed using observational data alone, as the underly-
71 ing emission-driven trends without influence from meteorological variability cannot be derived from data. Further, statistical
72 analyses often assume that the influence of meteorological variability on pollutant concentration can be cleanly separated from
73 the influence of anthropogenic emissions changes. This is not completely possible, as the impacts of meteorological variability

74 on pollutant concentration will also vary depending on the emissions. The degree to which this interaction affects the ability to
75 calculate emissions-related trends under changing meteorology also remains unknown.

76 Here, we conduct a model experiment to evaluate the performance of widely-used statistical models in correcting for me-
77 teorological variability and estimating emissions-driven trends in air quality (see figure 1). We focus on the impacts of an-
78 thropogenic emissions changes on annual $PM_{2.5}$ and summer O_3 in the US (2011-2017) and China (2013-2017), two periods
79 well-studied in previous literature. Using a 3-D atmospheric chemical transport model GEOS-Chem, we simulate two sets of
80 scenarios – “observational scenarios” with assimilated meteorological inputs (with interannual variability) and “counterfactual
81 scenarios” with constant meteorological inputs. Using simulated daily concentrations in the observational scenarios, we es-
82 timate meteorology-corrected trends for each grid cell from regression models using different statistical correction methods.
83 We then compare the derived trends with the emissions-driven trends in the counterfactual scenarios (which are free of mete-
84 orological variability by design), calculating the resulting “error” in trend estimation. We further design a correction method
85 based on GEOS-Chem constant emission simulations, and use it to quantify the degree to which attribution to meteorology and
86 emissions separately is possible. Finally, we apply the different statistical correction methods to observational data from sur-
87 face monitoring networks in the US and China, discussing the variability across different methods. We conclude by providing
88 recommendations for techniques to evaluate air pollution policies under changing meteorological conditions.

89 **2 Method**

90 **2.1 GEOS-Chem**

91 GEOS-Chem is a global three-dimensional chemical transport model driven by assimilated meteorological data from the God-
92 dard Earth Observation System (GEOS-5) of the NASA Global Modeling and Assimilation Office (GMAO) (Bey et al. (2001),
93 <http://www.geos-chem.org/>). The simulation of $PM_{2.5}$ in GEOS-Chem represents an external mixture of secondary inorganic
94 aerosols, carbonaceous aerosols, sea salt, and dust aerosols. GEOS-Chem includes detailed O_3 - NO_x -volatile organic carbon
95 (VOC)-aerosol-halogen tropospheric chemistry (Travis et al., 2016; Sherwen et al., 2016). The GEOS-Chem model has been
96 previously used to study the changes in $PM_{2.5}$ and O_3 during our studied periods, and model simulations have been shown to
97 be consistent with the observed concentrations (e.g., see Li et al. (2017a); Xie et al. (2019) for the US, and Li et al. (2018);
98 Lu et al. (2019); Zhai et al. (2021) for China). Studies in both regions show that the GEOS-Chem model is able to reproduce
99 the spatial, seasonal, and interannual variability and the long-term trends in observed pollutant concentrations, despite biases
100 in absolute concentrations in certain species and regions (Heald et al., 2012; Travis et al., 2016; Tian et al., 2021).

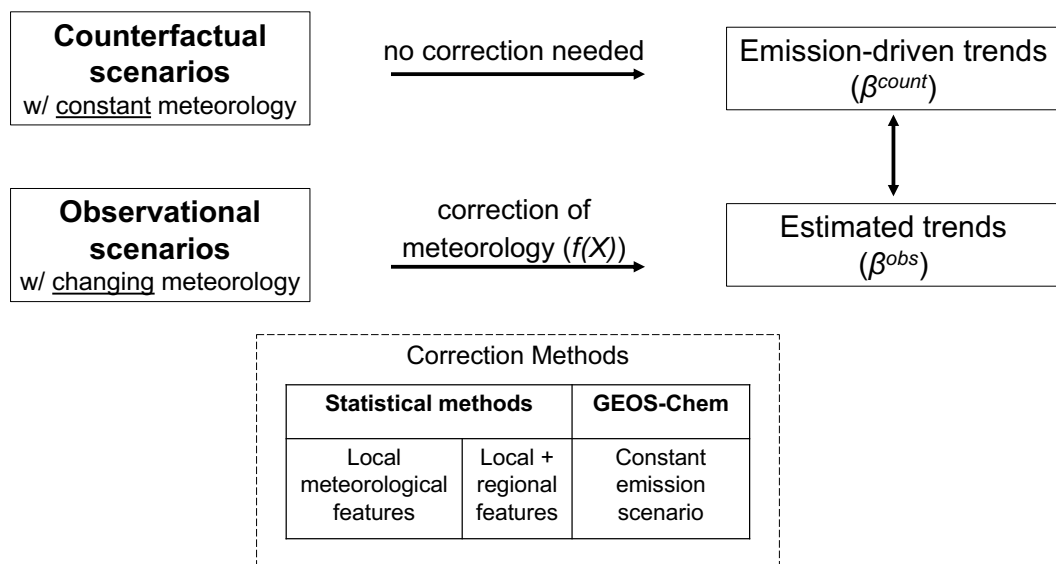

Figure 1. Overview of research methodology. Terms and coefficients are linked to the associated terms in equation 1 and table 1.

101 We use GEOS-Chem version 12.3.0 with a horizontal resolution of $0.5^\circ \times 0.625^\circ$ in North America and Asia (Wang et al.,
 102 2004). For each scenario, we first conduct a global run at a horizontal resolution of $4^\circ \times 5^\circ$, with a 12 month spin-up. These
 103 global runs are then used as the boundary conditions for nested simulations in US and Asia with finer resolution of $0.5^\circ \times 0.625^\circ$.

104 2.2 GEOS-Chem scenarios

105 Table 1 shows the simulations included in our model experiments. We simulate two sets of scenarios – “observational scenarios”
 106 with interannual variability in meteorology and “counterfactual scenarios” with constant meteorological inputs. Both scenarios
 107 use the same emissions inventory as input (see section 2.3). For each grid cell, we estimate the linear trends in pollutant
 108 concentrations from simulated daily $PM_{2.5}$ and O_3 concentrations. We focus on the daily 24-hour average $PM_{2.5}$ over all
 109 seasons, and the maximum daily average 8-hour (MDA8) O_3 in summer (June, July, August). Our focus on the three summer
 110 months is consistent with many previous studies (e.g., Shen et al. (2015)), although this may not capture the peak ozone
 111 season for certain regions of the US and China. Our GEOS-Chem simulations use meteorological fields from the Modern-
 112 Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2) (Gelaro et al., 2017). We aggregate the
 113 hourly meteorological data for consistency with the pollutant concentrations: a 24-hour average for $PM_{2.5}$ analysis and the
 114 corresponding 8-hour average for O_3 . Meteorological features that are used in the statistical models can be found in section
 115 2.4.

116 **2.2.1 Observational scenarios**

117 Observational scenarios simulate $\text{PM}_{2.5}$ and O_3 under changing emissions and changing meteorological fields. Trends es-
118 timated under the observational scenarios (β^{obs}) are subject to the influences of interannual meteorological variability. Our
119 model experiments were not specifically designed to reproduce observed air quality in these two regions, but rather to pro-
120 vide a realistic test case to evaluate the performances of statistical methods. Nevertheless, as shown in figure A1 and A2, the
121 simulated concentrations in $\text{PM}_{2.5}$ and O_3 largely reproduce the daily variability in observed pollutant concentrations. The
122 linear trends in simulated $\text{PM}_{2.5}$ and O_3 concentrations in the observational scenario are largely consistent with trends of the
123 measured concentrations. For example, the average trend (\pm one standard deviation) in the US is $-0.27 \pm 0.30 \mu\text{g}^{-3}/\text{year}$ (obser-
124 vation) and $-0.39 \pm 0.24 \text{ ppb}/\text{year}$ (GEOS-Chem) for $\text{PM}_{2.5}$, and $-0.91 \pm 0.98 \text{ ppb}/\text{year}$ (observation) and $-1.02 \pm 0.83 \text{ ppb}/\text{year}$
125 (GEOS-Chem) for O_3 . The only exception is that our model cannot reproduce the increasing $\text{PM}_{2.5}$ trends in the Northwest
126 US because we do not consider interannual variability in biomass burning emissions.

127 **2.2.2 Counterfactual scenarios**

128 Counterfactual scenarios simulate $\text{PM}_{2.5}$ and O_3 under changing emissions but constant meteorology. All simulation years in
129 the counterfactual scenario use the meteorological fields of the start year (2011 for US, 2013 for China). Trends estimated
130 under the counterfactual scenario (β^{count}) are not subject to interannual meteorological variability; we use this as a proxy for
131 the trends in pollutant concentrations driven by emissions changes alone. In a sensitivity analysis, we also simulate the counter-
132 factual scenario for China using the meteorological fields at the end year 2017 (at 4×5 degree resolution, due to computational
133 constraints). We find that the linear trend in $\text{PM}_{2.5}$ and O_3 for each grid cell is highly consistent in the counterfactual scenarios
134 across the choice of the meteorological years (see figure A5).

135 **2.2.3 Assumptions for GEOS-Chem experiments**

136 It is important to note that we do not assume our GEOS-Chem simulations perfectly represent the underlying pollutant con-
137 centration in the real world (although the model compares relatively well with the observational data). Rather, our main focus
138 is to evaluate how much different statistical methods can explain the differences between the observational and counterfactual
139 scenarios. The assumption here is that the differences between observational and counterfactual scenarios are useful approxima-
140 tions of the impacts of meteorological variability on pollutant concentrations. The implications of uncertainty in GEOS-Chem
141 for our results can be found in the discussion section.

GEOS-Chem scenarios	Emissions inventory	Meteorological fields	Trend estimates	Meteorological correction
Counterfactual scenarios	Changing 2011-2017 (US) 2013-2017 (China)	Constant 2011 (US) 2013 (China)	β^{count}	
Observational scenarios	Changing 2011-2017 (US) 2013-2017 (China)	Changing 2011-2017 (US) 2013-2017 (China)	$\beta^{uncorrected}$ β^{MLR} β^{GAM} β^{RF} $\beta^{LASSO-regional}$ $\beta^{RF-regional}$ β^{gc}	No correction Linear combination of local features GAM using local features RF using local features LASSO using local and regional features RF using local and regional features Use simulations from constant emissions scenarios
Constant emissions scenarios	Constant 2011 (US) 2013 (China)	Changing 2011-2017 (US) 2013-2017 (China)		

Table 1: Overview of GEOS-Chem scenarios and meteorological correction methods.

142 **2.3 Emissions inventory**

143 For the US, we use the National Emissions Inventory 2011 (NEI 2011) as a baseline emissions inventory and scale the emissions
144 in 2012 to 2017 to match the annual total emissions each year (U.S. Environmental Protection Agency, 2021b). For China,
145 we use the monthly Multi-resolution Emission Inventory for China (MEIC) during 2013 to 2017 (Li et al., 2017b; Zheng
146 et al., 2018). During the studied time periods, the US and China experienced dramatic decreases in anthropogenic emissions,
147 particularly in SO₂ and NO_x. In the US, total anthropogenic emissions of SO₂ decreased by 57% and NO_x emissions decreased
148 by 26% during 2011 to 2017 (see figure A3). In China, anthropogenic SO₂ emissions decreased by 59% and NO_x emissions
149 decreased by 21% during the 2013-2017 period (see figure A4).

150 Natural emissions of multiple chemical species are calculated online in the simulations (rather than prescribed) in the GEOS-
151 Chem model and thus can be influenced by meteorological variability (see Keller et al. (2014) for more details). Impacts of
152 meteorology on PM_{2.5} and O₃ concentrations through changes in the natural emissions are considered here as part of the
153 meteorology - concentration relationship. These emissions include NO_x emissions from lightning and soil processes, sea salt
154 emissions, dust emissions, and biogenic volatile organic carbon (VOC) emissions. However, biomass burning emissions are
155 prescribed in the GEOS-Chem model and we hold them constant at the level of the start year. We make this simplification
156 because the GEOS-Chem model uses biomass burning emissions from external inventories such as Global Fire Emissions
157 Database (Werf et al., 2017), and it is impossible to distinguish natural fire emissions (part of the meteorological variability)
158 from anthropogenic fire emissions (e.g., from farm residual burning). The role of natural emission changes in the meteorology-
159 air quality relationship is further expanded on in the discussion section.

