17 **Abstract.** The Winter Fog Experiment (WiFEX) was an intensive field campaign conducted at Indira Gandhi
18 International Airport (IGIA) Delhi, India, in the Indo-Gangetic Plain (IGP) during the winter of 2017-2018. Here,
19 we report the first comparison in South Asia of high temporal resolution simulation of ammonia (NH₃) along with
20 ammonium (NH₄⁺) and total NH_x (= NH₃ + NH₄⁺) using the Weather Research and Forecasting model coupled
21 with chemistry (WRF-Chem) and measurements made using the Monitor for AeRosols and Gases in Ambient Air
22 (MARGA) at the WiFEX research site. In the present study, we incorporated Model for Simulating Aerosol
23 Interactions and Chemistry (MOSAIC) aerosol scheme into the WRF-Chem. Despite simulated total NH_x
24 values/variability often agreed well with the observations, the model frequently simulated higher NH₃ and lower
25 NH₄⁺ concentrations than the observations. Under the winter conditions of high relative humidity (RH) in Delhi,
26 hydrogen chloride (HCl) was found to promote the increase in the particle fraction of NH₄⁺ (which accounted for
27 49.5 % of the resolved aerosol in equivalent units) with chloride (Cl⁻) (29.7 %) as the primary anion. By contrast,
28 the absence of chloride (HCl/Cl⁻) and their chemistry in the standard WRF-Chem model results in the prediction
29 of sulfate (SO₄²⁻) as the dominant inorganic aerosol anion. To understand the mismatch associated with the fraction
30 of NH_x in the particulate phase (NH₄⁺/NH_x), we added HCl/Cl⁻ to the model and evaluated the influence of its
31 chemistry by conducting three sensitivity experiments using the model: No HCl, Base Case HCl (using a published
32 waste burning inventory), and 3×Base HCl run. We found that 3×Base HCl increased the simulated average NH₄⁺
33 by 13.1 μg m⁻³ and NH_x by 9.8 μg m⁻³ concentration while reducing the average NH₃ by 3.2 μg m⁻³, which is more
34 in accord with the measurements. Thus HCl/Cl⁻ chemistry in the model increases total NH_x concentration, which
35 was further demonstrated by reducing NH₃ emissions by a factor of 3 (-3×NH₃_EMI) in the 3×Base HCl
36 simulation. Reducing NH₃ emissions in the 3×Base HCl simulation successfully addressed the discrepancy
37 between measured and modeled total NH_x. We conclude that modeling the fate of NH₃ in Delhi requires a correct
38 chemistry mechanism accounting for chloride dynamics with accurate inventories of both NH₃ and HCl emissions.

39 1 Introduction

40 The Indo-Gangetic Plain (IGP) is one of the global hotspots of atmospheric ammonia (NH₃) and faces a
41 range of environmental challenges, particularly during the winter season, including adverse air pollution episodes,
42 especially as NH₃ plays a substantial role in secondary aerosol formation (Ghude et al., 2020, 2008b, 2008a;
43 Kumar et al., 2021; Saraswati et al., 2019; Sharma et al., 2020; Singh et al., 2021). Atmospheric NH₃, along with
44 oxides of nitrogen (NO_x), together account for the largest source of reactive nitrogen (N_r), which is primarily
45 emitted by agricultural activities, livestock population, industrial activities, and transportation (Ghude et al., 2009,
46 2010, 2012, 2013; Móríng et al., 2021; Pawar et al., 2021; Sutton et al., 2017b). Ammonia in the environment
47 plays a crucial role in atmospheric chemistry and the eutrophication and acidification of ecosystems (Datta et al.,
48 2012; Mandal et al., 2013; Pawar et al., 2021; Sharma et al., 2008, 2012, 2014b). Control of NH₃ becomes a key
49 priority in an emerging international strategy to manage the global nitrogen cycle (Gu et al., 2021; Sutton et al.,
50 2020). Ammonia is one of the important aerosol precursor gases, and ammonium (NH₄⁺) is a major counter ion
51 for the three anions such as chloride (Cl⁻), nitrate (NO₃⁻), and sulfate (SO₄²⁻) contributing to PM_{2.5} composition
52 (Seinfeld et al., 2016). In addition, as the dominant alkaline gas in the atmosphere, NH₃ has attracted the interest
53 of scientific researchers since it has been known to promote new aerosol formation both in the initial homogeneous
54 nucleation and in the subsequent growth, especially during wintertime (Acharja et al., 2020, 2021; Ali et al., 2019;
55 Duan et al., 2021; Wagh et al., 2021).

56 In this study, we focus on wintertime **analyses**—since this season is characterized by low-to-dense fog
57 events, lower temperature (T), and variability of relative humidity (RH), which fluctuates from 40 to 100 %
58 (Ghude et al., 2017; Kumar et al., 2020). Ammonia acts as a neutralization agent for determining the acidity of
59 aerosol particles (Acharja et al., 2020; Ali et al., 2019; Ghude et al., 2017). It also affects PM_{2.5}, the acidity of
60 clouds, and the wet deposition of nitrogen by neutralizing acidic species (Gu et al., 2021; Xu et al., 2020).
61 Increasing NH₃ concentration over Delhi compared with the surrounding area leads to an increase in PM_{2.5}
62 concentrations (Ghude et al., 2022; Sharma et al., 2008, 2012, 2014a), which in turn affects air quality, human
63 health, and climate (Behera et al., 2013; Ghude, 2016; Ghude et al., 2008b; Nivdange et al., 2022; Sutton et al.,
64 2017a; Sutton and Howard, 2018).

65 Satellite observations (Van Damme et al., 2018; Warner et al., 2017), chemical transport models (CTMs)
66 (Clarisse et al., 2009, 2010; Wang et al., 2020b), and ground-based observations (Pawar et al., 2021) revealed that
67 the IGP is the largest regional hotspot of NH₃ concentrations on Earth. Previous studies have identified various
68 sources of NH₃, for example, agricultural activities, industrial sectors, motor vehicles, garbage, sewage, and urine
69 from rural populations at the global scale (Behera et al., 2013; Huang et al., 2012; Sutton et al., 2008). However,
70 in Delhi, agricultural activity (including surrounding arable and sub-urban livestock farming) is estimated to be
71 the dominant source of NH₃, along with traffic emissions (Kuttippurath et al., 2020; Móríng et al., 2021; Sharma
72 et al., 2020), but its emissions are subject to large uncertainty. Globally, various modeling efforts have investigated
73 the relative effectiveness of reducing NH₃ emissions in curtailing PM_{2.5} formation (Gu et al., 2021; Pinder et al.,
74 2007, 2008; Zhang et al., 2020). However, over India, the impact on reducing PM_{2.5} might be limited because
75 NH₃ emission reductions may be more challenging due to its **alkaline nature** **diverse** and area-wide sources.
76 Ianniello et al. (2010) and Lan et al. (2021) have investigated the variation of atmospheric NH₃ at an urban and
77 suburban site of Beijing with respect to meteorological factors, where RH was found to be a strong factor in
78 influencing the NH₃ mixing ratio. A few studies over Asia have highlighted the gas-to-particle conversion of NH₃

Formatted: Font color: Red

Formatted: Font color: Red

79 in Delhi (Acharja et al., 2021; Saraswati et al., 2019) and China and its subsequent impact on the aerosol formation
80 (Wang et al., 2015; Xu et al., 2020). Furthermore, excess NH_3 during fog can also enhance secondary aerosol
81 formation in Delhi during winter (Acharja et al., 2021). However, the wintertime behavior of NH_3 in Delhi in
82 CTMs has not yet been investigated and remains poorly understood (Ellis et al., 2011; Metzger et al., 2006). In a
83 recent study, Pawar et al. (2021) highlighted uncertainties associated with gas-to-particle partitioning of NH_3 in a
84 global model MOZART-4 and found a significant overestimation of NH_3 in the model compared with the
85 measurements. The overestimation of NH_3 in the model led the authors to hypothesize that a source specific NH_3
86 emission inventory in India, considering agricultural statistics on fertilizer use and animal distribution, was
87 missing. Also, there was a need for a high-resolution regional model with advanced chemistry to resolve the NH_3
88 emissions on the local scale.

