Abstract. The Winter Fog Experiment (WiFEX) was an intensive field campaign conducted at Indira Gandhi International Airport (IGIA) Delhi, India, in the Indo-Gangetic Plain (IGP) during the winter of 2017-2018. Here, we report the first comparison in South Asia of high temporal resolution simulation of ammonia (NH₃) along with ammonium (NH₄⁺) and total NH_x (= NH₃ + NH₄⁺) using the Weather Research and Forecasting model coupled with chemistry (WRF-Chem) and measurements made using the Monitor for Aerosols and Gases in Ambient Air (MARGA) at the WiFEX research site. In the present study, we incorporated Model for Simulating Aerosol Interactions and Chemistry (MOSAIC) aerosol scheme into the WRF-Chem. Despite simulated total NH_x values/variability often agreed well with the observations, the model frequently simulated higher NH₃ and lower NH₄⁺ concentrations than the observations. Under the winter conditions of high relative humidity (RH) in Delhi, hydrogen chloride (HCl) was found to promote the increase in the particle fraction of NH₄⁺ (which accounted for 49.5 % of the resolved aerosol in equivalent units) with chloride (Cl⁻) (29.7 %) as the primary anion. By contrast, the absence of chloride (HCl/Cl⁻) and their chemistry in the standard WRF-Chem model results in the prediction of sulfate (SO₄²⁻) as the dominant inorganic aerosol anion. To understand the mismatch associated with the fraction of NH_x in the particulate phase (NH₄⁺/NH_x), we added HCl/Cl⁻ to the model and evaluated the influence of its chemistry by conducting three sensitivity experiments using the model: No HCl, Base Case HCl (using a published waste burning inventory), and 3×Base HCl run. We found that 3×Base HCl increased the simulated average NH₄⁺ by 13.1 μg m⁻³ and NH_x by 9.8 μg m⁻³ concentration while reducing the average NH₃ by 3.2 μg m⁻³, which is more in accord with the measurements. Thus HCl/Cl⁻ chemistry in the model increases total NH_x concentration, which was further demonstrated by reducing NH₃ emissions by a factor of 3 (-3×NH₃_EMI) in the 3×Base HCl simulation. Reducing NH₃ emissions in the 3×Base HCl simulation successfully addressed the discrepancy between measured and modelled total NH_x. We conclude that modelling the fate of NH₃ in Delhi requires a correct chemistry mechanism accounting for chloride dynamics with accurate inventories of both NH₃ and HCl emissions.

40 **1 Introduction**

41 The Indo-Gangetic Plain (IGP) is one of the global hotspots of atmospheric ammonia (NH_3) and faces a
42 range of environmental challenges, particularly during the winter season, including adverse air pollution
43 episodes, especially as NH_3 plays a substantial role in secondary aerosol formation (Ghude et al., 2020, 2008b,
44 2008a; Kumar et al., 2021; Saraswati et al., 2019; Sharma et al., 2020; Singh et al., 2021). Atmospheric NH_3 ,
45 along with oxides of nitrogen (NO_x), together account for the largest source of reactive nitrogen (N_r), which is
46 primarily emitted by agricultural activities, livestock population, industrial activities, and transportation (Ghude
47 et al., 2009, 2010, 2012, 2013; M3ring et al., 2021; Pawar et al., 2021; Sutton et al., 2017b). Ammonia in the
48 environment plays a crucial role in atmospheric chemistry and the eutrophication and acidification of
49 ecosystems (Datta et al., 2012; Mandal et al., 2013; Pawar et al., 2021; Sharma et al., 2008, 2012, 2014b).
50 Control of NH_3 becomes a key priority in an emerging international strategy to manage the global nitrogen cycle
51 (Gu et al., 2021; Sutton et al., 2020). Ammonia is one of the important aerosol precursor gases, and ammonium
52 (NH_4^+) is a major counter ion for the three anions such as chloride (Cl^-), nitrate (NO_3^-), and sulfate (SO_4^{2-})
53 contributing to $\text{PM}_{2.5}$ composition (Seinfeld et al., 2016). In addition, as the dominant alkaline gas in the
54 atmosphere, NH_3 has attracted the interest of scientific researchers since it has been known to promote new
55 aerosol formation both in the initial homogeneous nucleation and in the subsequent growth, especially during
56 wintertime (Acharja et al., 2020, 2021; Ali et al., 2019; Duan et al., 2021; Wagh et al., 2021).