160 **2.4 Statistical and machine learning models**

161 **2.4.1 Model with local meteorological variables**

162 We assess the performance of statistical and machine learning models to correct for the meteorological variability in the
163 observational scenarios. We evaluate these methods with a commonly-used framework (e.g., used in Li et al. (2018) and
164 Zhai et al. (2019)) which models the air pollutant concentrations of each individual grid cell using an additive form of a
165 trend component, a meteorology component, and time fixed effects (to capture daily and monthly variability not related to
166 meteorology). More specifically, we estimate the following regression equation for each grid cell i :

$$167 \quad y_{it} = \beta_i^{obs} \times t + f_i(X_{it}) + \eta_{it} + \epsilon_{it} \quad (1)$$

168 where y_{it} denotes the $\text{PM}_{2.5}$ or O_3 concentration at grid cell i on day t . t is the time index (e.g., in the US, $t=1$ for January 1st,
169 2011 and $t=2$ for January 2nd, 2011). X_{it} denotes the local meteorology features (i.e. meteorological variables in grid cell i on
170 day t). η_{it} is the month-of-year \times day-of-month fixed effect to capture daily and monthly variability of pollutant concentrations
171 that are not related to the meteorological variability (e.g., seasonal cycle in O_3 and $\text{PM}_{2.5}$). ϵ_{it} is the normally-distributed error
172 term. β_i^{obs} represents the meteorology-corrected trend in $\text{PM}_{2.5}$ or O_3 concentration for grid cell i estimated with the standard
173 ordinary least square method. We use the absolute differences $|\beta_i^{obs} - \beta_i^{count}|$ to evaluate the performance of different methods
174 to correct for meteorological variability for any given grid cell i .

175 Here, $f_i(X_{it})$ represents the specifications of local meteorological features for grid cell i under different methods. In addition
176 to the commonly-used multiple linear regression (MLR) model, we also evaluate following models with higher flexibility:
177 polynomial regression models (quadratic, cubic), cubic spline models, generalized additive models (GAM, implemented with
178 R package “mgcv” by Wood (2011)), and Random Forest (RF) models. We refer to the trend estimates estimated without
179 $f_i(X_{it})$ as “uncorrected”. We focus on the methods in table 1 in the main manuscript, and the performance of the other
180 methods can be found in table A1 and A2. Note that the time fixed effects are modelled differently in RF models due to the
181 estimation procedure. More details on the implementation of RF can be found in SI.

182 We use the following ten variables from MERRA-2 as our selected meteorological features for the statistical analysis: surface
183 temperature, precipitation, humidity, planetary boundary layer height, cloud fraction, surface air pressure, and wind speed (U
184 and V direction, at surface and 850 hpa level). These variables are the most commonly used features in previous studies. We
185 also perform sensitivity analyses that include nine more meteorological features: direct photosynthetically-active radiation,
186 diffuse photosynthetically-active radiation, tropopause pressure, friction velocity, top soil moisture, root soil moisture, snow
187 depth, surface albedo, and surface air density. These features are selected because they are used as primary or intermediate
188 inputs for calculating $\text{PM}_{2.5}$ or O_3 concentrations in the GEOS-Chem model and may contain information that help explain
189 variability in pollutant concentrations.

190 **2.4.2 Model with local and regional meteorological variables**

191 We also evaluate models that use both local and regional meteorological features. Regional meteorological features are impor-
192 tant for explaining variability in local pollutant concentrations due to 1) pollution transport from neighboring locations, and
193 2) influences from meteorological systems at synoptic scale (i.e. large scale weather systems that span over 1000 kilometers
194 such as circulation patterns) (Tai et al., 2012; Shen et al., 2015; Zhang et al., 2018; Leung et al., 2018; Han et al., 2020). As
195 the incorporation of both local and regional features can quickly expand the dimensionality of the feature space, here we use
196 the Least Absolute Shrinkage and Selection Operator (LASSO) and the Random Forest (RF) model, two statistical models that

197 show good prediction performances with high dimensional data inputs. We estimate the following equations:

$$198 \quad y_{it} = \beta_i^{obs} \times t + g_i(X_{it}, Z_t) + \eta_{it} + \epsilon_{it} \quad (2)$$

199 where $g_i()$ denotes the functional form fitted by LASSO or RF. X_{it} again denotes the local meteorology features for grid cell
200 i on day t . Z_t denotes the regional scale meteorology features including the meteorological features for every grid cell in the
201 US on day t (98 cells in 4×5 degrees; we choose a relatively coarse resolution due to computational cost). Meteorological
202 information in each location in the US may help explain the pollutant concentrations in grid cell i . In total, we have 10 local
203 features (X_{it}) and $10 \times 98 = 980$ regional scale features (Z_t). The coefficient β_i^{obs} is obtained with the double machine learning
204 approach by Chernozhukov et al. (2018). In particular, the hyper-parameters and coefficients of LASSO and RF are selected
205 and fitted using 4-fold cross-validation to avoid the “overfitting risk”. More details on the implementation of LASSO and RF
206 can be found in SI.

207 **2.5 Correction approach using GEOS-Chem constant emissions scenario**

208 We further design and evaluate an approach to correct for meteorology variability with GEOS-Chem simulations (referred
209 to as “constant-emis” approach). The “constant-emis” approach uses GEOS-Chem simulations with constant anthropogenic
210 emissions and changing meteorological fields (“constant emissions scenarios” in table 1). All years in the constant emissions
211 scenario use anthropogenic emissions of the start year (2011 for US, 2013 for China). We estimate the following equations:

$$212 \quad y_{it} = \beta_i^{gc} \times t + SIM_{it} + \eta_{it} + \epsilon_{it} \quad (3)$$

213 where SIM_{it} denotes the simulated concentrations on day t in grid cell i in the constant emissions scenarios. SIM_{it} serves a
214 similar purpose as the term “ $f_i(X_{it})$ ” in equation 1, but comes from the GEOS-Chem simulation. Some previous studies have
215 also used model simulations with constant emissions input as a way to characterize meteorological variability (Zhong et al.,
216 2018; Zhao et al., 2020). β_i^{gc} is the estimated meteorology-corrected trend in $PM_{2.5}$ or O_3 concentration using this model-based
217 correction method.

218 Compared to previous statistical and machine learning approaches, the “constant-emis” approach better captures the meteo-
219 rological variability as simulated in GEOS-Chem (as SIM_{it} are directly taken from GEOS-Chem). Therefore, the difference
220 between the trend estimates (β^{gc}) and counterfactual trends (β^{count}) provides a conceptual minimum for estimation errors us-
221 ing the framework of equation 1 to perform meteorological corrections. The commonly-used framework of equation 1 assumes

222 that the impacts of meteorology variability can be separated from the impacts of anthropogenic emissions. In our experiments,
223 this assumption indicates that the differences between the counterfactual scenario and the observational scenario can be solely
224 explained by the meteorological variables. However, the difference in pollutant concentrations between these scenarios is also
225 in part driven by emissions in their interaction with meteorology (despite the fact that our different scenarios use the same
226 emissions inventory). We use $|\beta_i^{gc} - \beta_i^{count}|$ to quantify the estimation error associated with ignoring such interactions in this
227 framework.

228 **2.6 Air quality observation data**

229 We use the surface air quality measurements from the Air Quality Systems administered by the US EPA (U.S. Environmental
230 Protection Agency, 2021c). We use the daily 24-hour average of $PM_{2.5}$ concentrations for all months and the daily maximum
231 8-hour average (MDA8) O_3 concentrations for June, July and August. Figure A1 shows the locations, trends in measured
232 concentrations, and correlations between GEOS-Chem simulations and measured concentrations.

233 The surface air quality measurements in China come from the monitoring network from China's Ministry of Ecology and
234 Environment (2021). The monitoring network was launched in 2013 and has expanded to all prefecture level cities in mainland
235 China. We use the daily 24-hour average of $PM_{2.5}$ concentrations and the MDA8 O_3 concentrations for summer. Figure A2
236 shows the locations, trends in measured concentrations, and correlations between GEOS-Chem simulations and measured
237 concentrations.

238 We use the meteorological variables from MERRA-2 when performing meteorology corrections at these monitoring stations,
239 because the meteorology information is not available for all these variables at the station level. This is consistent with previous
240 analysis estimating the meteorology-corrected trends using observational air quality data (e.g., Li et al. (2018)).

241 **3 Results**

242 **3.1 Performance of different correction methods: US (2011-2017)**

243 Figure 2A and 2C show the trends in $PM_{2.5}$ and O_3 concentrations in the counterfactual scenarios in the US. When holding
244 meteorological fields constant across years, decreasing trends in the simulated $PM_{2.5}$ concentrations across the US result from
245 decreasing anthropogenic emissions. The counterfactual scenario also shows negative linear trends in O_3 concentrations in all
246 but three grid cells in the West. Increases in summer O_3 in these locations result from the non-linear relationship between O_3
247 concentrations and NO_x emissions.

248 Figure 2B and 2D show the degree to which different meteorological correction methods can recover the emissions-driven
249 trends in the counterfactual scenarios. When no correction for meteorology is performed (“uncorrected” in figure 2B), we
250 observe large estimation errors in trend estimates over the Northeast and Southern US by up to $0.25 \mu\text{g m}^{-3}/\text{year}$, an error
251 that is 50% of the counterfactual trends. We find that the widely-used MLR method does not help reduce these errors in $\text{PM}_{2.5}$
252 trend attributions. MLR has a modest impact on reducing the errors in Northeast US, but it does not decrease the errors over
253 the Southern US and leads to even higher errors over Midwest. Nationwide, the average magnitude of errors (relative to the
254 counterfactual scenario) *increases* with the MLR correction ($0.083 \mu\text{g m}^{-3}/\text{year}$) compared to the uncorrected case ($0.066 \mu\text{g}$
255 $\text{m}^{-3}/\text{year}$). Among the five methods, we find that the RF model using both local and regional scale features (“RF-regional” in
256 figure 2) offers the best performance in recovering the trends in the counterfactual scenarios and is the only method that yields
257 smaller errors than the uncorrected case (the nationwide average error decreased by $0.019 \mu\text{g m}^{-3}/\text{year}$, or 28% less). The
258 RF-regional model also outperforms the RF-local and LASSO-regional models, suggesting the importance of considering non-
259 linearity, interactions between different meteorological features, and regional meteorology information in correctly adjusting
260 for the impacts of meteorology.

261 Meteorological variability also has a substantial influence on the summertime O_3 trends in the US during this period (as
262 shown in figure 2D). Relative to the counterfactual scenario, the uncorrected O_3 trends are biased by over 1-2 ppb/year in large
263 areas of California, Midwest and Southern US (as much as 320% of the counterfactual trends). This is largely driven by the fact
264 that the 2011 and 2012 summer was particularly hot in these regions and led to higher concentrations of O_3 at the beginning of
265 this 7-year period (see figure A7 for the Southern and Midwest US). Therefore, failure to correct for meteorological variability
266 results in much more negative trend estimates in the O_3 concentrations in these areas compared to the counterfactual scenario
267 (see figure A6). Meteorology corrections with MLR or GAM help reduce these estimation errors substantially (nationwide
268 average error is reduced by 51% using MLR or 57% using GAM compared to uncorrected trends), while large errors still
269 persist in the Midwest and South. Similar to the case of $\text{PM}_{2.5}$, the RF-regional model offers the best performance in correcting
270 for meteorological variability (the national average error is further reduced by 42%, compared to MLR), and it is especially
271 helpful in reducing the errors over the Midwest and South (regional average error is reduced by 64% and 44%, respectively,
272 compared to MLR).

273 3.2 Performance of different correction methods: China (2013-2017)

274 Figure 3A and 3C show the trends in $\text{PM}_{2.5}$ and O_3 concentrations in the counterfactual scenarios in China. We find a sub-
275 stantial decline in simulated $\text{PM}_{2.5}$ concentration during 2013 to 2017, particularly in eastern and central China. In contrast,
276 there is little change in the simulated $\text{PM}_{2.5}$ concentrations in western China in the counterfactual scenario, where $\text{PM}_{2.5}$ is

Figure 2. Trend estimates of daily annual $PM_{2.5}$ (Panels A and B) and summer O_3 (C and D) in the US. Panels A and C show trend estimates under the counterfactual scenario (β^{count}). Panels B and D show the absolute magnitude of errors of trend estimates under different correction methods compared with the counterfactual scenarios ($|\beta^{obs} - \beta^{count}|$). The average of the absolute errors for each method is shown in the figure. Unit of trend estimate is $\mu\text{g m}^{-3}/\text{year}$ for $PM_{2.5}$ or ppb/year for O_3 .

277 dominated by dust species largely driven by natural processes (see figure A9). For summer O₃, there are decreasing trends in
278 the counterfactual scenario in most parts of China, except for North China and some urban areas. This is largely consistent with
279 previous studies that attempt to attribute emissions-related changes in O₃ concentrations during this period based on modeling
280 or observational data (Li et al., 2018, 2020; Lu et al., 2020).