89 The present study utilizes the regional Weather Research and Forecasting model coupled with chemistry
90 (WRF-Chem) interpreted using measurements from the Winter fog Experiment (WiFEX), including NH_3 , water-
91 soluble ions in $\text{PM}_{2.5}$, other trace gases, and meteorological parameters during December-January, 2017-18. For
92 the first time in South Asia, we discuss and compare the modeled and observed temporal variation in gaseous
93 NH_3 , particulate NH_4^+ , and total NH_x ($= \text{NH}_3 + \text{NH}_4^+$). Since we found that the total modeled NH_x matches well
94 with the observations, we investigate the ability of the model to accurately describe the gas-to-particle partitioning
95 of the measurements (MARGA) by evaluating the fraction of NH_x in the particulate phase ($\text{NH}_4^+/\text{NH}_x$). We
96 conducted several sensitivity experiments with and without adding anthropogenic waste burning emissions of
97 hydrochloric acid (HCl) in the model. The updated model with HCl/Cl chemistry was used to analyze and
98 compare the temporal variation of NH_3 , NH_4^+ , and total NH_x from the WiFEX measurements.

99 **2. Data and methodology**

100 **2.1 Observational datasets**

101 **2.1.1 Description of MARGA**

102 In the present study, we used the same dataset which was previously published by Acharja et al. (2020)
103 and 2021), which described the aerosol time-series and chemistry measured with a Monitor for AeRosols and
104 Gases in Ambient Air-model 2S instrument (MARGA). The MARGA system has two channels, one for sampling
105 PM_{10} and the other for sampling $\text{PM}_{2.5}$ for ground-based observations. The MARGA (two sampling boxes,
106 analytical box, and connected pumps) was located inside the Indira Gandhi International Airport (IGIA), New
107 Delhi (28.56°N , 77.09°E), with the inlet PM_{10} and $\text{PM}_{2.5}$ impactors fixed on the terrace with 2 m long inlet lines
108 sampling outdoor air at 8 m above ground and 2 m above the rooftop. Measurements covered a winter period (19
109 December 2017 to 21 January 2018) with frequent moderate to dense fog events. Following intake through the
110 PM_{10} and $\text{PM}_{2.5}$ impactors, the air was passed through two parallel inlet tubes 2 m long and 14 mm inner diameter
111 PolyTetraFluoroEthylene (PTFE) to the PM_{10} and $\text{PM}_{2.5}$ sampling channels of the MARGA. The air flow rate in
112 each MARGA sampling box is regulated to a volumetric flow of $1 \text{ m}^3 \text{ h}^{-1}$. The measurements are close to real-
113 time, as two sets of syringes are employed to collect the samples in which a set of syringes collects the sample
114 and another set sends the collected samples from the previous hour for analysis. Each MARGA sampling system
115 consists of a steam jet aerosol collector (SJAC) and a wet rotating denuder (WRD) for collecting and measuring

116 water-soluble inorganic particulate species and gases in the ambient air. The continuous coating of the WRD by
117 a thin film of absorption solution (10 ppm hydrogen peroxide (H₂O₂)) allows the diffusion of gases into the
118 absorption solution. By contrast, the low diffusion velocity of sub-micron particles restricts the ability of water-
119 soluble aerosols to diffuse into the absorption solution. The absorption solution is continually changed to replace
120 that abstracted for ion chromatography (IC) analysis of the dissolved gases. The air stream, depleted of gases by
121 the WRD, subsequently enters the SJAC, where the steam enhances water-soluble aerosols to grow, allowing their
122 mechanical capture in a cyclone. The aqueous solutions deriving from two cyclones (for PM₁ and PM_{2.5},
123 respectively) are then supplied to the IC for chemical analysis (Acharja et al., 2020).

124 Ambient surface concentrations of NH₃ along with other trace gases (HCl, nitrous acid (HONO), nitric
125 acid (HNO₃), and sulfur dioxide (SO₂) and water-soluble inorganic components of PM₁ and PM_{2.5} (Cl⁻, nitrate
126 (NO₃⁻), SO₄²⁻, NH₄⁺, sodium (Na⁺), potassium (K⁺), magnesium (Mg²⁺), and calcium (Ca²⁺) were then quantified
127 online by anion and cation chromatography in the analytical box at an hourly resolution. We have used only PM_{2.5}
128 inorganic water-soluble components and the gaseous measurements (available from both the PM₁ and PM_{2.5}
129 MARGA collection systems). Since NH₄⁺ with the three major anions: Cl⁻, NO₃⁻ and SO₄²⁻ constituted 97.3 %
130 of the total measured ions in PM_{2.5} (Acharja et al., 2020), we consider these four significant ions in our present
131 study. In contrast, the remaining ionic species (i.e., Na⁺, K⁺, Mg²⁺ and Ca²⁺) contributed only about 3 % of the
132 total measured ions and were neglected as it would not impact our present study significantly (Acharja et al.,
133 2020). Anions are separated in a Metrosep A Supp-10 (75/4.0) column with sodium carbonate (Na₂CO₃) and
134 sodium bi-carbonate (NaHCO₃) (7/8 mmol l⁻¹) eluent. Whereas for cations separation, a Metrosep C4 (100/4.0)
135 cation column with 3.2 mmol l⁻¹ HNO₃ eluent was used (Acharja et al., 2020). To suppress the eluent background
136 conductivity of anion chromatographs, three ion exchange units were used to ensure that the ion exchange unit is
137 regenerated in each analysis. 1 M Phosphoric acid (H₃PO₄) was used for this purpose. This was performed to
138 improve the signal-to-noise (S/N) of the anion chromatographs. Details of the MARGA instrument can be found
139 in Makkonen et al. (2012), Thomas et al. (2009), Twigg et al. (2015).

140 2.1.2 Quality assurance/quality control (QA/QC) of MARGA

141 To ensure the observation's accuracy and check the data's quality, we have ~~taken~~ followed best practices all the
142 ~~precautionary measures~~ during the study. The eluents, absorption, and regenerant solutions were prepared with
143 minimum manual intervention. The operational parameters like anion ~~and~~ cation conductivity, SJAC heater
144 temperature, column oven temperature, and airflow were regularly monitored to keep them within the safe limit.
145 In addition to these, before injection of each sample into the anion and cation IC columns, the Lithium Bromide
146 (LiBr) internal standard solution containing 320 µg l⁻¹ lithium (Li⁺) and 3680 µg l⁻¹ bromide (Br⁻) was mixed with
147 each sample to provide calibration of each analysis. This ensures that each analysis is calibrated, and the
148 concentration of gaseous and ionic samples are measured accurately. The PM₁ and PM_{2.5} impactors were typically
149 cleaned fortnightly to remove any material that may ~~have stuck~~ on the surface and inlets of the impactors. The
150 lower detection limits (LODs) of the species monitored by MARGA were mentioned in Acharja et al. (2021). It
151 shows that concentrations of species like Cl⁻, NO₃⁻, SO₄²⁻, NH₄⁺, SO₂, and NH₃ were always higher than LODs
152 during the winter period. But, concentrations of species like Na⁺, K⁺, Ca²⁺, Mg²⁺, HCl, HONO, and HNO₃ were
153 sometimes below LODs, but the fraction of it was less than ~10 % of the total observation period. We have omitted
154 these values and treated them as NA. As the fraction of observational hours is less and these species contribute