57 In this study, we focus on wintertime since this season is characterized by low-to-dense fog events,
58 lower temperature (T), and variability of relative humidity (RH), which fluctuates from 40 to 100 % (Ghude et
59 al., 2017; Kumar et al., 2020). Ammonia acts as a neutralization agent for determining the acidity of aerosol
60 particles (Acharja et al., 2020; Ali et al., 2019; Ghude et al., 2017). It also affects $\text{PM}_{2.5}$, the acidity of clouds,
61 and the wet deposition of nitrogen by neutralizing acidic species (Gu et al., 2021; Xu et al., 2020). Increasing
62 NH_3 concentration over Delhi compared with the surrounding area leads to an increase in $\text{PM}_{2.5}$ concentrations
63 (Ghude et al., 2022; Sharma et al., 2008, 2012, 2014a), which in turn affects air quality, human health, and
64 climate (Behera et al., 2013; Ghude, 2016; Ghude et al., 2008b; Nivdange et al., 2022; Sutton et al., 2017a;
65 Sutton and Howard, 2018).

66 Satellite observations (Van Damme et al., 2018; Warner et al., 2017), chemical transport models
67 (CTMs) (Clarisse et al., 2009, 2010; Wang et al., 2020b), and ground-based observations (Pawar et al., 2021)
68 revealed that the IGP is the largest regional hotspot of NH_3 concentrations on Earth. Previous studies have
69 identified various sources of NH_3 , for example, agricultural activities, industrial sectors, motor vehicles, garbage,
70 sewage, and urine from rural populations at the global scale (Behera et al., 2013; Huang et al., 2012; Sutton et
71 al., 2008). However, in Delhi, agricultural activity (including surrounding arable and sub-urban livestock
72 farming) is estimated to be the dominant source of NH_3 , along with traffic emissions (Kuttippurath et al., 2020;
73 M3ring et al., 2021; Sharma et al., 2020), but its emissions are subject to large uncertainty. Globally, various
74 modeling efforts have investigated the relative effectiveness of reducing NH_3 emissions in curtailing $\text{PM}_{2.5}$
75 formation (Gu et al., 2021; Pinder et al., 2007, 2008; Zhang et al., 2020). However, over India, the impact on
76 reducing $\text{PM}_{2.5}$ might be limited because NH_3 emission reductions may be more challenging due to its diverse
77 and area-wide sources. Ianniello et al. (2010) and Lan et al. (2021) have investigated the variation of
78 atmospheric NH_3 at an urban and suburban site of Beijing with respect to meteorological factors, where RH was
79 found to be a strong factor in influencing the NH_3 mixing ratio. A few studies over Asia have highlighted the

80 gas-to-particle conversion of NH_3 in Delhi (Acharja et al., 2021; Saraswati et al., 2019) and China and its
81 subsequent impact on the aerosol formation (Wang et al., 2015; Xu et al., 2020). Furthermore, excess NH_3
82 during fog can also enhance secondary aerosol formation in Delhi during winter (Acharja et al., 2021).
83 However, the wintertime behavior of NH_3 in Delhi in CTMs has not yet been investigated and remains poorly
84 understood (Ellis et al., 2011; Metzger et al., 2006). In a recent study, Pawar et al. (2021) highlighted
85 uncertainties associated with gas-to-particle partitioning of NH_3 in a global model MOZART-4 and found a
86 significant overestimation of NH_3 in the model compared with the measurements. The overestimation of NH_3 in
87 the model led the authors to hypothesize that a source specific NH_3 emission inventory in India, considering
88 agricultural statistics on fertilizer use and animal distribution, was missing. Also, there was a need for a high-
89 resolution regional model with advanced chemistry to resolve the NH_3 emissions on the local scale.

90 The present study utilizes the regional Weather Research and Forecasting model coupled with
91 chemistry (WRF-Chem) interpreted using measurements from the Winter fog Experiment (WiFEX), including
92 NH_3 , water-soluble ions in $\text{PM}_{2.5}$, other trace gases, and meteorological parameters during December-January,
93 2017-18. For the first time in South Asia, we discuss and compare the modelled and observed temporal variation
94 in gaseous NH_3 , particulate NH_4^+ , and total NH_x ($= \text{NH}_3 + \text{NH}_4^+$). Since we found that the total modelled NH_x
95 matches well with the observations, we investigate the ability of the model to accurately describe the gas-to-
96 particle partitioning of the measurements (MARGA) by evaluating the fraction of NH_x in the particulate phase
97 ($\text{NH}_4^+/\text{NH}_x$). We conducted several sensitivity experiments with and without adding anthropogenic waste
98 burning emissions of hydrochloric acid (HCl) in the model. The updated model with HCl/Cl chemistry was used
99 to analyze and compare the temporal variation of NH_3 , NH_4^+ , and total NH_x from the WiFEX measurements.