281 Figure 3B shows the magnitude of estimation errors in the trend estimates of annual PM_{2.5} in China under different correction
282 methods. We find the underlying meteorological variability has a substantial impact on PM_{2.5} trends in China during this
283 period. We observe large differences between the uncorrected and counterfactual trends in simulated PM_{2.5} concentrations,
284 particularly in Northwest and Northeast China. Similar to the model experiments in the US, we find that MLR and GAM
285 methods fail to correct for this underlying meteorological variability and lead to further increases in estimation errors in many
286 locations. Relative to the counterfactual scenario, the nationwide average error increases to 0.90 μg m⁻³/year with MLR
287 and 1.06 μg m⁻³/year with GAM (compared to 0.89 μg m⁻³/year with no correction). We find that the RF-regional model
288 recovers the counterfactual trends better than other methods (nationwide average error: 0.64 μg m⁻³/year; an improvement by
289 30% relative to MLR), but it is still not able to correct for the persistent estimation errors over Northwest China. We further
290 analyze the performance of correction methods for the different component species of PM_{2.5}. As shown in figure A10 and
291 A11, the MLR model is particularly unable to correct for the impacts of meteorological variability on nitrate and dust species.
292 Compared with MLR, the RF-regional model better corrects for the impacts of meteorology on secondary organic aerosol
293 species in South and Central China and ammonium in Northeast, but only yields modest improvement in correcting for the
294 errors in dust concentrations over Northwest China (see figure A12). In a sensitivity analysis, we use an approach that first fits
295 RF-regional models of each individual PM_{2.5} species, and then combines predictions for each species to derive trend estimates.
296 The results are largely similar to the main approach that directly fits the total PM_{2.5} concentration (see figure A13).

297 Figure 3D shows the magnitude of errors in the trend estimates for summer O₃ under different correction methods in
298 China. We find that the MLR model only modestly reduces the estimation errors compared to the uncorrected cases, and the
299 RF-regional model offers the best overall performance. The nationwide average error is reduced to 0.28 ppb/year using the RF-
300 regional model (relative to 0.43 ppb/year uncorrected and 0.41 ppb/year with MLR). Similar to the evaluation of summer time
301 O₃ in the US, we find the non-linear models (GAM, RF-local) perform better than MLR, but are not as good as the RF-regional
302 model. Surprisingly, the LASSO-regional model performs the worst in recovering the counterfactual trends. Compared to the
303 US case, we find that the impacts of meteorological variability on O₃ and the method performances are much more spatially
304 heterogeneous (see figure A6, A8), which may be partially due to the more heterogeneous O₃ regimes in China during this
305 period.

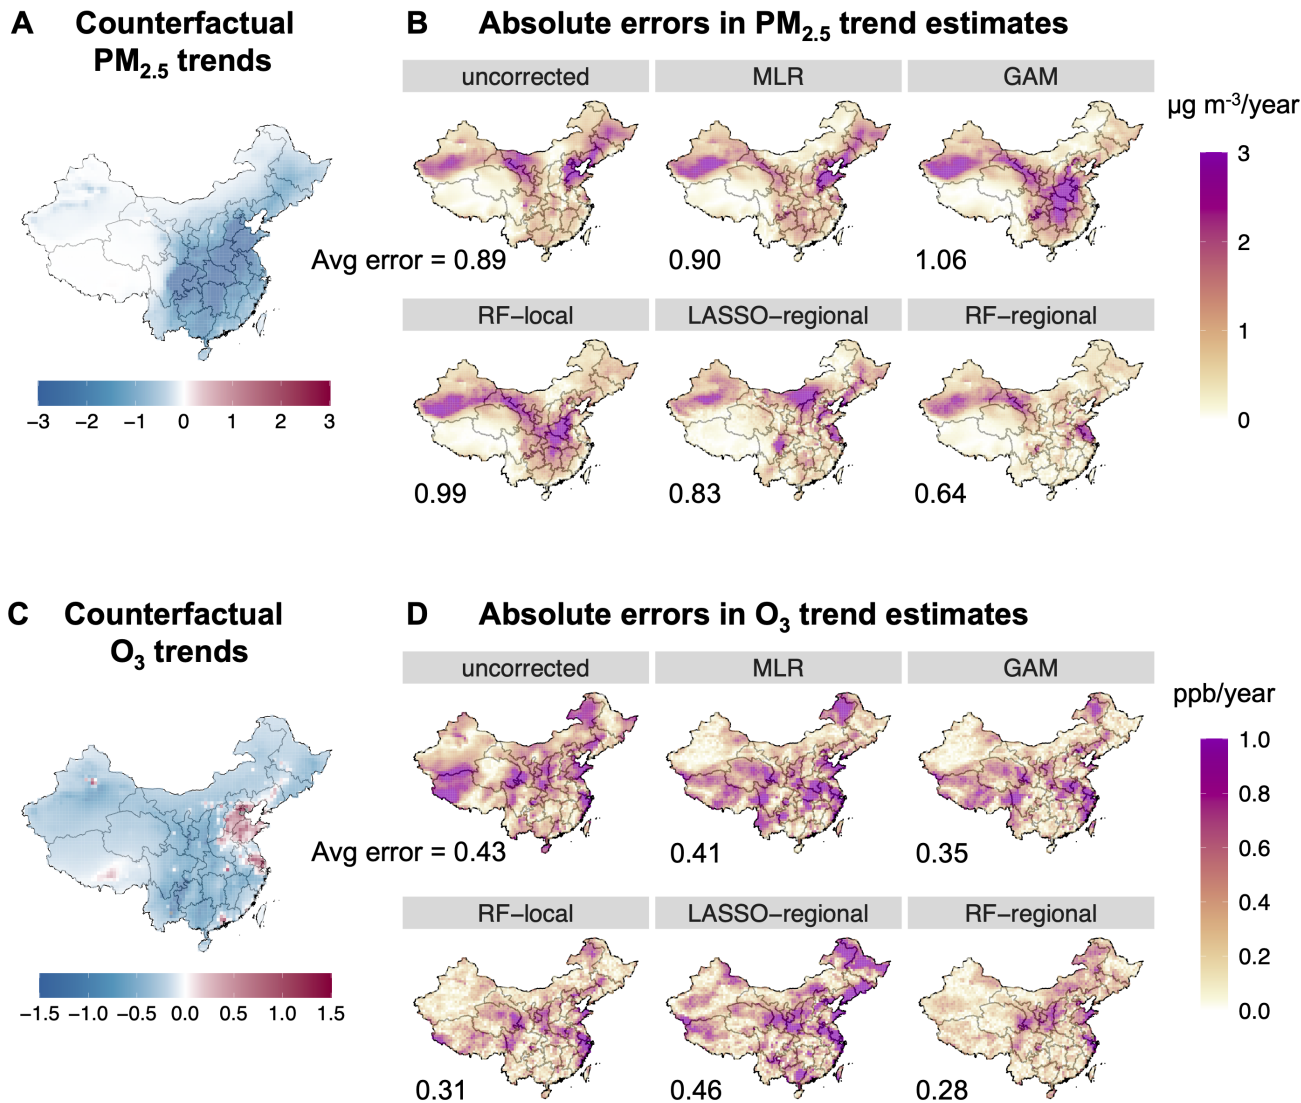

Figure 3. Trend estimates of daily annual PM_{2.5} (Panels A and B) and summer O₃ (C and D) in China. Panels A and C show trend estimates under the counterfactual scenario (β^{count}). Panels B and D show the absolute magnitude of errors of trend estimates under different correction methods compared with the counterfactual scenarios ($|\beta^{obs} - \beta^{count}|$). The average of the absolute errors for each method is shown in the figure. The unit of the trend estimate is $\mu\text{g m}^{-3}/\text{year}$ for PM_{2.5} or ppb/year for O₃.

306 **3.3 Limitations in separating meteorological and emissions influence: quantified with constant emission scenarios**

307 In our model experiments in both US and China, we find large differences remain between the trends evaluated with statistical
308 models (even the best-performing RF-regional model) and counterfactual trends. The remaining differences could result from
309 two different factors: 1) the statistical model cannot capture the complex relationship between meteorology and pollutant
310 concentrations, and/or 2) the differences between the observational scenarios and counterfactual scenarios depend not only
311 on the meteorological variability but also the anthropogenic emissions in their interaction with meteorology (i.e. impacts of
312 meteorology on air quality also depend on the level of emissions).

313 We quantify the potential magnitude of this second factor using our constant-emis approach. As the constant-emis approach
314 captures the exact relationship between meteorology and pollutant concentrations in GEOS-Chem, the error of the constant-
315 emis approach is only associated with the second factor above and thus provides a conceptual minimum of the estimation errors
316 that can be achievable by any statistical approach. Figure 4 shows the estimation errors of trend estimates using the constant
317 emissions scenarios simulated by GEOS-Chem. We focus on the trends in summer O_3 in the US and annual $PM_{2.5}$ in China, for
318 which we see the largest impacts of meteorological variability on the pollutant trends and the largest improvements in reducing
319 estimation errors from the correction methods. Compared to the statistical models (e.g., MLR and RF-regional in figure 4A
320 and 4C), trends evaluated using the constant-emis approach are very similar to the trends in the counterfactual scenarios. The
321 national average error of trend estimates is only 0.04 ppb/year for the O_3 trends in the US (relative to 0.33 ppb/year under MLR
322 or 0.19 ppb/year under RF-regional), and only 0.08 $\mu g m^{-3}/year$ for the $PM_{2.5}$ trends in China (relative to 0.91 $\mu g m^{-3}/year$
323 under MLR or 0.64 $\mu g m^{-3}/year$ under RF-regional).

324 However, the estimation errors calculated above are still non-negligible and can be large in certain regions. As shown in Fig-
325 ure 4B and 4D, the constant-emis approach generally yields trend estimates biased by 10% relative to the counterfactual trends,
326 but the errors can be up to 40% in certain areas. This error term is the result of ignoring how emissions could potentially influ-
327 ence the impacts of meteorology on the pollutant concentrations – that is, the impacts of the same meteorological variability
328 on concentrations may be different in the start year (with high emissions) compared to the end year (with low emissions).

329 **3.4 Application to observational data**

330 Figure 5 shows the regional trends in O_3 in the US and trends in $PM_{2.5}$ in China estimated from the observaional data from
331 surface monitoring networks and the GEOS-Chem simulations (only grid cells that overlap with monitor locations are shown
332 here). Here, to correct for the meteorology variability in observational data, we implement the same set of statistical methods
333 as shown in Table 1, but with different numerical coefficients directly derived from the observational data. When applying

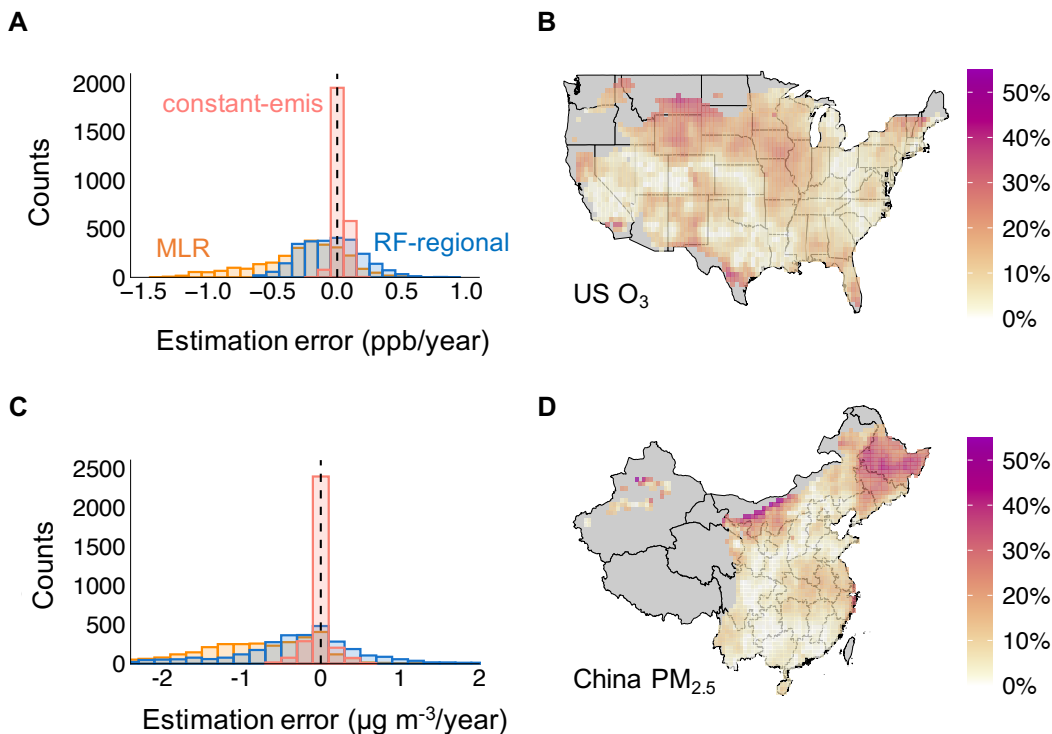

Figure 4. Panels A and C show the histogram of estimation errors in trend estimates assessed using MLR, RF-regional and constant-emis. Panels B and D show the errors assessed with the constant-emis method as a percentage of the trends in the counterfactual scenario ($|\beta^{gc} - \beta^{count}|/|\beta^{count}|$). Panels B and D only show grid cells with a trend in the counterfactual scenarios >0.2 ppb/year or >0.2 $\mu\text{g m}^{-3}$ /year; remaining grid cells are shown in gray. Panels A and B illustrate the summer O₃ trends in the US. Panels C and D illustrate the annual PM_{2.5} trends in China.