Formatted: Font color: Red

Formatted: Font color: Red

Formatted: Font color: Red

Formatted: Font color: Red

155 much less to the PM₁ and PM_{2.5} mass concentrations, we believe below LODs values would not significantly
156 deviate our results. The quality of the data obtained was then checked using the ion-balance method. As an
157 additional quality check, the ratio of the sum of cations to anions (neq m⁻³) was used as an indicator for the viable
158 data. We have checked the cation-to-anion ratio of each hourly sample expressed in the unit of neq m⁻³. We
159 accepted only those values near to unity and rejected those not within the 10 % error bar limit. Based on this
160 evaluation method, overall, for the campaign, the ratio was near unity (1.06 for PM₁ and 0.96 for PM_{2.5}). Excellent
161 charge balance between anions and cations measured by the system also confirms that there are no significant
162 contamination issues associated with the aerosol measurements. Values in slight excess of unity may indicate the
163 presence of formate and acetate in the aerosol, which MARGA does not measure. Further detail on the quality
164 control of MARGA can be found in Acharja et al. (2020).

165 2.1.3 Other ground-based measurements

166 Hourly NO_x measurements were made by the chemiluminescence method, and hourly ozone (O₃) measurements
167 were made by the UV photometric method (CPCB, 2011) at the nearest air quality monitoring station (AQMS) of
168 IGIA operated by the Central Pollution Control Board (CPCB). CPCB follows the United States Environmental
169 Protection Agency (USEPA) approved AC32M NO_x and 42M O₃ analyzer manufactured by Environment S. A.
170 India Private Limited. We used one-hour monitored NO_x and O₃ values in our study. These air quality monitoring
171 stations' quality control and assurance processes were followed as outlined in CPCB (2014, 2020). For data quality
172 of CPCB, we omitted all those observed values which fell below LOD of the instrument (2 µg m⁻³ for NO_x and 4
173 µg m⁻³ for O₃) (Technical specifications for CAAQM station, 2019) and above 500 µg m⁻³ for NO_x and 140 µg m⁻³
174 for O₃ and treated them as NA at a given site. For the NO_x and O₃ datasets, only a small fraction of data (2 %)
175 were outside the instrument operating ranges specified. This step aims to remove any short-term local influence
176 that the models cannot capture and retain the regional-scale variability because the nearest sites are located in the
177 urban environment. We removed a single spike represented by a change of more than 100 µg m⁻³ in just 1 hour
178 (h) for all the data in CPCB monitoring stations to filter out random fluctuations in the observations. We removed
179 some very high NO_x and O₃ values that appeared in the time series right after measurement gaps. Meteorological
180 parameters, including air temperature (T), relative humidity (RH), wind speed, and wind direction, were measured
181 with the automatic weather station (AWS) platform on a 20 m flux tower (Ghude et al., 2017). For detailed
182 information on the measurement site and its meteorological parameters, refer to (Ali et al., 2019).

183 2.2 WRF-Chem v 3.9.1 model

184 The Weather Research and Forecasting model coupled with chemistry (WRF-Chem v3.9.1) was employed in this
185 study to simulate atmospheric gases and aerosols over Delhi during the peak winter period, starting from 19
186 December 2017 to 21 January 2018. We recently used a similar model configuration to simulate the air quality
187 over Delhi (Ghude et al., 2020; Kulkarni et al., 2020). This study used the Model for Ozone And Related chemical
188 Tracers (MOZART-4) gas-phase chemical mechanism coupled with the Model for Simulating Aerosol
189 Interactions and Chemistry (MOSAIC) aerosol scheme, that simulates SO₄²⁻, NH₄⁺, NO₃⁻, methanesulfonate, Na⁺,
190 Ca²⁺, Cl⁻, carbonate, black carbon (BC), and primary organic mass (OC). Other inert minerals, trace elements, and
191 inorganic species are lumped together as different inorganic masses. MOSAIC allows gas-to-particle formation,
192 which includes NH₃, HCl, sulfuric acid (H₂SO₄), HNO₃, and methane sulfonic acid (MSA), and also includes

193 secondary organic aerosols (SOA). Aerosol size distributions are represented by a sectional aerosol bin approach
194 with four size bins (Georgiou et al., 2018). MOSAIC incorporates the thermodynamic and gas-particle partitioning
195 module described by Zaveri et al. (2008). To reduce the computational cost, we selected a 4-bin MOSAIC
196 mechanism that simulates thermodynamic equilibrium and other aerosol processes such as condensation,
197 coagulation, and nucleation. The same mechanism has been widely used with WRF-Chem for simulations outside
198 India (Bucaram and Bowman, 2021; Sha et al., 2019; Yang et al., 2018), but only a limited number of studies
199 have applied it to the Indian domain to include more detailed chemistry and species (Gupta and Mohan, 2015;
200 Jena et al., 2020; Kumar et al., 2018). The SOA formation in MOSAIC is simulated using the volatility basis set
201 approach (Knote et al., 2015). For consistency with the PM_{2.5} MARGA measurements, we have chosen 3-bins
202 according to simulated aerosols size (0.04–0.156 μm; 0.156–0.625 μm; 0.625–2.5 μm) in accordance with the
203 WRF-Chem aerosol size distribution.

204 The model domain covers the entire northern region of India, but here model simulations are compared
205 with the observations at IGIA, New Delhi (28.56° N, 77.09° E). The domain was set with a horizontal grid-spacing
206 of 10 km in both the latitudinal and longitudinal directions. The model top vertical grid included 47 vertical levels,
207 with the model top set to 10 hPa. The physical parameterization schemes of model configuration are the same as
208 those described by Ghude et al. (2020) and Jena et al. (2021). EDGAR-HTAP (Emission Database for Global
209 Atmospheric Research for Hemispheric Transport of Air Pollution) for the year 2010 at 0.1° x 0.1° grid resolution
210 was used in this study for anthropogenic emissions of aerosols and trace gases (PM_{2.5}, PM₁₀, OC, BC, CO, NO_x,
211 etc.) and are scaled to 2018 as per Jena et al. (2021). Biogenic emissions are calculated online using the Model of
212 Emissions of Gases and Aerosols from Nature version 2.1 (MEGAN2.1) (Guenther et al., 2006), and dust
213 emissions are based on the traditional Goddard Global Ozone Chemistry Aerosol Radiation and Transport
214 (GOCART) dust scheme that works with MOSAIC (Ginoux et al., 2001). Fire INventory from NCAR (FINNv1.5)
215 was used in this study for daily open biomass burning emissions that are vertically distributed within the model
216 using Freitas et al. (2007). The chemical initial and lateral boundary conditions come from the global model
217 simulations from the Model for Ozone and Related Chemical Tracers (MOZART-4), and the meteorological initial
218 and lateral boundary conditions are provided from the fifth generation European Centre for Medium-Range
219 Weather Forecasts (ECMWF) atmospheric reanalysis of the global climate (ERA5) with six-hourly temporal
220 resolution. The simulations were reinitialized every fifth day to limit the growth of meteorological errors in our
221 simulations, but the chemical fields were carried forward from the previous simulation.