100 **2. Data and methodology**

101 **2.1 Observational datasets**

102 **2.1.1 Description of MARGA**

103 In the present study, we used the same dataset which was previously published by Acharja et al. (2020)
104 and 2021), which described the aerosol time-series and chemistry measured with a Monitor for AeRosols and
105 Gases in Ambient Air-model 2S instrument (MARGA). The MARGA system has two channels, one for
106 sampling PM_1 and the other for sampling $\text{PM}_{2.5}$ for ground-based observations. The MARGA (two sampling
107 boxes, analytical box, and connected pumps) was located inside the Indira Gandhi International Airport (IGIA),
108 New Delhi (28.56° N, 77.09° E), with the inlet PM_1 and $\text{PM}_{2.5}$ impactors fixed on the terrace with 2 m long inlet
109 lines sampling outdoor air at 8 m above ground and 2 m above the rooftop. Measurements covered a winter
110 period (19 December 2017 to 21 January 2018) with frequent moderate to dense fog events. Following intake
111 through the PM_1 and $\text{PM}_{2.5}$ impactors, the air was passed through two parallel inlet tubes 2 m long and 14 mm
112 inner diameter PolyTetraFluoroEthylene (PTFE) to the PM_1 and $\text{PM}_{2.5}$ sampling channels of the MARGA. The
113 air flow rate in each MARGA sampling box is regulated to a volumetric flow of $1 \text{ m}^3 \text{ h}^{-1}$. The measurements are
114 close to real-time, as two sets of syringes are employed to collect the samples in which a set of syringes collects
115 the sample and another set sends the collected samples from the previous hour for analysis. Each MARGA
116 sampling system consists of a steam jet aerosol collector (SJAC) and a wet rotating denuder (WRD) for

117 collecting and measuring water-soluble inorganic particulate species and gases in the ambient air. The
118 continuous coating of the WRD by a thin film of absorption solution (10 ppm hydrogen peroxide (H₂O₂)) allows
119 the diffusion of gases into the absorption solution. By contrast, the low diffusion velocity of sub-micron
120 particles restricts the ability of water-soluble aerosols to diffuse into the absorption solution. The absorption
121 solution is continually changed to replace that abstracted for ion chromatography (IC) analysis of the dissolved
122 gases. The air stream, depleted of gases by the WRD, subsequently enters the SJAC, where the steam enhances
123 water-soluble aerosols to grow, allowing their mechanical capture in a cyclone. The aqueous solutions deriving
124 from two cyclones (for PM₁ and PM_{2.5}, respectively) are then supplied to the IC for chemical analysis (Acharja
125 et al., 2020).

126 Ambient surface concentrations of NH₃ along with other trace gases (HCl, nitrous acid (HONO), nitric
127 acid (HNO₃), and sulfur dioxide (SO₂)) and water-soluble inorganic components of PM₁ and PM_{2.5} (Cl⁻, nitrate
128 (NO₃⁻), SO₄²⁻, NH₄⁺, sodium (Na⁺), potassium (K⁺), magnesium (Mg²⁺), and calcium (Ca²⁺)) were then quantified
129 online by anion and cation chromatography in the analytical box at an hourly resolution. We have used only
130 PM_{2.5} inorganic water-soluble components and the gaseous measurements (available from both the PM₁ and
131 PM_{2.5} MARGA collection systems). Since NH₄⁺ with the three major anions: Cl⁻, NO₃⁻ and SO₄²⁻ constituted
132 97.3 % of the total measured ions in PM_{2.5} (Acharja et al., 2020), we consider these four significant ions in our
133 present study. In contrast, the remaining ionic species (i.e., Na⁺, K⁺, Mg²⁺ and Ca²⁺) contributed only about 3 %
134 of the total measured ions and were neglected as it would not impact our present study significantly (Acharja et
135 al., 2020). Anions are separated in a MetrosepA Supp-10 (75/4.0) column with sodium carbonate (Na₂CO₃) and
136 sodium bi-carbonate (NaHCO₃) (7/8 mmol l⁻¹) eluent. Whereas for cations separation, a Metrosep C4 (100/4.0)
137 cation column with 3.2 mmol l⁻¹ HNO₃ eluent was used (Acharja et al., 2020). To suppress the eluent
138 background conductivity of anion chromatographs, three ion exchange units were used to ensure that the ion
139 exchange unit is regenerated in each analysis. 1 M Phosphoric acid (H₃PO₄) was used for this purpose. This was
140 performed to improve the signal-to-noise (S/N) of the anion chromatographs. Details of the MARGA instrument
141 can be found in Makkonen et al. (2012), Thomas et al. (2009), Twigg et al. (2015).