334 different meteorological correction methods to the observational data, our analysis reveals that the choice of methods for
 335 meteorological correction can yield very different results for certain regions. For example, the regional average uncorrected O₃
 336 trend is -1.49 ppb/year and -1.15 ppb/year in Midwest and Southern US, respectively, which overestimates the reductions in
 337 concentrations attributable to anthropogenic emissions changes (figure 5A). Correcting for the meteorological variability with
 338 MLR model yields regional average trend at -0.54 ppb/year in Midwest (a decrease by 53% in magnitude relative to uncorrected
 339 trends) and -0.71 ppb/year in the Southern US (a decrease by 52%). RF-regional model further reduces the absolute magnitude
 340 of the declines in O₃ attributable to emissions reductions to -0.02 ppb/year for Midwest and -0.40 ppb/year for the Southern
 341 US. Importantly, these patterns are consistent with the results from our model experiments in these regions: the RF-regional
 342 model also estimates a much less negative emissions-driven trend in the Southern US compared to the uncorrected case and
 343 MLR estimates in the GEOS-Chem simulations. For the GEOS-Chem simulations, RF-regional estimates are 39% smaller than

344 MLR estimates, and this is comparable to the magnitude changes for the observational data (RF-regional estimates are 44%
 345 smaller than MLR). As the RF-regional model outperforms the other correction methods in recovering counterfactual trends in
 346 the GEOS-Chem simulations, this potentially also suggests a better performance of RF-regional in recovering the underlying
 347 emission-driven trends when applying to the observational data.

348 We find similar consistency of the method performances between observational data and GEOS-Chem simulations in China
 349 as well (figure 5B). When applying to the observational data from the surface monitoring network, much smaller reduction
 350 of $\text{PM}_{2.5}$ concentrations is attributed to anthropogenic emissions changes in the North, Northeast and East of China using
 351 the RF-regional model, relative to the MLR estimates. For example, the average emissions-driven trend estimated from the
 352 observational data is $-4.9 \mu\text{g m}^{-3}/\text{year}$ in Beijing under the RF-regional model, compared with $-9.6 \mu\text{g m}^{-3}/\text{year}$ under the
 353 MLR model. These patterns are consistent with the patterns of the trend estimates estimated from our GEOS-Chem simulations
 354 with different statistical methods.

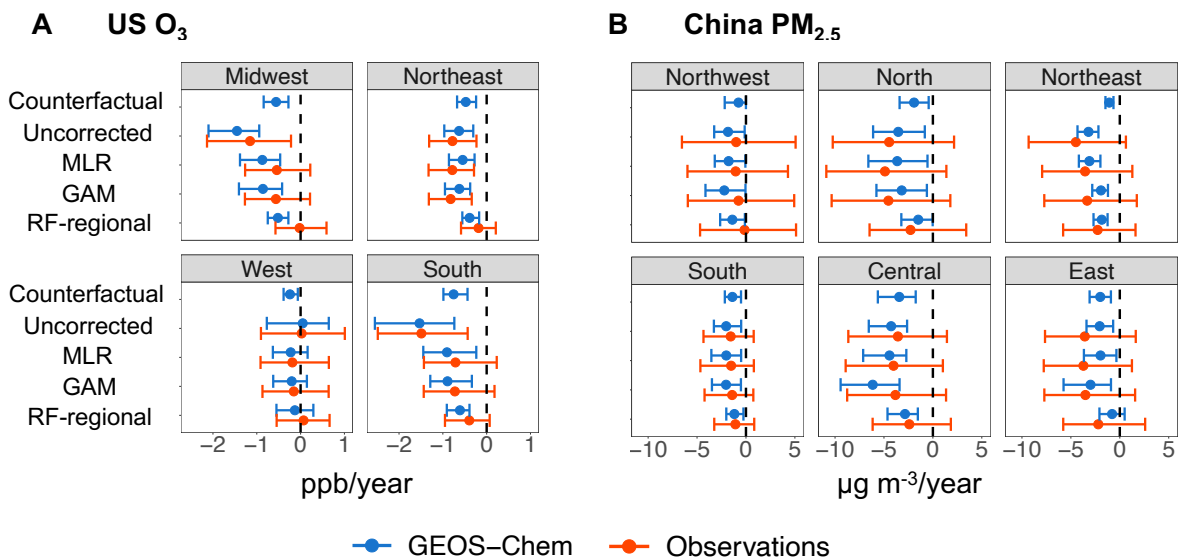

Figure 5. Trends in O_3 in the US (panel A) and $\text{PM}_{2.5}$ in China (panel B) estimated from the observational data (red) and GEOS-Chem simulations (blue) under different correction methods. Trends in pollutant concentrations are estimated at the monitor level (for the observational data) or at the grid cell level (for GEOS-Chem simulations). The point indicates the average value of the assessed trends of all monitors (or grid cells) within a region. The error bars show the 10th and 90th percentile of the assessed trends of all monitors/grid cells within a region. Panel A illustrates the summer O_3 trends in the US (unit: ppb/year). Panel B illustrates the annual $\text{PM}_{2.5}$ trends in China (unit: $\mu\text{g}/\text{m}^3/\text{year}$). We classify the US states into four regions according to the US Census Bureau and classify China's provinces into six regions based on the structure of China's subnational electric grid. Observational data are derived from U.S. Environmental Protection Agency (2021c) and China's Ministry of Ecology and Environment (2021).

355 4 Discussion

356 We designed a model experiment that enables us to directly quantify the performance of different statistical models to evaluate
357 the trends in pollutant concentrations driven by anthropogenic emissions changes. Based on our evaluations of either PM_{2.5}
358 or O₃ trends across US and China during periods of recent emission declines, our analysis shows that widely-used MLR
359 and GAM methods do not perform well in correcting for the meteorological variability and recovering simulated emissions-
360 driven trends. We propose a random forest model that uses both local and regional meteorological features, which offers the
361 best overall performance in recovering the emissions-driven trends across both species and countries. Applying this model to
362 observational data suggests that estimates based on MLR or similar methods may overestimate the impacts of anthropogenic
363 emissions changes on the decline of pollutant concentrations in certain regions in the US and China. However, the RF-regional
364 method does not outperform all the other approaches in every location despite its better overall performance (see figures A14
365 and A15). This suggests that using multiple statistical approaches may be necessary to derive robust conclusions for attributing
366 pollutant trends to emission changes.

367 With our model experiments, we also quantify the estimation errors in assuming emission impacts can be perfectly separated
368 from meteorological variability. These errors likely bound the estimation errors that can be achieved by any statistical methods
369 with this assumption. In the future, more complex statistical and machine learning methods could be applied to distinguish
370 emissions- and meteorologically-driven changes, but attribution solely based on observed concentrations and meteorology will
371 be limited by physical interactions between emissions and meteorology. We find that the estimation errors resulting from these
372 interactions are overall much smaller compared to the estimation errors of the existing statistical methods, but can still be
373 important for certain regions at certain times. However, the intertwined relationships between anthropogenic emissions and
374 meteorology are often much more complex in reality compared to our model experiments. For example, meteorology can also
375 directly influence anthropogenic emissions (e.g., increased electricity consumption during extreme weather conditions (U.S.
376 Energy Information Agency, 2019; He et al., 2020)). Therefore, the estimation errors that can be achieved by more flexible
377 statistical models can potentially be even larger than the errors quantified with our constant-emis approach.

378 While the GEOS-Chem model provides us with a framework to test statistical methods, its use in our model experiments
379 introduces some uncertainty and limitations. Specifically, our experiments assess the performance of statistical methods in cor-
380 recting for the meteorology-pollution relationships encoded in GEOS-Chem, which may differ from the complex relationships
381 in the observational data. Several studies have shown that GEOS-Chem and similar models do not capture certain meteorology-
382 pollution relationships in the observational data (e.g., temperature - O₃ relationship (Porter and Heald (2019)) and influence
383 of regional meteorological patterns (Fiore et al. (2009))). The relationships encoded in GEOS-Chem may be different from

384 the underlying meteorology-pollution relationships in the following three ways: (1) parameters in GEOS-Chem that describe
385 these relationships are uncertain; (2) the relationships in GEOS-Chem are incorrect or incomplete; and (3) the relationships
386 in GEOS-Chem are deterministic compared to the potential stochastic underlying processes. Therefore, the performance of
387 any individual statistical method is likely to be worse in the real world compared to its ability to reproduce a deterministic
388 meteorology-pollution relationship encoded in GEOS-Chem. Further model-based experiments could apply our methods to
389 different atmospheric models in order to test if these conclusions differ by different models.

390 Changes in natural emissions due to meteorological variability play an important role in the air quality-meteorology relation-
391 ship. Our model experiment considers natural emission changes that can be simulated online with assimilated meteorological
392 fields in GEOS-Chem, including soil NO_x emissions, biogenic VOC emissions, and dust emissions. We find that the statistical
393 models (such as RF-regional) performs notably worse in correcting for the variability in dust-related $\text{PM}_{2.5}$ (see figure A12),
394 likely because dust $\text{PM}_{2.5}$ is extremely variable, with zero concentration in most non-dust days but extremely high concentra-
395 tion during the occasional dust storms. Our findings can potentially shed light on another important source of natural emissions,
396 wildfire emissions, which are also quite variable but have become an increasingly important contributor to $\text{PM}_{2.5}$ and O_3 in
397 certain regions (e.g., western US) (Burke et al., 2021). While emissions from biomass burning are held constant in our model
398 experiments as the wildfire emissions are prescribed in GEOS-Chem, wildfire emissions are significantly influenced by climatic
399 variability (Abatzoglou and Williams, 2016; Xie et al., 2022) and will likely be a substantial challenge for any meteorological
400 correction method in the future that attempts to separate changes in anthropogenic emissions from the variability in climate
401 and associated natural emissions.

402 Our research reveals multiple directions for future research to enhance our understanding of the usage of statistical models
403 to evaluate trends in pollutant concentrations under changing meteorological conditions. One key but challenging question
404 is to better understand the estimation errors of these existing approaches, e.g. why the MLR model is able to correct for the
405 meteorological variability in some locations but not others. In this paper, we only test a selection of methods based on their
406 popularity in the existing literature and propose a simple-to-use model (RF-regional). More complex models (such as convo-
407 lutional neural networks) may offer better performance, but the estimation error will likely be bounded by the errors of the
408 constant-emis approach. Our work only evaluates the statistical and machine learning models in expressions 1 and 2, which
409 only represent one (popular) set of evaluations that performs location-specific trend estimation with adjustments for meteo-
410 rology and secular trends. However, other statistical model specifications specifically targeted to questions of meteorological
411 interaction or that permit borrowing information across locations may generate different results. Constrained by computational
412 resources and availability of emission inventories, our simulation only covers a relatively short time period which could result
413 in additional uncertainty in the linear trend estimates. When possible, future studies could evaluate performances of the statisti-

414 cal models with longer simulations and alternative trend estimates (such as the Theil-Sen estimator). A deeper investigation of
415 the estimation error due to assuming perfect separation between meteorology and emission is also essential for understanding
416 how we should interpret studies that use these statistical methods. For example, further work could explore how these errors
417 will vary by the magnitude of emissions reductions and the chemistry regimes.

418 **5 Recommendations for attributing trends to emissions changes**

419 Using statistical methods to causally infer relationships between simulated air pollutant concentrations and anthropogenic
420 emissions is challenging, and doing so in contexts of observational data is even more challenging. Understanding the uncer-
421 tainty of statistical models in characterizing the meteorology-pollution relationship is essential to evaluating the effectiveness
422 of policy interventions with observational data. Here, we make several recommendations to researchers and policy makers
423 based on our analysis.