222 3. Results and Discussion

223 3.1 Comparison of temporal variation in NH₃, NH₄⁺, and total NH_x using WRF-Chem and MARGA

224 3.1.1 Diurnal variation

225 To investigate how well a state-of-the-art chemical transport model performs in capturing the diurnal behavior of
226 NH₃ and NH₄⁺, we compared observed and model-simulated diurnal profiles of NH₃ and NH₄⁺. Figure 1 displays
227 the comparison of diurnal variation (00:00 to 23:00 Indian Standard Time (IST)) in meteorological parameters (T
228 and RH) at the IGIA site in Delhi (Fig. 1a) along with NH₃ and NH₄⁺ averaged over the study period (Fig. 1b)
229 between observations and model. We adopted diurnal variation in emissions from a recent study by Jena et al.

230 (2021). Note that diurnal variability in the model simulations is primarily controlled by the planetary boundary
231 layer mixing. We first investigated the ability of WRF-Chem to accurately predict the meteorological parameters
232 of RH and T, which are important determinants of the gas-to-aerosol partitioning of (semi-) volatile compounds.
233 As shown in Fig. 1a-, simulated T and RH are in reasonable agreement with the observations, with the simulated
234 RH values falling in the range of 50–90 %. Overall, it can be seen that the model shows cold and wet bias compared
235 to the observations but shows warm bias (about 2-3 °C) and dry bias (about 10-12 %) in the afternoon hours. In
236 spite of the small change in the amplitude of the diurnal cycle of RH, the phase characteristics of the diurnal cycle
237 of both T and RH are reasonably well captured by the model. Figure 1b shows that simulated NH₃ and NH₄⁺ are
238 very different compared with the MARGA measurements. The model predicts an average NH₃ and NH₄⁺ ± 1σ
239 mass loading of 56.7 ± 14.3 and 14.7 ± 4.9 μg m⁻³, respectively, while MARGA measurements indicate an average
240 NH₃ and NH₄⁺ ± 1σ mass loading of 28.2 ± 12.4 and 36.9 ± 15.1 μg m⁻³, respectively. We find the diurnal variation
241 of gas-phase NH₃ is significantly overestimated by the model (Normalised Mean Bias (NMB) = 1.02). On the
242 contrary, NH₄⁺ is underestimated by about 60 % (NMB = -0.60). Simulated NH₃ concentrations peak between
243 07:00-09:00 and 22:00-23:00 h with bimodal variation, whilst MARGA shows a single peak around 12:00-13:00
244 h. On the contrary, a nearly flat diurnal profile of NH₄⁺ is predicted by the model, whereas the average MARGA
245 NH₄⁺ concentration maxima and minima were observed during night-time (16:00-03:00 h) and daytime (03:00-
246 08:00 and 09:00-16:00 h), respectively.

247 We also looked into the average diurnal profile of NO_x and the-NH₃ during dense fog events, and the
248 details can be found in the supplement (Fig. S1 and S2 in the Supplement). It is evident that the observed daytime
249 peak of NH₃ did not coincide with NO_x peaks, suggesting that traffic emissions do not contribute significantly to
250 the observed NH₃ rise. The observed correlation between fog water and enhanced NH₃ pulses is consistent with
251 what would also be expected from the evaporation of dew (Sutton et al., 1998; Wentworth et al., 2014, 2016) (S2
252 in the Supplement) but is not sufficient to identify whether it is the main cause of the daytime increase of NH₃. In
253 the future, measurements of the dew water NH₄⁺ and the accumulation of dew water would be ideal for
254 illuminating the contributing processes. The daytime increase in NH₃ concentration could be associated with NH₄⁺
255 aerosol volatilization driven by an associated sharp change in T and RH (~ 11:00-12:00 h) (Sutton et al., 2009a,
256 2013) off-ground surfaces. The fastest increase in T is 12:00 h, which is indeed when NH₃ was at maximum
257 concentration indicating gas-to-particle partitioning may impact the diurnal behavior of NH₃ at Delhi during
258 winter (Sutton et al., 2009a, 2009b). However, in the model, because the largest increase in simulated NH₃ also
259 precedes the large changes in simulated meteorological parameters, and because the simulated particulate NH₄⁺
260 is flat compared to observations, simulated meteorology is ruled out as a significant contribution to high bias in
261 simulated NH₃. Also, the current model does not include the bidirectional exchange of NH₃ with surfaces such as
262 dew and fog water.

263 3.1.2 Daily mean variation

264 To assess the validity of the model, ~~the ratio between simulated and observed the ratio between observed~~
265 ~~and simulated values~~-(model/obs) was tested. Figure 2 displays the model/obs ratio of daily mean variations in
266 the NH₃, NH₄⁺, and total NH_x concentrations. The model shows large differences in NH₃ and NH₄⁺ compared with
267 observations. We find a model/obs higher than 1 (1.5-4.5) in simulated NH₃, indicating the model is biased high
268 (NMB = 1.02), while there is a poor agreement for NH₄⁺ (model/obs less than 0.5), indicating model is biased low

Formatted: Font color: Red

269 (NMB = -0.62). There is good agreement between the modeled total NH_x , which is mostly consistent with the
270 observation (model/obs close to 1) with a small bias (NMB = 0.08). Despite the adequate ability of the model to
271 reproduce the accurate total NH_x , the model is biased low for NH_4^+ and high for NH_3 , indicating that the model's
272 representation of the gas-to-particle partitioning is not correct. It is, therefore, necessary to understand missing
273 chemical processes in gas-to-particle partitioning responsible for the overestimation of NH_3 and underestimation
274 of NH_4^+ in the model.

275 3.2 Gas-to-particle partitioning

276 We investigated the ability of the model to accurately describe the gas-to-particle partitioning of the measurements
277 (MARGA) by evaluating the fraction of total NH_x in the particulate phase ($\text{NH}_4^+/\text{NH}_x$) (Ellis et al., 2011; Wang
278 et al., 2015) for which statistical values are summarized in Table 1. The correlation coefficient (r) indicates an
279 inverse relationship of $\text{NH}_4^+/\text{NH}_x$ with NH_3 for both MARGA and model (r = -0.57, -0.58, respectively). A strong
280 correlation of the MARGA ratio $\text{NH}_4^+/\text{NH}_x$ with the dominant anion concentration (Cl^- : r = 0.79) was observed.
281 However, the measurement shows a poor relationship between SO_4^{2-} and $\text{NH}_4^+/\text{NH}_x$ followed by NO_3^- , which is
282 probably due to very low concentrations that do not change $\text{NH}_4^+/\text{NH}_x$ significantly even when SO_4^{2-} and NO_3^-
283 are neutralized (see Fig. 6). By contrast, the model shows a strong correlation between $\text{NH}_4^+/\text{NH}_x$ with SO_4^{2-}
284 concentration (r = 0.77). MARGA indicates high particulate fractions of NH_4^+ and Cl^- while the modeled
285 composition is dominated by NH_4^+ and SO_4^{2-} . This mismatch is due to the complete absence of Cl^- chemistry in
286 the standard model. The measured $\text{NH}_4^+/\text{NH}_x$ suggests that anthropogenic HCl may be promoting this increase in
287 particle fraction of NH_4^+ and Cl^- via partitioning into the aerosol, deprotonating in the aerosol water, followed by
288 NH_3 partitioning and being protonated by the ionization of the strong electrolyte HCl (Chen et al., 2022; Gunthe
289 et al., 2021).