142 **2.1.2 Quality assurance/quality control (QA/QC) of MARGA**

143 To ensure the observation's accuracy and check the data's quality, we have followed best practices during the
144 study. The eluents, absorption, and regenerant solutions were prepared with minimum manual intervention. The
145 operational parameters like anion and cation conductivity, SJAC heater temperature, column oven temperature,
146 and airflow were regularly monitored to keep them within the safe limit. In addition to these, before injection of
147 each sample into the anion and cation IC columns, the Lithium Bromide (LiBr) internal standard solution
148 containing 320 µg l⁻¹ lithium (Li⁺) and 3680 µg l⁻¹ bromide (Br⁻) was mixed with each sample to provide
149 calibration of each analysis. This ensures that each analysis is calibrated, and the concentration of gaseous and
150 ionic samples are measured accurately. The PM₁ and PM_{2.5} impactors were typically cleaned fortnightly to
151 remove any material that may have stuck on the surface and inlets of the impactors. The lower detection limits
152 (LODs) of the species monitored by MARGA were mentioned in Acharja et al. (2021). It shows that
153 concentrations of species like Cl⁻, NO₃⁻, SO₄²⁻, NH₄⁺, SO₂, and NH₃ were always higher than LODs during the
154 winter period. But, concentrations of species like Na⁺, K⁺, Ca²⁺, Mg²⁺, HCl, HONO, and HNO₃ were sometimes
155 below LODs, but the fraction of it was less than ~10 % of the total observation period. We have omitted these

156 values and treated them as NA. As the fraction of observational hours is less and these species contribute much
157 less to the PM_1 and $PM_{2.5}$ mass concentrations, we believe below LODs values would not significantly deviate
158 our results. The quality of the data obtained was then checked using the ion-balance method. As an additional
159 quality check, the ratio of the sum of cations to anions ($neq\ m^{-3}$) was used as an indicator for the viable data. We
160 have checked the cation-to-anion ratio of each hourly sample expressed in the unit of $neq\ m^{-3}$. We accepted only
161 those values near to unity and rejected those not within the 10 % error bar limit. Based on this evaluation
162 method, overall, for the campaign, the ratio was near unity (1.06 for PM_1 and 0.96 for $PM_{2.5}$). Excellent charge
163 balance between anions and cations measured by the system also confirms that there are no significant
164 contamination issues associated with the aerosol measurements. Values in slight excess of unity may indicate
165 the presence of formate and acetate in the aerosol, which MARGA does not measure. Further detail on the
166 quality control of MARGA can be found in Acharja et al. (2020).

167 **2.1.3 Other ground-based measurements**

168 Hourly NO_x measurements were made by the chemiluminescence method, and hourly ozone (O_3) measurements
169 were made by the UV photometric method (CPCB, 2011) at the nearest air quality monitoring station (AQMS)
170 of IGIA operated by the Central Pollution Control Board (CPCB). CPCB follows the United States
171 Environmental Protection Agency (USEPA) approved AC32M NO_x and 42M O_3 analyzer manufactured by
172 Environment S. A. India Private Limited. We used one-hour monitored NO_x and O_3 values in our study. These
173 air quality monitoring stations' quality control and assurance processes were followed as outlined in CPCB
174 (2014, 2020). For data quality of CPCB, we omitted all those observed values which fell below LOD of the
175 instrument ($2\ \mu g\ m^{-3}$ for NO_x and $4\ \mu g\ m^{-3}$ for O_3) (Technical specifications for CAAQM station, 2019) and
176 above $500\ \mu g\ m^{-3}$ for NO_x and $140\ \mu g\ m^{-3}$ for O_3 and treated them as NA at a given site. For the NO_x and O_3
177 datasets, only a small fraction of data (2 %) were outside the instrument operating ranges specified. This step
178 aims to remove any short-term local influence that the models cannot capture and retain the regional-scale
179 variability because the nearest sites are located in the urban environment. We removed a single spike
180 represented by a change of more than $100\ \mu g\ m^{-3}$ in just 1 hour (h) for all the data in CPCB monitoring stations
181 to filter out random fluctuations in the observations. We removed some very high NO_x and O_3 values that
182 appeared in the time series right after measurement gaps. Meteorological parameters, including air temperature
183 (T), relative humidity (RH), wind speed, and wind direction, were measured with the automatic weather station
184 (AWS) platform on a 20 m flux tower (Ghude et al., 2017). For detailed information on the measurement site
185 and its meteorological parameters, refer to (Ali et al., 2019).