424 For those who aim to infer causal effects of emissions changes on air quality based on observational data on concentrations
425 and meteorology, we recommend using multiple statistical methods to correct for meteorological variability when evaluating
426 the impacts of policies or interventions on air quality. From our two case studies, we find a relatively large variation between the
427 trend parameters estimated by different statistical methods (especially at the grid cell or monitor level). Some methods perform
428 better in certain locations but not in others (though RF-regional is the best-performing method overall). Using multiple ap-
429 proaches (linear/non-linear and at local/regional scale) may help to quantify uncertainty related to meteorological corrections.
430 These findings also suggest that empirical analyses may benefit from considering the impacts of meteorological variability on
431 air quality separately for each region or even for each monitor location (if data permits), instead of attempting to determine a
432 general relationship between meteorological variability and air pollution over a large spatial domain. Finally, analysts should
433 be particularly cautious when using statistical methods to estimate impacts of anthropogenic emissions on air quality in regions
434 where pollution variability is dominated by meteorologically-influenced environmental processes such as dust emissions, as
435 we consistently show that typical statistical methods (in combination with the standard set of meteorological variables) do not
436 work well in those regions.

437 Due to the non-negligible estimation errors in recovering the counterfactual trends even with the best-performing statistical
438 approach we test, we believe these statistical analyses are most useful in understanding the patterns of anthropogenic emissions
439 on air quality when aggregated across larger spatial areas, rather than providing specific trends for individual monitor locations.
440 There is a higher degree of consistency among the trend estimates across different methods when aggregated at regional level,
441 but assessment at local level is more sensitive to method choice. The absolute magnitude of monitor-level trends needs to be

442 interpreted with caution, considering both the uncertainty from the statistical methods and also the limit of meteorological
443 correction due to ignoring the interactions between meteorology and emissions.

444 Because measured pollutant concentrations are subject to the influence of underlying meteorological variability, many efforts
445 have attempted to correct for the impacts of meteorological variability and use “meteorology-corrected” concentrations and
446 trends to assist in evaluating the effectiveness of air quality policies. Our study evaluates existing methods that aim to correct for
447 the meteorological variability and finds many of these methods do not perform well. This raises potential concerns about the use
448 of “meteorology-corrected” concentrations as targets for policy evaluation. Meteorology-corrected concentrations and trends
449 remain useful metrics to quantify the influence of emissions. However, a more comprehensive evaluation of the effectiveness
450 of policy requires interpreting measurements with all available tools, ideally including both statistical analyses and physical
451 models.

452 *Code and data availability.* The GEOS-Chem simulation of different scenarios and the R code for implementing the different statistical
453 methods are available at the following repository.

454 *Author contributions.* M.Q. and N.E.S. designed the research. M.Q. performed the statistical analysis and GEOS-Chem modeling simula-
455 tions. All authors interpreted the results and wrote the paper.

456 *Competing interests.* The authors declare no competing interests.

457 *Acknowledgements.* We thank Colette Heald and Valerie Karplus for helpful comments and discussions. We thank Yixuan Zheng for assis-
458 tance with the MEIC emissions inventory. We thank Ke Li for sharing code of step-wise MLR analysis. This publication was supported by
459 US EPA grant RD-835872-01. Its contents are solely the responsibility of the grantee and do not necessarily represent the official views of

461 Appendix: Supplementary methods

462 Implementation of LASSO and RF

463 As the incorporation of both local and regional features can quickly expand the dimensionality of the feature space, we use the
464 Least Absolute Shrinkage and Selection Operator (LASSO) and the Random Forest (RF) model to assess the importance of
465 regional meteorological features. Both methods are commonly-used approaches with good prediction performance with high
466 dimensional data inputs, and are thus appropriate for an analysis with a large number of regional meteorological features. For
467 these two methods, we rewrite equation 1 as the following:

$$468 \quad y_{it} = \beta_i^{obs} \times t + g_i(X_{it}, Z_t, W_t) + \epsilon_{it} \quad (1)$$

469 where $g_i()$ denotes the functional form fitted by LASSO or RF. X_{it} again denotes the local meteorological features for grid cell
470 i on day t . Z_t denotes the regional scale meteorology features including those for all grid cells in the US on day t (98 cells in
471 4×5 degrees; we choose a relatively coarse resolution due to computational cost). Meteorological information in each location
472 in the US may help explain the pollutant concentrations in grid cell i . In total, we have 10 local features (X_{it}) and $10 \times 98 = 980$
473 regional scale features (Z_t). W_t denotes the day and month variable to model the daily and monthly variability in pollutant
474 concentrations that are unrelated to meteorological variability. For LASSO, we use month-of-year \times day-of-month fixed effect
475 (same as all the other methods except for RF), and these fixed effects are not penalized in the LASSO regression. For RF, we
476 use the month-of-year variable (from 1 to 12), and day-of-month variable (from 1 to 31), due to the inefficient performance of
477 RF working with a large number of fixed effects. Thus, the difference between RF and the other methods may also come from
478 the different choices in modeling monthly and daily variability.

479 The coefficient β_i^{obs} is obtained with the following procedure using the double machine learning approach by Chernozhukov
480 et al. (2018):

481 (1) We first partition the time series of $\{y_{it}, X_{it}, Z_t, W_t\}$ into 4 folds. We use 75% of the data as training data and the
482 remaining 25% for predictions. We train the following two models on the training data:

$$483 \quad y_{it} = f(X_{it}, Z_t, W_t)$$

$$484 \quad t = g(X_{it}, Z_t, W_t)$$

485 (2) We then apply models $f(\cdot)$ and $g(\cdot)$ to the prediction set to get predictions of y_{it} and t for the rest 25% of the data. The
486 above process is repeated four times to derive predictions for the entire time series (predictions denoted as \widehat{y}_{it} and \widehat{t}).

487 (3) We calculate the residuals of each model $\widetilde{y}_{it} = y_{it} - \widehat{y}_{it}$ and $\widetilde{t} = t - \widehat{t}$. The coefficient of interest β_i^{obs} is then calculated
488 as:

$$489 \beta_i^{obs} = \frac{\sum_t \widetilde{t} \widetilde{y}_{it}}{\sum_t \widetilde{t} \widetilde{t}}$$

490 This is equivalent to setting up a linear regression of $\widetilde{y}_{it} \sim \widetilde{t}$ and obtaining the slope coefficients (as shown by Chernozhukov
491 et al. (2018)).

492 The hyper-parameters of RF and LASSO are tuned with 4-fold cross validation. We also perform two sensitivity analyses: 1)
493 with a different spatial resolution for the regional scale features (2×2.5 degrees instead of 4×5 degrees), and 2) with different
494 numbers of folds to estimate the trend coefficients. Our results are similar across these sensitivity analyses (see figure A16).

495 The double machine learning framework involves a sample partition procedure (steps (1) and (2) above). This procedure,
496 however, does not fit the purpose of including time fixed effects in the LASSO model (as randomly partitioned training and
497 test sets could have very unbalanced number of observations from a given month-day pair). Therefore, step (1) and (2) are only
498 implemented for the RF model, and coefficients of the LASSO model are directly derived from step (3) without sample splitting.
499 This is acceptable for the LASSO model as the risk of “overfitting” has already been eliminated by using the tuned penalizing
500 factor (i.e. the hyper-parameters) derived from a 4-fold cross-validation. It is important to note that we quantify the performance
501 of RF and other methods using the differences between “meteorology-corrected” trends (β^{obs}) and the counterfactual trends
502 (β^{count}), instead of their performance in predicting the pollutant concentration. Therefore, if the RF model “overfits the data”,
503 it would actually result in a large error, because the overly fit RF model would attribute all variability of $PM_{2.5}$ and O_3 to the
504 meteorological variables and estimate a close-to-zero trend.

Model	Annual PM _{2.5} in the US			Summer O ₃ in the US		
	average error	median relative error	cells with relative error >50%	average error	median relative error	cells with relative error >50%
No correction	0.066	28%	27%	0.67	154%	84%
MLR (5 features)	0.092	43%	44%	0.38	84%	71%
MLR (10 features)	0.083	40%	40%	0.33	71%	64%
Quadratic	0.088	40%	42%	0.29	60%	58%

RF-regional	0.047	25%	23%	0.19	46%	47%

Table A1. Estimation errors of trend estimates in the US under different correction methods. The average estimation errors, median relative error, and fraction of grid cells with relative error greater than 50% are shown in the table. Relative errors are calculated as the ratio of estimation error to the trend estimate in the counterfactual scenario. MLR (5 features) only use temperature, precipitation, humidity, and surface wind speed (U,V directions) as the meteorological features.

Model	Annual PM _{2.5} in China			Summer O ₃ in China		
	average error	median relative error	cells with relative error >50%	average error	median relative error	cells with relative error >50%
No correction	0.89	224%	77%	0.43	95%	74%

Table A2. Estimation errors of trend estimates in China under different correction methods. The average estimation errors, median relative error, and fraction of grid cells with relative error greater than 50% are shown in the table. Relative errors are calculated as the ratio of estimation error to the trend estimate in the counterfactual scenario. MLR (5 features) only use temperature, precipitation, humidity, and surface wind speed (U,V directions) as the meteorological features.

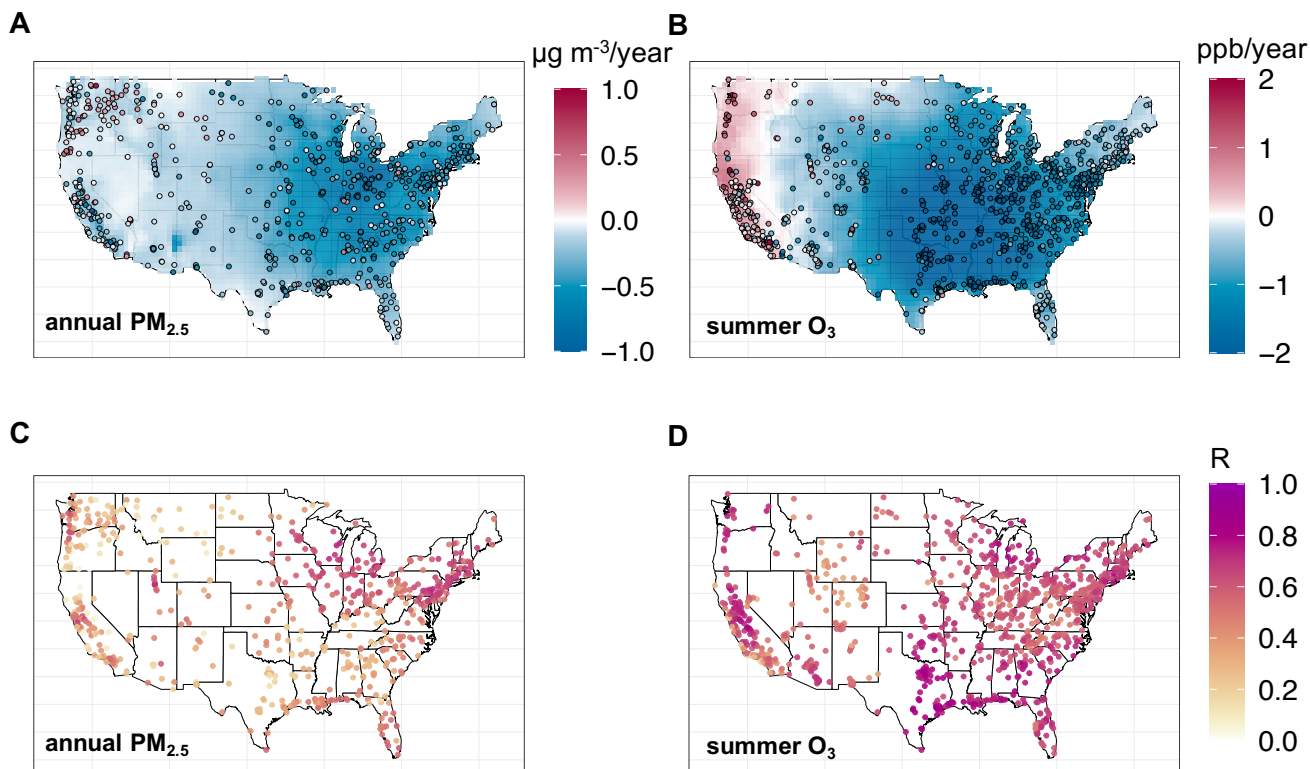

Figure A1. Comparison between the annual $\text{PM}_{2.5}$ (Panels A and C) and summer O_3 (Panels B and D) concentrations measured by the monitoring network and GEOS-Chem simulations in the US (2011-2017). Panels A and B show the trends in monitored concentrations (dots) and trends in the observational scenarios in GEOS-Chem simulations (background) without meteorology corrections. Panels C and D show the Pearson correlation coefficient (R) between the daily measured concentrations and simulated concentrations. Observational air quality data is derived from U.S. Environmental Protection Agency (2021c).