290 Figure 3 shows the percentage contribution of gases (NH_3 , SO_2 , HCl, HNO_3 , and HONO) and $\text{PM}_{2.5}$
291 aerosol (NH_4^+ , SO_4^{2-} , NO_3^- and Cl^-) during the WIFEX measurements. The pie charts for the gases show that NH_3
292 (accounting for 53.3 % of the measured total gas concentration) dominates the gas phase, followed by sulfur
293 dioxide (SO_2) (35.61 %), whereas $\text{PM}_{2.5}$ aerosol show NH_4^+ (49.5 %) as a major cation and Cl^- (29.7 %) as a
294 significant anion followed by NO_3^- (11.7 %) and SO_4^{2-} (9 %). There is also a very high amount of SO_2 reaching
295 the site from the nearby industrial area, which is not converted to SO_4^{2-} very quickly (Acharja et al., 2021). In a
296 normally NH_3 -rich atmosphere, gas-phase oxidation of SO_2 is much slower than the aqueous phase oxidation **by**
297 **of** O_3 , and due to nearby sources, much of the sulfur is present as SO_2 (Li et al., 2007). **(Fig. S3 in the Supplement).**
298 This appears to be because of the slow rate of gas phase oxidation of SO_2 . Although the atmosphere is rich in
299 NH_3 , in principle favoring aqueous phase oxidation via O_3 , it appears that O_3 concentrations are often insufficient
300 (mean = 36.3, median = 33.8, minimum = 26.5, and maximum = 53.9, $\mu\text{g m}^{-3}$ respectively) at the IGIA site (Fig.
301 S3 in the Supplement). Hence for many periods during the WIFEX campaign, SO_4^{2-} and NO_3^- are very low, with
302 the result that the $\text{NH}_4^+/\text{NH}_x$ ratio does not change appreciably when SO_4^{2-} is neutralized (Table 1).

303 According to thermodynamic equilibrium theory, an aqueous solution maintains charge neutralization
304 initially by balancing NH_3 uptake with the uptake of sulfuric acid (H_2SO_4) before HNO_3 and HCl can partition
305 into the aqueous aerosol; hence all SO_4^{2-} in the condensed phase will be fully neutralized before any HNO_3 , or
306 HCl can partition (Behera et al., 2013). Typical Delhi winter conditions of excess NH_3 , high RH, and low T favor
307 gas-to-particle partitioning of NH_3 . The principal inorganic chemical reactions that occur in aqueous atmospheric

Formatted: Font color: Red

308 aerosols form pairs of non-volatile NH_4^+ and acid anions (SO_4^{2-} , NO_3^- , and Cl^-) are summarized in reactions R1
309 to R3 (Seinfeld et al., 1998).

313
314 NH_4^+ and Cl^- (R3), which are favored by low T and high RH, form a reversible equilibrium with NH_3 and HCl
315 (Ianniello et al., 2011; Seinfeld and Pandis, 2016), which was the case during WIFEX. It is likely that high Cl^- in
316 Delhi resulted from gas-to-particle partitioning of HCl into aerosol water in the presence of excess NH_3 (R3),
317 with aqueous phase Cl^- stimulating further water uptake and jointly driving aerosol mass composition and growth
318 through co-condensation (Chen et al., 2022; Gunthe et al., 2021). Hence, to understand the driver of the measured
319 NH_4^+ and the role of aqueous chemistry, we plotted the fraction of the ratio of HCl to Cl^- (HCl/Cl^-) as a function
320 of NH_4^+ concentration and RH in Fig. 4. **The decrease in the fraction of HCl/Cl^- is associated with an increase in**
321 **NH_4^+ concentration at high RH between 70-100 %. Fraction of particulate phase Cl^- increases at high RH between**
322 **70-100 % and thus increases the NH_4^+ concentration.** The HCl/Cl^- is highly anticorrelated ($r = -0.53$) with NH_4^+
323 concentration in the presence of high RH (70-100 %), further supporting the view that HCl promotes the increase
324 in the particle fraction of NH_4^+ (49.5 %) with Cl^- (29.7 %) the primary anion.

325 We investigated the directions of local emission sources associated with concentration increases of NH_3 ,
326 NH_4^+ , Cl^- and NH_x through bivariate polar graphs using the OpenAir software (Carslaw and Ropkins, 2012) at the
327 IGIA site. Figure 5 shows the bivariate polar plots of mean NH_3 (Fig. 5a), NH_4^+ (Fig. 5b), Cl^- (Fig. 5c), and total
328 NH_x (Fig. 5d) concentration for the observation period in relation to wind speed and wind direction. The 270-300°
329 sector dominated the wind direction at IGIA (Acharja et al., 2021). Figure 5a shows that the highest NH_3
330 concentration was associated with the winds coming from the east and southeast of the site, where it could have
331 been emitted from dairy farms, including animal houses, yards, and manure storage, as well as by the application
332 to the farmland of urea and other ammoniacal fertilizers, ammoniacal wastes and ruminant urine located at this
333 region (Hindustan Times, 2021; Leytem et al., 2018; Sherlock et al., 1994). Such sources of NH_3 volatilization
334 (Hristov et al., 2011; Laubach et al., 2013) can also explain the higher concentrations of total NH_4^+ (and, by
335 definition NH_x) for air coming from the southeast of the measurement site (Fig. 5b and d). This enhancement in
336 the southeast region is not only affected by emissions but also by meteorology and chemistry. Thus higher NH_3
337 concentration may also be due to the lack of turbulent mixing, which restricts the dilution of plumes from local
338 point sources at lower wind speeds (Ianniello et al., 2010). The bivariate polar plots of NH_4^+ (Fig. 5b) and Cl^-
339 (Fig. 5c) concentration point to the west direction as a principal source for thermodynamic partitioning of NH_3
340 and HCl to the condensed phase to form NH_4^+ and Cl^- . Two industrial sources are located in this direction: the
341 site is impacted by a cluster in northwest Delhi of industrial processes, such as steel pickling industries, and others
342 include metal finishing and electroplating, which are known to be vital HCl emitters (Acharja et al., 2021;
343 Jaiprakash et al., 2017). Near the source, abundant quantities of NH_3 may drive the partitioning of HCl to the
344 condensed phase resulting in high concentrations of NH_4^+ and Cl^- towards the west at lower wind speeds. Thus,
345 high NH_4^+ and Cl^- correspond to the lowest NH_3 concentration region (inverse relation), which can be observed
346 in Fig. 5a, b, and c, highlighting the importance of nearby HCl industrial sources in driving the particle fraction
347 of NH_4^+ and Cl^- .

Formatted: Font color: Red

348 To gain insight into the role of NH_4^+ in the neutralization of anions (SO_4^{2-} , NO_3^- and Cl^-), the aerosol
349 neutralization ratio (ANR) was calculated using the observed data. The ANR is defined as the equivalent ratio of
350 NH_4^+ to the sum of SO_4^{2-} , NO_3^- and Cl^- because these species represent the dominant cations and anions in $\text{PM}_{2.5}$,
351 respectively. Figure 6 demonstrates, on average, how well the charge balance works between Cl^- , NO_3^- and SO_4^{2-}
352 (in $\mu\text{eq m}^{-3}$) as the anions and NH_4^+ as the major cation (ANR close to unity), with Cl^- as the most significant
353 anion followed by NO_3^- and SO_4^{2-} . The mean $\pm 1\sigma$ ANR value for $\text{PM}_{2.5}$ during the observed period was $0.96 \pm$
354 0.14 . It ranges from a minimum of 0.35 ± 0.04 to a maximum of 2.31 ± 0.08 . Higher values than unity may indicate
355 the presence of organic acids in the aerosol, which MARGA does not measure (Acharja et al., 2020). Also, high
356 standard error in Fig.6 indicates the possibility of uncertainties associated with the breakthrough of NH_3 spikes on
357 the denuder at high concentration ($\sim 1\%$) (Stieger et al., 2019). However, the good charge balance indicates this
358 wasn't a major issue. There also were certain periods where low concentrations were observed of Cl^- and NO_3^-
359 (03-06 January 2018 and 16-17 January 2018) in Fig. 6. Comparing the model/obs for NH_3 , NH_4^+ and total NH_x
360 during these periods provides some degree of validation of the model where sulfur chemistry dominates the
361 reaction with NH_3 . Figure S4 (in the supplement) shows that model/obs indicates substantial variability which
362 appears to be overestimating NH_3 (model/obs >1) while underestimating total NH_4^+ (model/obs <1) on average
363 in the model.