186 **2.2 WRF-Chem v 3.9.1 model**

187 The Weather Research and Forecasting model coupled with chemistry (WRF-Chem v3.9.1) was employed in
188 this study to simulate atmospheric gases and aerosols over Delhi during the peak winter period, starting from 19
189 December 2017 to 21 January 2018. We recently used a similar model configuration to simulate the air quality
190 over Delhi (Ghude et al., 2020; Kulkarni et al., 2020). This study used the Model for Ozone And Related
191 chemical Tracers (MOZART-4) gas-phase chemical mechanism coupled with the Model for Simulating Aerosol
192 Interactions and Chemistry (MOSAIC) aerosol scheme, that simulates SO_4^{2-} , NH_4^+ , NO_3^- , methanesulfonate,
193 Na^+ , Ca^{2+} , Cl^- , carbonate, black carbon, and primary organic mass. Other inert minerals, trace elements, and

194 inorganic species are lumped together as different inorganic masses. MOSAIC allows gas-to-particle formation,
195 which includes NH_3 , HCl, sulfuric acid (H_2SO_4), HNO_3 , and methane sulfonic acid (MSA), and also includes
196 secondary organic aerosols (SOA). Aerosol size distributions are represented by a sectional aerosol bin approach
197 with four size bins (Georgiou et al., 2018). MOSAIC incorporates the thermodynamic and gas-particle
198 partitioning module described by Zaveri et al.(2008). To reduce the computational cost, we selected a 4-bin
199 MOSAIC mechanism that simulates thermodynamic equilibrium and other aerosol processes such as
200 condensation, coagulation, and nucleation. The same mechanism has been widely used with WRF-Chem for
201 simulations outside India (Bucaram and Bowman, 2021; Sha et al., 2019; Yang et al., 2018), but only a limited
202 number of studies have applied it to the Indian domain to include more detailed chemistry and species (Gupta
203 and Mohan, 2015; Jena et al., 2020; Kumar et al., 2018). The SOA formation in MOSAIC is simulated using the
204 volatility basis set approach (Knote et al., 2015). For consistency with the $\text{PM}_{2.5}$ MARGA measurements, we
205 have chosen 3-bins according to simulated aerosols size (0.04–0.156 μm ; 0.156–0.625 μm ; 0.625–2.5 μm) in
206 accordance with the WRF-Chem aerosol size distribution.

207 The model domain covers the entire northern region of India, but here model simulations are compared
208 with the observations at IGIA, New Delhi (28.56° N, 77.09° E). The domain was set with a horizontal grid-
209 spacing of 10 km in both the latitudinal and longitudinal directions. The model top vertical grid included 47
210 vertical levels, with the model top set to 10 hPa. The physical parameterization schemes of model configuration
211 are the same as those described by Ghude et al. (2020) and Jena et al. (2021). EDGAR-HTAP (Emission
212 Database for Global Atmospheric Research for Hemispheric Transport of Air Pollution) for the year 2010 at 0.1°
213 x 0.1° grid resolution was used in this study for anthropogenic emissions of aerosols and trace gases ($\text{PM}_{2.5}$,
214 PM_{10} , OC, BC, CO, NO_x , etc.) and are scaled to 2018 as per Jena et al. (2021). Biogenic emissions are
215 calculated online using the Model of Emissions of Gases and Aerosols from Nature version 2.1 (MEGAN2.1)
216 (Guenther et al., 2006), and dust emissions are based on the traditional Goddard Global Ozone Chemistry
217 Aerosol Radiation and Transport (GOCART) dust scheme that works with MOSAIC (Ginoux et al., 2001). Fire
218 INventory from NCAR (FINNv1.5) was used in this study for daily open biomass burning emissions that are
219 vertically distributed within the model using Freitas et al. (2007). The chemical initial and lateral boundary
220 conditions come from the global model simulations from the Model for Ozone and Related Chemical Tracers
221 (MOZART-4), and the meteorological initial and lateral boundary conditions are provided from the fifth
222 generation European Centre for Medium-Range Weather Forecasts (ECMWF) atmospheric reanalysis of the
223 global climate (ERA5) with six-hourly temporal resolution. The simulations were reinitialized every fifth day to
224 limit the growth of meteorological errors in our simulations, but the chemical fields were carried forward from
225 the previous simulation.