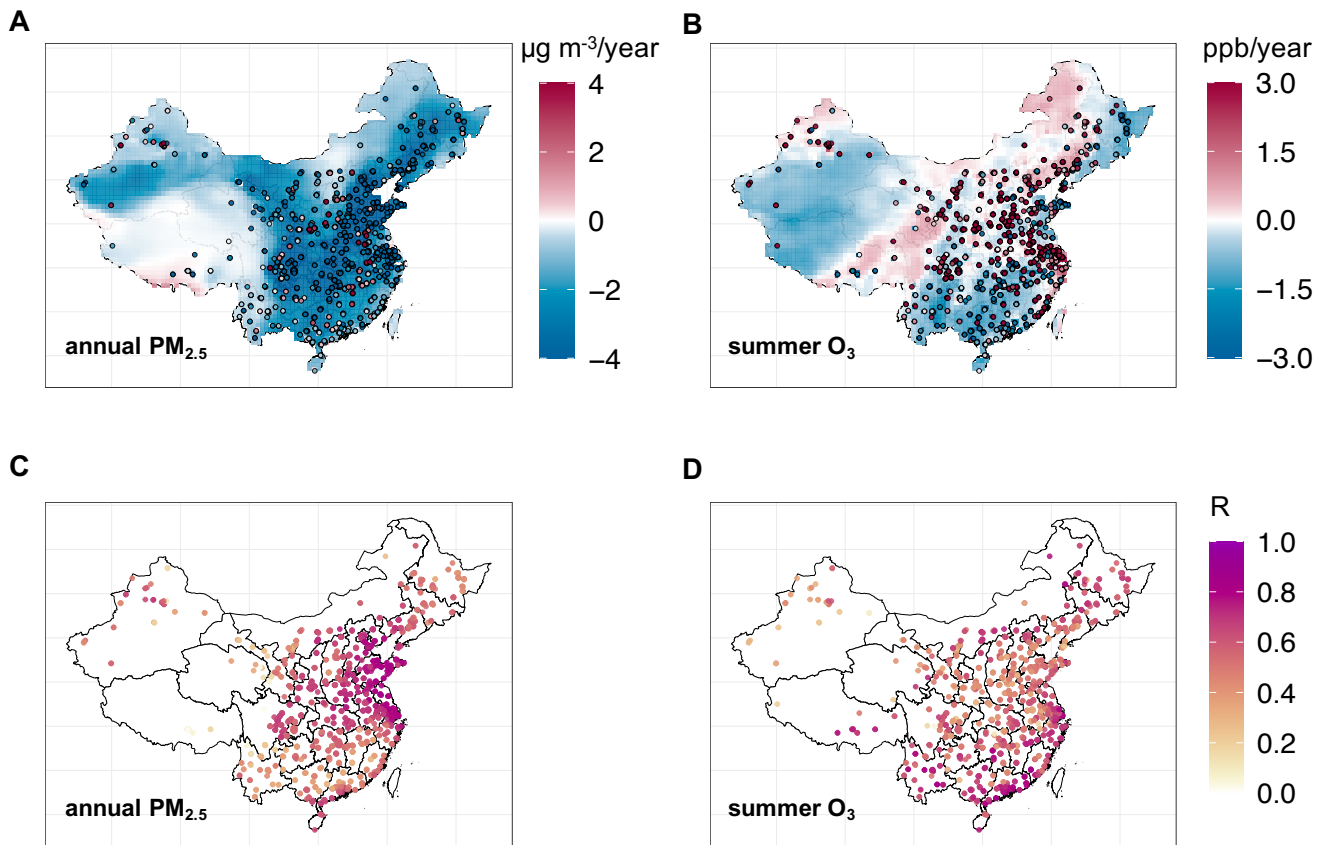

Figure A2. Comparison between the annual $\text{PM}_{2.5}$ (Panels A and C) and summer O_3 (Panels B and D) concentrations measured by the surface monitoring network and GEOS-Chem simulations in China (2014-2017). Panels A and B show the trends in monitored concentrations (dots) and trends in the observational scenarios in GEOS-Chem simulations (background) without meteorology corrections. Panels C and D show the Pearson correlation coefficient (R) between the daily measured concentrations and simulated concentrations. Observational air quality data is derived from China's Ministry of Ecology and Environment (2021).

Figure A3. National total anthropogenic emissions in the US (2011- 2017). The emissions data is derived from the national total emissions of criteria air pollutants reported by the US EPA Air Emissions Inventory (U.S. Environmental Protection Agency, 2021a). Changes in emissions between 2011 and 2017 as percentages of the emissions in 2011 are presented in the figure.

Figure A4. National total anthropogenic emissions in China (2013- 2017). The emissions data is derived from the Multi-resolution Emission Inventory (MEIC) (Li et al., 2017b). Changes in emissions between 2013 and 2017 as percentages of the emissions in 2013 are presented in the figure.

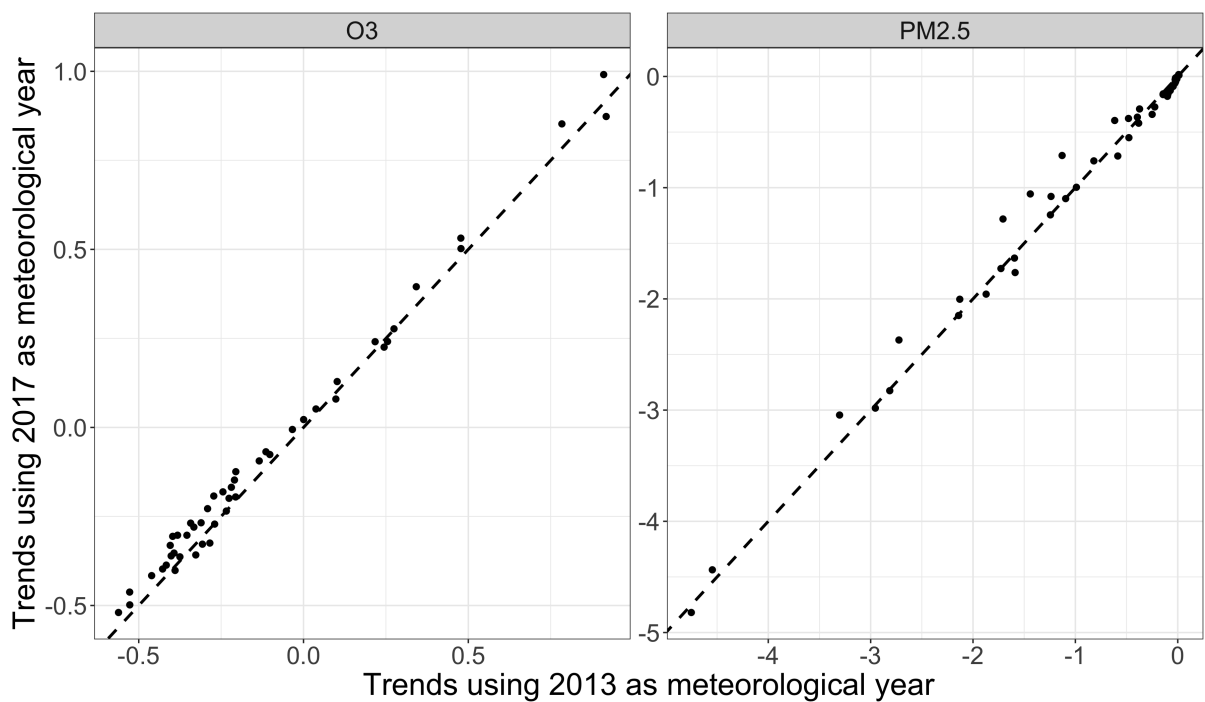

Figure A5. Counterfactual trends in O_3 (unit: ppb/yr) and $PM_{2.5}$ (unit: $\mu g m^{-3}/year$) in China with different meteorological years. Each dot represents one grid cell in China. The x-axis shows the trends in air quality in the counterfactual scenario using the meteorological field in 2013, and the Y-axis shows the trends in air quality in the counterfactual scenario using the meteorological field in 2017. Results here are derived from simulation at 4×5 degrees.

A Counterfactual PM_{2.5} trends

B Errors in PM_{2.5} trend estimates

C Counterfactual O₃ trends

D Errors in O₃ trend estimates

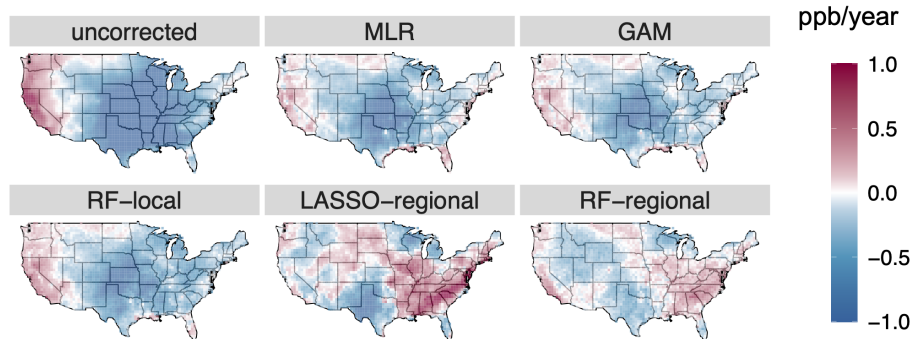

Figure A6. Trend estimates of daily annual PM_{2.5} (Panels A and B) and summer O₃ (C and D) in the US. Panels A and C show trend estimates under the counterfactual scenario (β^{count}). Panels B and D show the estimation errors of trend estimates under different correction methods compared with the counterfactual scenarios ($\beta^{obs} - \beta^{count}$). The average of the absolute error for each method is shown in the figure. Unit of trend estimate is $\mu\text{g m}^{-3}/\text{year}$ for PM_{2.5} or ppb/year for O₃.

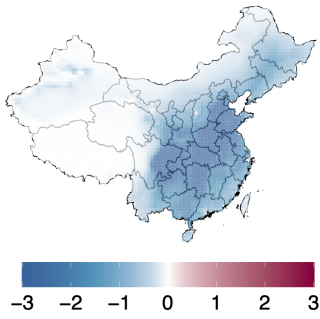

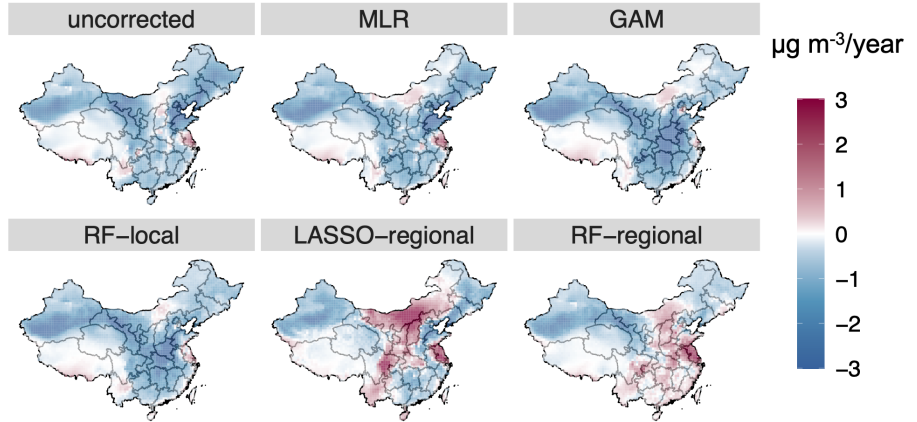

Figure A7. Deviations of meteorological features from the 7-year average in the US (South and Midwest). The deviation is quantified in the units of standard deviation (SD) across the 7-year period. Zero indicates the 7-year average. This plot shows the summer time average of daily MDA8 meteorological variables for each year aggregated over South and Midwest US.