364 3.3 Influence of HCl/Cl⁻ chemistry in WRF-Chem

365 We further conducted three scenario simulations for the period 7-16 January 2018 (10 days) to explore the
366 potential impacts of the addition of anthropogenic chloride (HCl/Cl⁻) emissions in the concentrations of NH_3 ,
367 NH_4^+ and total NH_x . We employ the HCl emissions from trash-burning activities in Delhi, as predicted by Sharma
368 et al. (2019) in our model set-up. We tested the three sensitivity experiments named: No HCl ($0 \text{ mol km}^{-2} \text{ h}^{-1}$),
369 Base Case HCl ($3 \times$ Sharma et al., 2019; $24.8 \text{ mol km}^{-2} \text{ h}^{-1}$), and $3 \times$ Base HCl ($74 \text{ mol km}^{-2} \text{ h}^{-1}$) scenario, reflecting
370 adjustments which are consistent with the more recent upward adjustments in the amount of waste burned in
371 landfills by Chaudhary et al. (2021) and also to reflect additional industrial HCl sources not accounted for in the
372 inventory. Figure 7 presents the box-whiskers plots for secondary inorganic aerosols and trace gases from the
373 observations (MARGA), and those simulated by the model for the three sensitivity experiments. Daily mean $\pm 1\sigma$
374 values are summarized in Table 2 for three different model scenarios. As can be observed from Fig. 7(a-c),
375 increasing the HCl emissions (Fig. 7g) in the model partitions more NH_3 to the condensed phase due to its high
376 concentrations, reaching maximum mass loadings of NH_4^+ and Cl^- of 70 and $110 \mu\text{g m}^{-3}$, respectively, in the
377 $3 \times$ Base HCl scenario, while increasing the total mean NH_x concentration by $15 \mu\text{g m}^{-3}$ compared to the No HCl
378 run presumably reflecting the longer residence time of NH_4^+ for near-surface air measurements.

379 The simulated NO_3^- concentration (Fig. 7e) generally exceeds the measurements in all three experiments;
380 since the main neutralizing species for NO_3^- is NH_4^+ , it is controlled via the equilibrium between NO_3^- , HNO_3 , and
381 NH_3 , but also the competition with HCl for free NH_3 . Simulated HNO_3 is significantly underestimated (by $\sim 3 \mu\text{g}$
382 m^{-3}) (Fig. 7h) by the model compared to the observations. As a consequence, the model suggests that NO_3^-
383 formation from gaseous NH_3 and HNO_3 cannot occur. The gas fraction of observed HNO_3 will be determined by
384 aerosol pH and liquid water content based on NH_3 and NO_3^- availability (Nenes et al., 2020). The over-prediction
385 of NH_3 concentration in the model compared with the observations generates more NO_3^- (and simultaneously
386 reduces HNO_3), with the total fraction of $\text{HNO}_3 + \text{NO}_3^-$ (THNO_3) concentration in the model also exceeding the

387 observed THNO₃, which is more strongly affected by reducing the NH₃ emissions in the model (Fig. S5 in the
388 Supplement). On average, THNO₃ reduced by only 0.38 μg m⁻³ in 3×Base HCl compared to the No HCl run. But
389 reducing NH₃ emissions by a factor of 3 (-3×NH₃_EMI) in the 3×Base HCl scenario reduced mean THNO₃ by a
390 further 4.71 μg m⁻³. The extent of partitioning and accumulation of NH₄NO₃ depends on T, aerosol water, pH, as
391 well as NH₃ availability (Nenes et al., 2020). Our model simulations find that the presence of HCl/Cl⁻ does not
392 significantly alter THNO₃ but that the excess NH₃ with missing chloride chemistry is a major contributor and will
393 lead to mismatches in the model between measured simulated gas and particulate matter concentrations.

394 The simulated SO₄²⁻ concentration (Fig. 7f) was underestimated (by ~ 7.5 μg m⁻³), while gas-phase SO₂
395 (Fig. 7i) was found to be overestimated by about 16 μg m⁻³ in all three experiments compared with the observations.
396 This may be caused by the fact that the drivers for typical sulfate production via OH or aqueous H₂O₂ oxidation
397 pathway are likely to be wrong in the model. The missing chemistry may underly this mismatch and requires
398 further sensitivity studies considering different SO₂ oxidation pathways. This requires further study, such as
399 scenario evaluation of altered SO₂ emissions in the model, to examine the main pathway(s) for SO₂ to SO₄²⁻
400 conversion. Measurements of OH and other radicals in Delhi are currently lacking, making it difficult to constrain
401 the associated chemical schemes. To investigate the further impact of 3×Base HCl in the model, uptake of gaseous
402 NH₃ to form NH₄⁺ and Cl⁻ was analyzed via a strong correlation coefficient values of r = 0.84 for NH₄⁺/NH_x with
403 Cl⁻ concentration, indicating a fraction of gas-to-particle conversion in the model correlates well with the Cl⁻
404 concentration and was reasonably well simulated in the 3×Base HCl run.

405 **3.4 Comparison of the temporal variation in NH₃, NH₄⁺, and NH_x using WRF-Chem (HCl/Cl⁻) and** 406 **MARGA**

407 **3.4.1 Diurnal variation**

408 Here, diurnal variations of monitored aerosol compounds and gases were analysed to investigate the gas-to-
409 particle conversion of NH₃ in the model. We analyzed the simulation results of the 3×Base HCl run. The diurnal
410 variations for NH₃ and NH₄⁺ are controlled mainly by thermodynamic gas-to-particle partitioning, boundary layer
411 mixing, emission and deposition processes, along with vertical and horizontal advection (Meng et al., 2018).
412 Figure 8 (top) presents the diurnal variations of NH₃ and NH₄⁺ (in μg m⁻³) along with particulate NH₄⁺, Cl⁻, NO₃⁻,
413 SO₄²⁻, SO₂, HCl, and HNO₃ concentrations (in μeq m⁻³) measured (Fig. 8a (top)) and modeled (Fig. 8b (top))
414 along with its meteorological parameters such as T and RH (Fig. 8 (bottom)). We adopted diurnal variation in
415 emissions from Jena et al. (2021) based on boundary layer mixing. It can be seen in Fig. 8a (top and bottom) that
416 a much bigger peak in NH₃ concentration is observed in the daytime than the modeled (despite turbulence
417 differences), indeed suggesting a much stronger NH₃ in the middle of the day (11:00-01:00 h). As evaporation
418 proceeds mainly in the morning (08:00-12:00) getting warmer, the peak is near midday (11:00-13:00 h), rather
419 than in the afternoon (13:00-14:00 h) when warmest, similar to what was also observed in Sutton et al. (1998).
420 Indeed, the decreasing NH₄⁺ and Cl⁻ during the late morning (10:00 h) corresponds to the increasing NH₃ peak,
421 which reflects the fact that warming promotes the shift of aerosols to the gas phase. Ammonium decreases more
422 than NH₃ during the day, as this also evaporates to form NH₃. Similarly, Cl⁻ evaporates during the day since the
423 HCl concentration increases. However, it can be seen that NO₃⁻ and SO₄²⁻ are slightly changed diurnally, inferring
424 longer range transport perhaps, whereas HCl and Cl⁻ are from more local sources. The diurnal variability in gases
425 and aerosols in 3×Base HCl simulations in Fig. 8b (top) is primarily controlled by the planetary boundary layer