226 **3. Results and Discussion**

227 **3.1 Comparison of temporal variation in NH_3 , NH_4^+ , and total NH_x using WRF-Chem and MARGA**

228 **3.1.1 Diurnal variation**

229 To investigate how well a state-of-the-art chemical transport model performs in capturing the diurnal behavior
230 of NH_3 and NH_4^+ , we compared observed and model-simulated diurnal profiles of NH_3 and NH_4^+ . Figure 1

231 displays the comparison of diurnal variation (00:00 to 23:00 Indian Standard Time (IST)) in meteorological
232 parameters (T and RH) at the IGIA site in Delhi (Fig. 1a) along with NH_3 and NH_4^+ averaged over the study
233 period (Fig. 1b) between observations and model. We adopted diurnal variation in emissions from a recent study
234 by Jena et al. (2021). Note that diurnal variability in the model simulations is primarily controlled by the
235 planetary boundary layer mixing. We first investigated the ability of WRF-Chem to accurately predict the
236 meteorological parameters of RH and T, which are important determinants of the gas-to-aerosol partitioning of
237 (semi-) volatile compounds. As shown in Fig. 1a, simulated T and RH are in reasonable agreement with the
238 observations, with the simulated RH values falling in the range of 50–90 %. Overall, it can be seen that the
239 model shows cold and wet bias compared to the observations but shows warm bias (about 2–3 °C) and dry bias
240 (about 10–12 %) in the afternoon hours. In spite of the small change in the amplitude of the diurnal cycle of RH,
241 the phase characteristics of the diurnal cycle of both T and RH are reasonably well captured by the model.
242 Figure 1b shows that simulated NH_3 and NH_4^+ are very different compared with the MARGA measurements.
243 The model predicts an average NH_3 and $\text{NH}_4^+ \pm 1\sigma$ mass loading of 56.7 ± 14.3 and $14.7 \pm 4.9 \mu\text{g}$
244 m^{-3} , respectively, while MARGA measurements indicate an average NH_3 and $\text{NH}_4^+ \pm 1\sigma$ mass loading of $28.2 \pm$
245 12.4 and $36.9 \pm 15.1 \mu\text{g m}^{-3}$, respectively. We find the diurnal variation of gas-phase NH_3 is significantly
246 overestimated by the model (Normalised Mean Bias (NMB) = 1.02). On the contrary, NH_4^+ is underestimated
247 by about 60 % (NMB = -0.60). Simulated NH_3 concentrations peak between 07:00–09:00 and 22:00–23:00 h
248 with bimodal variation, whilst MARGA shows a single peak around 12:00–13:00 h. On the contrary, a nearly
249 flat diurnal profile of NH_4^+ is predicted by the model, whereas the average MARGA NH_4^+ concentration
250 maxima and minima were observed during night-time (16:00–03:00 h) and daytime (03:00–08:00 and 09:00–
251 16:00 h), respectively.