A Counterfactual PM_{2.5} trends

B Errors in PM_{2.5} trend estimates

C Counterfactual O₃ trends

D Errors in O₃ trend estimates

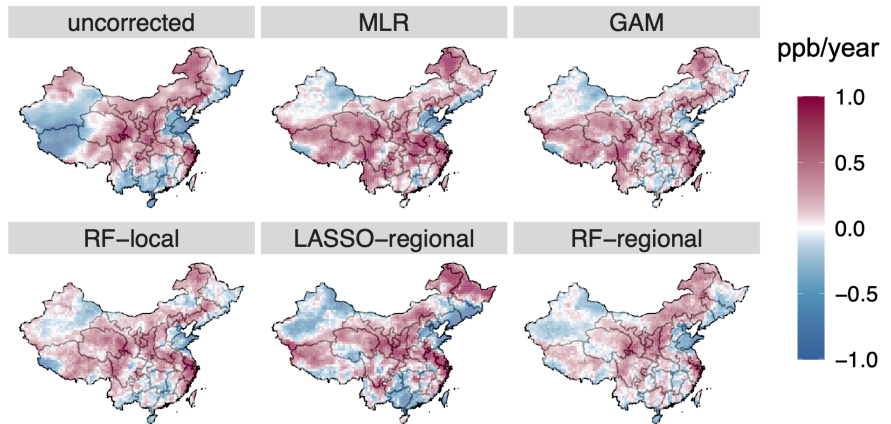

Figure A8. Trend estimates of daily annual PM_{2.5} (Panels A and B) and summer O₃ (C and D) in China. Panels A and C show trend estimates under the counterfactual scenario (β^{count}). Panels B and D show the estimation errors of trend estimates under different correction methods compared with the counterfactual scenarios ($\beta^{obs} - \beta^{count}$). The average of the absolute error for each method is shown in the figure. Unit of trend estimate is $\mu\text{g m}^{-3}/\text{year}$ for PM_{2.5} or ppb/year for O₃.

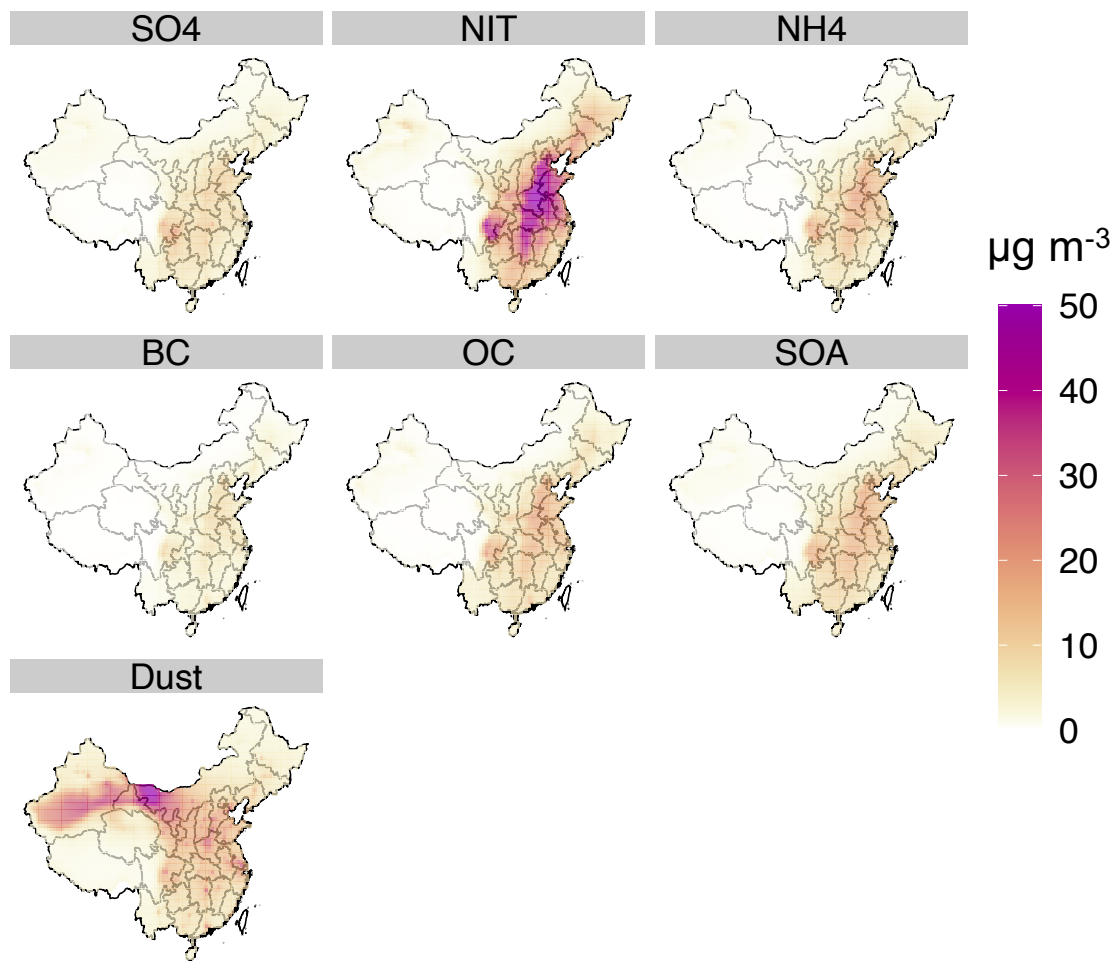

Figure A9. Concentrations of component species of PM_{2.5} in China (average across 2013-2017). The figure shows concentrations of sulfate (SO₄), nitrate (NIT), ammonium (NH₄), black carbon (BC), organic carbon (OC), secondary organic aerosol (SOA), and dust.

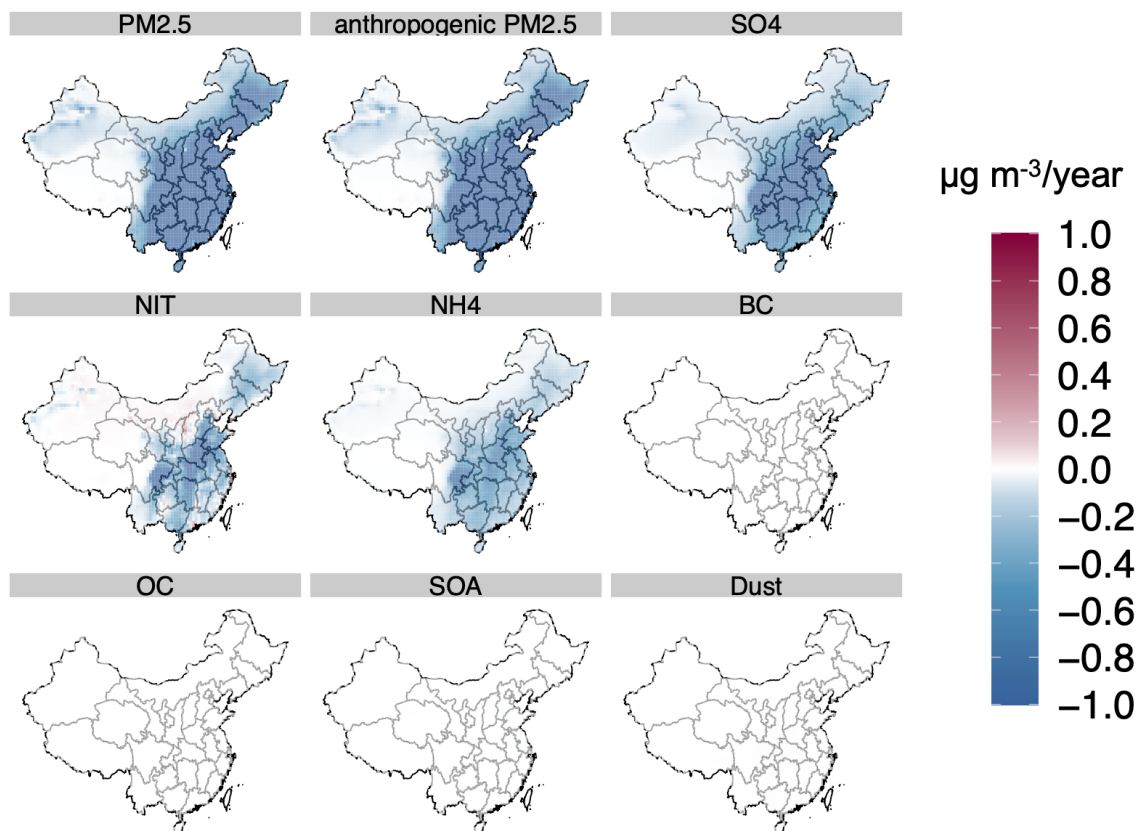

Figure A10. Counterfactual trends of component species of PM_{2.5} in China. The figure shows counterfactual trends of total PM_{2.5}, anthropogenic PM_{2.5} (total PM_{2.5} excluding dust and sea salt), sulfate (SO₄), nitrate (NIT), ammonium (NH₄), black carbon (BC), organic carbon (OC), secondary organic aerosol (SOA), and dust.

Figure A11. Differences between counterfactual trends and trends evaluated under MLR ($\beta^{MLR} - \beta^{count}$) of component species of $\text{PM}_{2.5}$ in China. The figure shows estimation errors of total $\text{PM}_{2.5}$, anthropogenic $\text{PM}_{2.5}$ (total $\text{PM}_{2.5}$ excluding dust and sea salt), sulfate (SO_4), nitrate (NIT), ammonium (NH_4), black carbon (BC), organic carbon (OC), secondary organic aerosol (SOA) and dust.

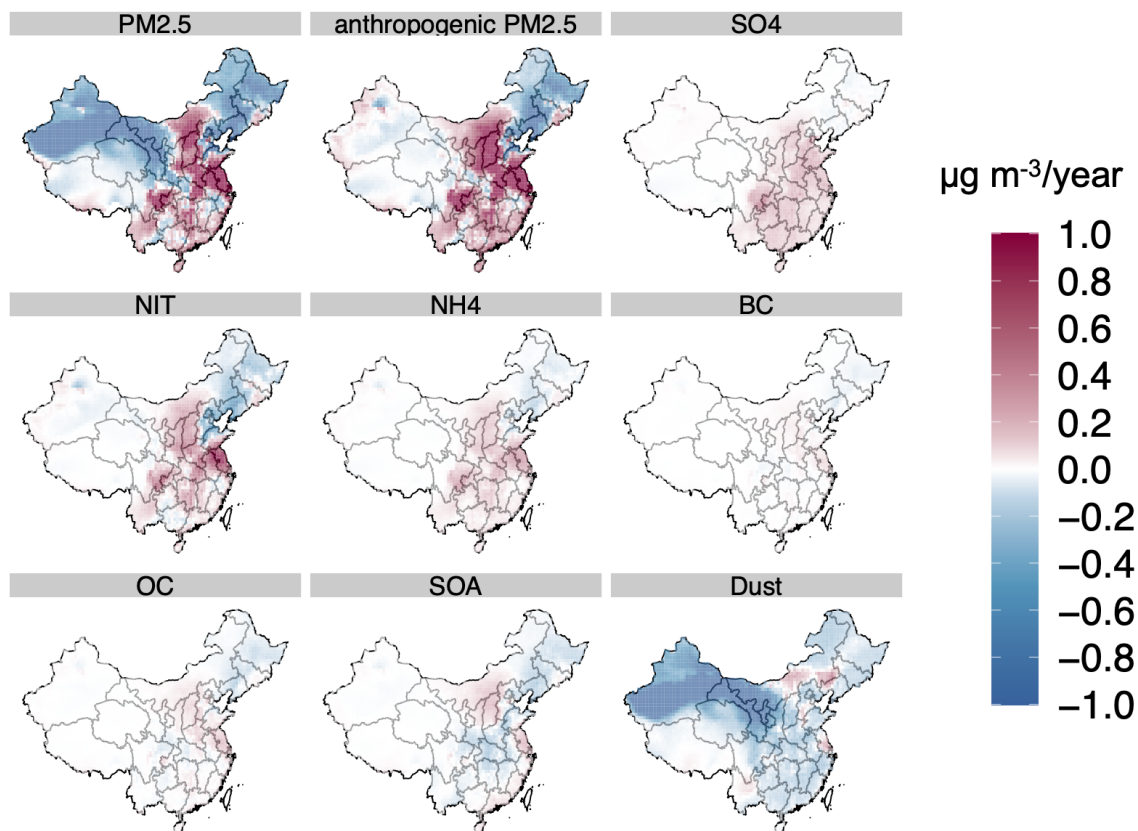

Figure A12. Differences between counterfactual trends and trends evaluated under RF-regional ($\beta^{RF-regional} - \beta^{count}$) of component species of $\text{PM}_{2.5}$ in China. The figure shows estimation errors of total $\text{PM}_{2.5}$, anthropogenic $\text{PM}_{2.5}$ (total $\text{PM}_{2.5}$ excluding dust and sea salt), sulfate (SO_4), nitrate (NIT), ammonium (NH_4), black carbon (BC), organic carbon (OC), secondary organic aerosol (SOA) and dust.