426 mixing, meteorology/dispersion, environment (T and RH in Fig. 8b (bottom)), and transport. So presumably,
427 maximum NH₃ at 08:00 h is due to limited turbulence/boundary layer, with dilution by mixing after 08:00 h.
428 However, the model is able to represent well the diurnal variation of NH₄⁺ and Cl⁻ both in terms of amount and
429 pattern, which was not the case in the No HCl run where NH₄⁺ was observed to be flat in Section 1. During the
430 hours of 09:00 and 11:00 h, when measured NH₃ rises, the model predicts a large decrease in NH₃, while during
431 19:00-23:00 h, when measured NH₃ decreases, the model predicts a large increase. Furthermore, the modeled HCl
432 and HNO₃ are very low compared to the measurements, whereas SO₂ concentration matches well with the
433 observations. It can be seen that NO₃⁻ and SO₄²⁻ are flat in the model. This highlights the need to develop accurate
434 diurnal variability in NH₃ emissions over this region.

435 Figure 9 presents the differences in diurnal variation of mean NH₃ (Fig. 9a), NH₄⁺ (Fig. 9b), and total
436 NH_x (Fig. 9c) concentration for the three sensitivity experiments. While the simulated NH₃ concentrations
437 decrease in the 3×Base HCl compared to the No HCl and Base Case HCl run (Table 2), none of the model
438 experiments capture the diurnal cycle of NH₃. Higher levels of observed NH₃ during daytime and modeled NH₃
439 during night-time highlight the need to improve diurnal variability in NH₃ emissions over this region based on the
440 nature and strength of the actual sources. Between the No HCl and the 3×Base HCl run, the NMB for NH₃ reduced
441 from 1.38 to 1.13, and NMB for NH₄⁺ systematically improved from -0.61 to -0.03. In contrast, NMB for total
442 NH_x increased from 0.12 to 0.39. Table 3 summarizes the statistical indicators for the three sensitivity
443 experiments. An increase in HCl emissions in the 3×Base HCl leads to a higher mass concentration of NH₄⁺ and
444 Cl⁻, which also increases total mean NH_x concentration by 22.4 μg m⁻³, presumably reflecting the longer
445 atmospheric lifetime of NH₄⁺ compared with NH₃. We find consistent high bias in all the simulations for NH₃,
446 which is highest during the early morning and at night-time. In order to better understand the relationship between
447 NH₃, NH₄⁺ and NH_x concentrations in the diurnal profile of model, one sensitivity study is conducted in the best
448 case HCl experiment to simulate the response of NH₃ concentrations by changing NH₃ emissions. In these
449 simulations, only NH₃ emissions were reduced further by a factor of 3 (-3×NH₃ EMI) in the 3×Base HCl
450 experiment, while all other processes and chemical schemes were unchanged. Figure S6 in the Supplement shows
451 the diel profile of model/obs ratio for NH₃ (Fig. S6a), NH₄⁺ (Fig. S6b), and total NH_x (Fig. S6c) concentration
452 simulated with the 3×Base HCl and -3×NH₃ EMI scenario. Reducing NH₃ emissions in the model (-3×NH₃ EMI)
453 significantly improves model-measurement agreement for NH₃ (mean model/obs = 1.9), NH₄⁺ (mean model/obs
454 = 0.9), and total NH_x concentration (mean model/obs = 1.2) compared to the 3×Base HCl run, further suggesting
455 that the longer lifetime of NH₄⁺ may be the controlling driver for the total NH_x concentration in the model.

456 3.4.2 Variation of daily means

457 Figure S76 in the Supplement illustrates a time-series graph that compares daily mean NH₃ (Fig. S76a), NH₄⁺
458 (Fig. S76b), and total NH_x concentrations (Fig. S76c) for the three sensitivity experiments, and Table 2 shows the
459 mean ± 1σ of these variables. The results show that compared to the No HCl run, NH₃ mean concentrations
460 decreased by 2 μg m⁻³ in the Base Case HCl and decreased by a further 3.2 μg m⁻³ in the 3×Base HCl run. On the
461 contrary, NH₄⁺ mean concentration increases in the Base Case HCl by 7.5 μg m⁻³ and further increases by 13.1
462 μg m⁻³ (3×Base HCl). This decrease in NH₃ is associated with the enhanced gas-to-particle conversion of NH₃ to
463 NH₄⁺. Associated with these changes, total mean NH_x also increased by 5.5 and 9.8 μg m⁻³ in the Base Case HCl
464 and 3×Base HCl, respectively, compared to the No HCl. This is likely due to associated increases in the

Formatted: Font color: Red

Formatted: Font color: Red

Formatted: Font color: Red

465 atmospheric lifetime of NH_x with respect to deposition as the partitioning shifted from the faster depositing gas
466 phase to the aerosol phase. The lifetime of NH_3 is very short, a few hours, while that of NH_4^+ is 1 to 15 days
467 (Aneja et al., 1998; Nair and Yu, 2020; Pawar et al., 2021; Wang et al., 2020a).

468 To understand further the overestimation of total NH_x ~~in the daily mean variation~~ by the model, we
469 ~~compared 3×Base HCl and -3×NH₃ EMI sensitivity experiment. performed a sensitivity test with the HCl~~
470 ~~emissions that led to the best model/obs comparison (3×Base HCl emissions) by additionally reducing NH₃~~
471 ~~emissions by a factor of 3 (-3×NH₃-EMI).~~ Figure 10 shows the ratio of model/obs for NH_3 (Fig. 10a), NH_4^+ (Fig.
472 10b) and total NH_x (Fig. 10c) concentration. It can be seen that the model-measurement agreement improves
473 significantly (model/obs closer to 1) after reducing NH_3 emissions for all three metrics. -3×NH₃-EMI would
474 reduce the mean NH_3 , NH_4^+ , and total NH_x concentration by $\sim 8.1 \mu\text{g m}^{-3}$, $3.2 \mu\text{g m}^{-3}$, and $11.3 \mu\text{g m}^{-3}$, respectively,
475 compared to the 3×Base HCl run. Even though reducing NH_3 emissions, it is still sufficient to react rapidly with
476 the varying HCl in the sensitivity experiments contributing to an increase in NH_4^+ . As can be seen in Fig. 10b,
477 initially, NH_4^+ is somewhat lower, but it increases later and matches the 3×Base HCl run. This suggests that NH_4^+
478 formation in the model is more sensitive to changes in HCl than changes in NH_3 emission, while total NH_x agrees
479 well by reducing the NH_3 emissions. In general, CTMs have higher NH_3 concentration than observations, further
480 supporting models having too much NH_3 . A few factors might contribute to the model discrepancies for NH_3 :
481 there are uncertainties in the emission inventory of the bottom-up approach of NH_3 , and the model does not
482 currently include the bidirectional exchange of NH_3 with surfaces, such as dew and fog water. Also model does
483 not have accurate industrial sources of HCl emission. Diurnal emission profiles are uncertainty for both NH_3 and
484 HCl. Furthermore, gas-to-particle partitioning associated with SO_2 oxidation pathways in the model is not correct
485 at present.