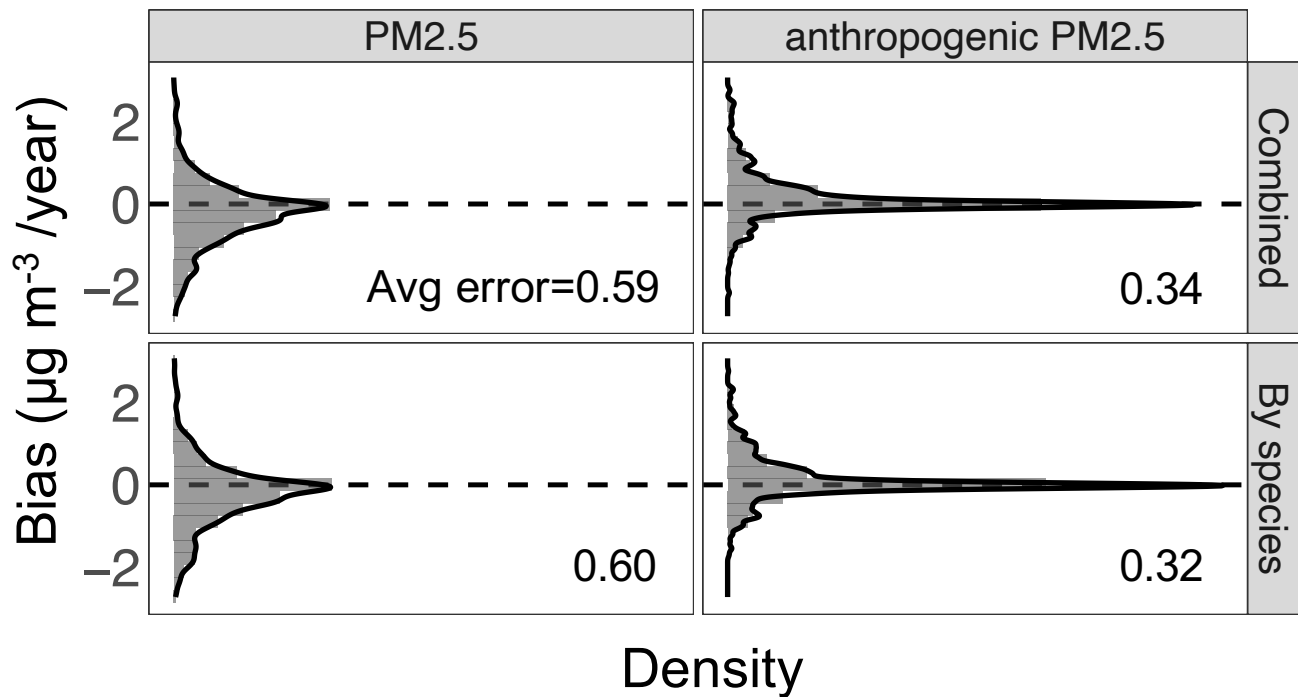

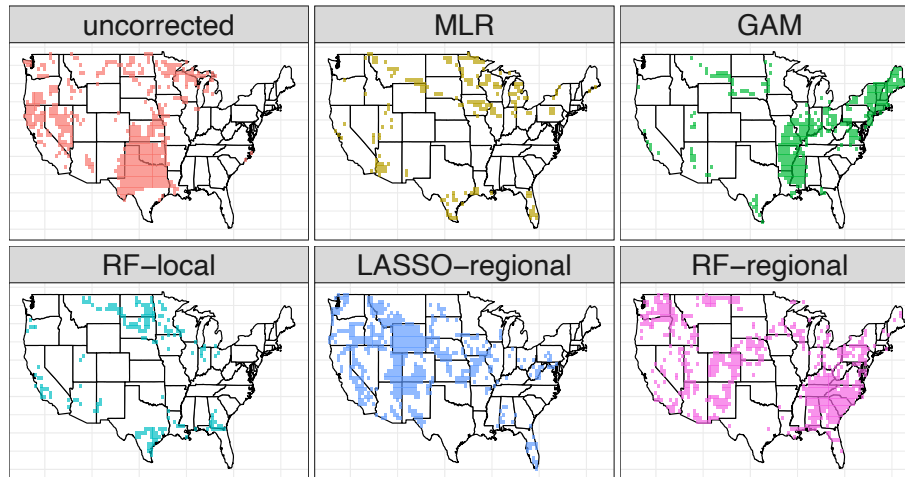

Figure A13. Histograms of estimation errors of trend estimates in $PM_{2.5}$ under two implementations of the *RF-regional* method (applied to China). The upper panels (*Combined*) show results of fitting RF models to the total concentrations of $PM_{2.5}$ to directly estimate trends (the main results). The lower panels (*By species*) show results of fitting RF models to individual $PM_{2.5}$ species and then combine predictions to estimate trends. The left panels show results for total $PM_{2.5}$ and right panels show results for anthropogenic $PM_{2.5}$ (total $PM_{2.5}$ excluding dust and sea salt). Average of the estimation errors across all grid cells is shown in the figure.

A annual $PM_{2.5}$

B summer O_3

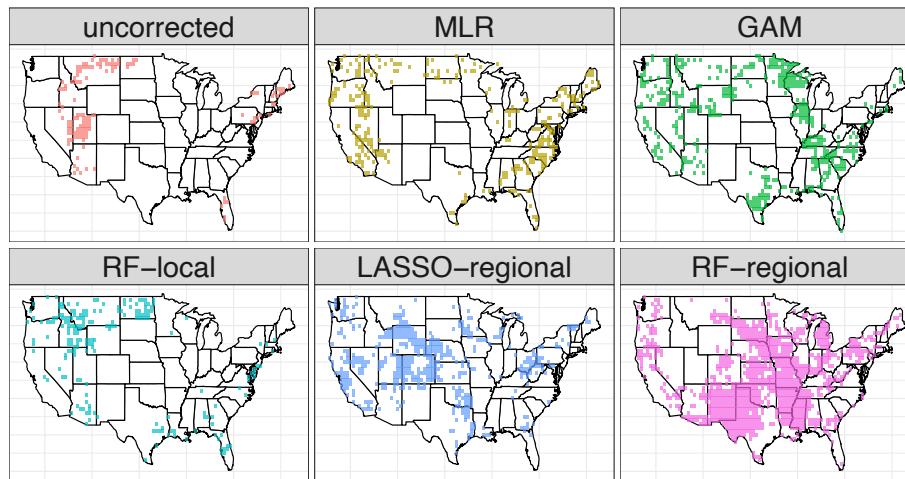

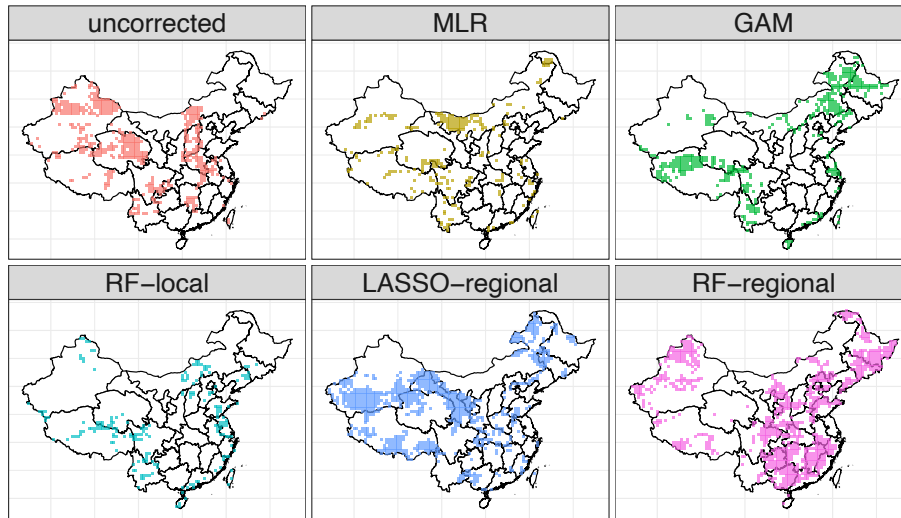

Figure A14. Best-performing correction method for each grid cell (US). For each method, the figure shows the grid cells at which the trend estimate has the smallest estimation error (i.e. closest to the trend in the counterfactual scenario) among the tested methods.

A annual $PM_{2.5}$

B summer O_3

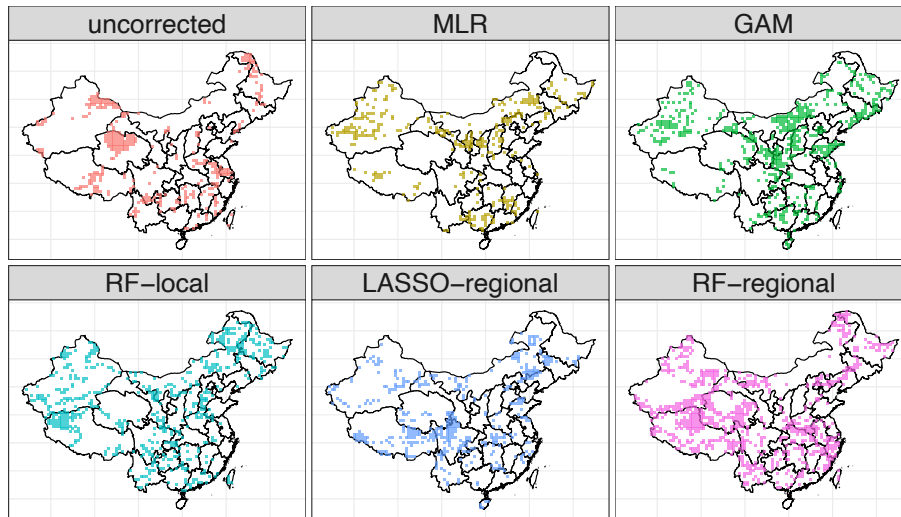

Figure A15. Best-performing correction method for each grid cell (China). For each method, the figure shows the grid cells at which the trend estimate has the smallest estimation error (i.e. closest to the trend in the counterfactual scenario) among the tested methods.

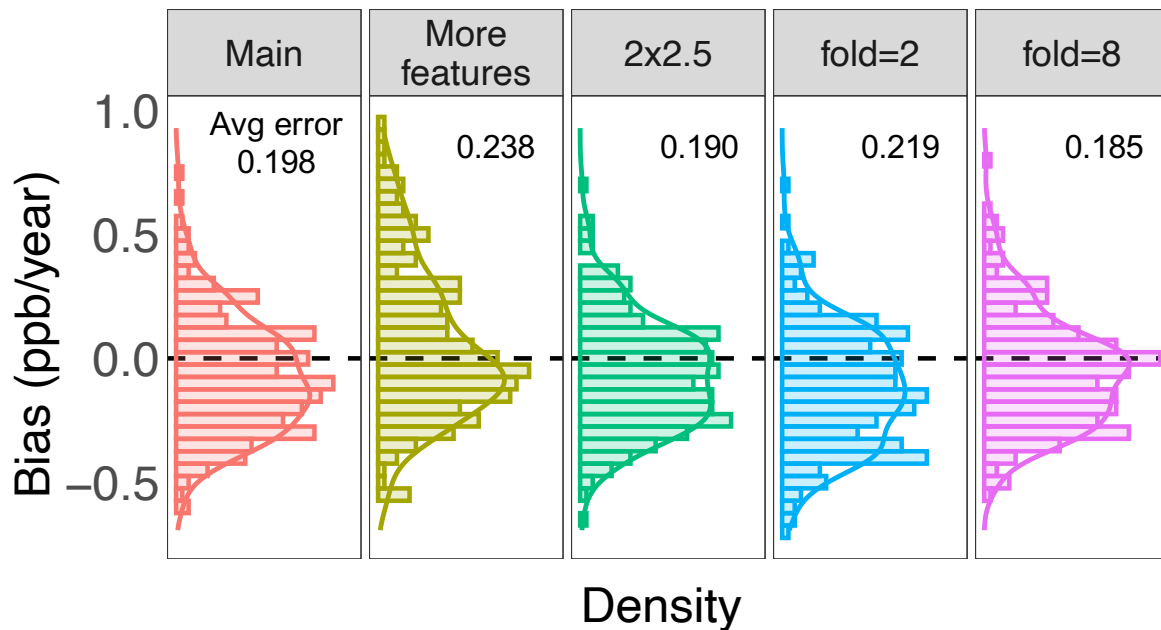

Figure A16. Histograms of estimation errors of trend estimates in O_3 under different implementations of the *RF-regional* method (applied to the US). From left to right: Main (the main results), More features (including 9 extra meteorological features), 2x2.5 (using regional features with spatial resolution at $2 \times 2.5^\circ$, instead of $4 \times 5^\circ$), fold=2 (using 2 folds for data-splitting and cross-fitting), fold=8 (using 8 folds for data-splitting and cross-fitting). Average of the absolute error for each implementation is shown in the figure. Here we only use a random subset of all the grid cells in the US due to high computational cost.