486 4. Conclusions

487 In this study, we have evaluated for the first time in South Asia the performance of a chemical transport model
488 (WRF-Chem) in modeling NH_3 , NH_4^+ , and total NH_x , by comparing against the WiFEX measurements
489 (MARGA). ~~The model predicted average NH_3 and NH_4^+ mass loadings of 56.7 ± 14.3 and $14.7 \pm 4.9 \mu\text{g m}^{-3}$
490 respectively, whereas the measurements depicted 28.2 ± 12.4 and $36.9 \pm 15.1 \mu\text{g m}^{-3}$, respectively, in the diurnal
491 concentration. Simulated NH_3 concentrations peaked with bimodal variation, though observations showed a
492 daytime rise around 12:00–13:00 h. Ammonia peaks during the daytime suggested that the NH_4^+ volatilization is
493 causing its rise. Also, the role of fog and dew in enhancing NH_3 pulses requires further attention, and it is currently
494 not incorporated into the model.~~ In daily means, we find NH_3 is significantly overestimated by the model, NH_4^+
495 was underestimated while simulated total NH_x agreed well with the measurement, indicating incorrect gas-to-
496 particle partitioning along with missing chemical process may impacts this mismatch in the model. The ability of
497 the model to accurately describe the gas-to-particle partitioning of the MARGA was evaluated by the fraction of
498 total NH_x ($= \text{NH}_3 + \text{NH}_4^+$) in the particulate phase ($\text{NH}_4^+/\text{NH}_x$). A strong relation of MARGA $\text{NH}_4^+/\text{NH}_x$ was
499 observed with dominant anion (Cl^-) ($r = 0.79$), whereas the standard model showed a strong correlation between
500 $\text{NH}_4^+/\text{NH}_x$ with dominant anion (SO_4^{2-}) ($r = 0.77$), pointing to the missing chloride (HCl/Cl^-) chemistry in the
501 model. ~~Measured HCl/Cl^- correlated highly ($r = -0.53$) with the NH_4^+ levels, in the presence high RH (70–100 %),
502 indicated HCl promoting the increase in the particle fraction of NH_4^+ (49.5 %) with Cl^- (29.7 %) as the primary~~

503 anion. On average, the measured aerosol neutralization ratio (ANR) was close to unity (0.96) with Cl⁻ the most
504 significant anion followed by NO₃⁻ and SO₄²⁻.

505 We further incorporated HCl/Cl⁻ emissions in the model and conducted three sensitivity experiments of
506 varying HCl emissions, named as No HCl (0 mol km⁻² h⁻¹), Base Case HCl (3× Sharma et al., 2019; 24.8 mol km⁻²
507 h⁻¹) and 3×Base HCl (74 mol km⁻² h⁻¹) run. The revised model shows that by adding HCl emissions in the model
508 were more NH₃ was partitioned to the condensed phase improving agreement with the observations,
509 due to its high concentrations, reaching maximum mass loadings of NH₄⁺ and Cl⁻ of 70 and 110 μg m⁻³ μg m⁻³,
510 respectively, in the 3×Base HCl run, while increasing the total mean NH_x concentration by 15 μg m⁻³ compared
511 to the No HCl run. 3×Base HCl was able to represent well the diurnal variation of NH₄⁺ and Cl⁻ both in terms of
512 amount and pattern with improved NMB for NH₃. Additional sensitivities tests in changing NH₃ emissions
513 (reduction by a factor of 3) in the 3×Base HCl also improved NH₃, NH₄⁺, and NH_x concentrations. We find excess
514 NH₃ along with longer lifetime of NH₄⁺ may act as a controlling driver for NH_x overestimation in the model.
515 These results highlight the need to include correct industrial sources of HCl emissions along with appropriate
516 emissions of NH₃ to reduce biases in NH_x.

517 The NMB for NH₃ was found to be reduced from 1.38 to 1.13 while NMB for NH₄⁺ systematically
518 improved from -0.61 to -0.03 in 3×Base HCl. By contrast, NMB for NH_x increased from 0.12 to 0.39, respectively,
519 for the No HCl and 3×Base HCl simulations. Our modeling results suggest reducing NH₃ emissions by a factor
520 of 3 (3×NH₃_EMI) in the 3×Base HCl was successful in reducing the mean NH₃, NH₄⁺ and total NH_x
521 concentration by ~8.1 μg m⁻³, 3.2 μg m⁻³, and 11.3 μg m⁻³, respectively, compared to the 3×Base HCl. Developing
522 the appropriate NH₃ emissions using country-specific emission inventories, which are currently under
523 development as part of the Global Challenges Research Fund (GCRF), South Asian Nitrogen Hub (SANH). Also,
524 there is potential to develop top-down constraints on NH₃ emissions by taking inference from the satellite, model,
525 and ground-based observations. We find excess NH₃ along with longer lifetime of NH₄⁺ may act as a controlling
526 driver for NH_x overestimation in the model. Challenges remain in simulating NH₃ as a contributor to particulate
527 matter due to temporal factors in ammonia peaks including the role of fog and dew where more work is needed.
528 This work also suggests model improvements to SO₂ oxidation pathways could improve NH_x partitioning.

529 Hence, in the future, it is necessary to evaluate the impact of the addition of correct industrial sources of
530 HCl emission along with appropriate emissions of NH₃ and their diurnal variability, and improvements to the
531 chemistry in model are suggested to address the challenges of simulating NH₃ as a contributor to particulate
532 matter. Additionally, it is required to understand different SO₂ oxidation pathways in the model. To our
533 knowledge, this is the first study to qualitatively examine the influence of HCl/Cl⁻ chemistry in WRF-Chem in
534 determining the fraction of NH₄⁺/NH_x. The present study suggests that the bias in NH_x could be reduced by
535 including both the accurate HCl and NH₃ emissions in the model. Developing the appropriate NH₃ emissions
536 using country specific emission inventories, which are currently under development as part of the Global
537 Challenges Research Fund (GCRF), South Asian Nitrogen Hub (SANH). Also, there is potential to develop top-
538 down constraints on NH₃ emissions by taking inference from the satellite, model, and ground-based observations.

539 **Data availability**

540 The $0.1^\circ \times 0.1^\circ$ emission grid maps can be downloaded from the EDGAR website on
541 https://edgar.jrc.ec.europa.eu/htap_v2/index.php?SECURE=_123 per year per sector. Gridded emissions in t y^{-1}
542 on a $0.1^\circ \times 0.1^\circ$ for HCl emissions can be downloaded from Mendeley data: <http://dx.doi.org/10.17632/546f9249bv.1>. The model data is available at Aditya, Indian Institute of Tropical Meteorology
543 (IITM) super-computer and can be provided upon request to the corresponding author. The observational and
544 meteorological data of WiFEX are available by contacting the corresponding author.
545

546 **Author contributions**

547 SDG designed the research; PVP performed the WRF-Chem model simulations and led the analysis; PA and RK
548 contributed to data collection and its quality control and assurance; GG, RK, and PG helped with the model set
549 up; PVP and SDG wrote the paper with contributions from all co-authors.

550 **Competing interests**

551 The authors declare that they have no conflict of interest.

552 **Acknowledgments**

553 We thank the Director, IITM, for his continuous support and encouragement. IITM is funded by the Ministry of
554 Earth Sciences (MoES), Government of India. We wish to thank the MoES for supporting the WiFEX campaign.
555 The lead author's fellowship was supported by the National Supercomputing Mission (NSM) program grant at C-
556 DAC, and Ph.D. fees are covered by the Natural Environment Research Council (NERC) of UK Research and
557 Innovation (UKRI)-Global Challenges Research Fund (GCRF), South Asian Nitrogen Hub (SANH), and we are
558 grateful to the Executive Director and the Director-General of C-DAC and the SANH Director and Chair of the
559 Executive Board. We acknowledge the availability of CPCB-NO_x, NO₂, and O₃ data from the CPCB web portal