252 We also looked into the average diurnal profile of NO_x and NH_3 during dense fog events, and the
253 details can be found in the supplement (Fig. S1 and S2 in the Supplement). It is evident that the observed
254 daytime peak of NH_3 did not coincide with NO_x peaks, suggesting that traffic emissions do not contribute
255 significantly to the observed NH_3 rise. The observed correlation between fog water and enhanced NH_3 pulses is
256 consistent with what would also be expected from the evaporation of dew (Sutton et al., 1998; Wentworth et al.,
257 2014, 2016) (S2 in the Supplement) but is not sufficient to identify whether it is the main cause of the daytime
258 increase of NH_3 . In the future, measurements of the dew water NH_4^+ and the accumulation of dew water would
259 be ideal for illuminating the contributing processes. The daytime increase in NH_3 concentration could be
260 associated with NH_4^+ aerosol volatilization driven by an associated sharp change in T and RH (~ 11:00–12:00 h)
261 (Sutton et al., 2009a, 2013) off-ground surfaces. The fastest increase in T is 12:00 h, which is indeed when NH_3
262 was at maximum concentration indicating gas-to-particle partitioning may impact the diurnal behavior of NH_3 at
263 Delhi during winter (Sutton et al., 2009a, 2009b). However, in the model, because the largest increase in
264 simulated NH_3 also precedes the large changes in simulated meteorological parameters, and because the
265 simulated particulate NH_4^+ is flat compared to observations, simulated meteorology is ruled out as a significant
266 contribution to high bias in simulated NH_3 . Also, the current model does not include the bidirectional exchange
267 of NH_3 with surfaces such as dew and fog water.

268 3.1.2 Daily mean variation

269 To assess the validity of the model, the ratio between simulated and observed (model/obs) was tested.
270 Figure 2 displays the model/obs ratio of daily mean variations in the NH_3 , NH_4^+ , and total NH_x concentrations.
271 The model shows large differences in NH_3 and NH_4^+ compared with observations. We find a model/obs higher
272 than 1 (1.5-4.5) in simulated NH_3 , indicating the model is biased high (NMB = 1.02), while there is a poor
273 agreement for NH_4^+ (model/obs less than 0.5), indicating model is biased low (NMB = -0.62). There is good
274 agreement between the modelled total NH_x , which is mostly consistent with the observation (model/obs close to
275 1) with a small bias (NMB = 0.08). Despite the adequate ability of the model to reproduce the accurate total
276 NH_x , the model is biased low for NH_4^+ and high for NH_3 , indicating that the model's representation of the gas-
277 to-particle partitioning is not correct. It is, therefore, necessary to understand missing chemical processes in gas-
278 to-particle partitioning responsible for the overestimation of NH_3 and underestimation of NH_4^+ in the model.

279 3.2 Gas-to-particle partitioning

280 We investigated the ability of the model to accurately describe the gas-to-particle partitioning of the
281 measurements (MARGA) by evaluating the fraction of total NH_x in the particulate phase ($\text{NH}_4^+/\text{NH}_x$) (Ellis et
282 al., 2011; Wang et al., 2015) for which statistical values are summarized in Table 1. The correlation coefficient
283 (r) indicates an inverse relationship of $\text{NH}_4^+/\text{NH}_x$ with NH_3 for both MARGA and model ($r = -0.57, -0.58$,
284 respectively). A strong correlation of the MARGA ratio $\text{NH}_4^+/\text{NH}_x$ with the dominant anion concentration (Cl^- : r
285 = 0.79) was observed. However, the measurement shows a poor relationship between SO_4^{2-} and $\text{NH}_4^+/\text{NH}_x$
286 followed by NO_3^- , which is probably due to very low concentrations that do not change $\text{NH}_4^+/\text{NH}_x$ significantly
287 even when SO_4^{2-} and NO_3^- are neutralized (see Fig. 6). By contrast, the model shows a strong correlation
288 between $\text{NH}_4^+/\text{NH}_x$ with SO_4^{2-} concentration ($r = 0.77$). MARGA indicates high particulate fractions of NH_4^+
289 and Cl^- while the modeled composition is dominated by NH_4^+ and SO_4^{2-} . This mismatch is due to the complete
290 absence of Cl^- chemistry in the standard model. The measured $\text{NH}_4^+/\text{NH}_x$ suggests that anthropogenic HCl may
291 be promoting this increase in particle fraction of NH_4^+ and Cl^- via partitioning into the aerosol, deprotonating in
292 the aerosol water, followed by NH_3 partitioning and being protonated by the ionization of the strong electrolyte
293 HCl (Chen et al., 2022; Gunthe et al., 2021).

294 Figure 3 shows the percentage contribution of gases (NH_3 , SO_2 , HCl, HNO_3 , and HONO) and $\text{PM}_{2.5}$
295 aerosol (NH_4^+ , SO_4^{2-} , NO_3^- and Cl^-) during the WifEX measurements. The pie charts for the gases show that
296 NH_3 (accounting for 53.3 % of the measured total gas concentration) dominates the gas phase, followed by
297 sulfur dioxide (SO_2) (35.61 %), whereas $\text{PM}_{2.5}$ aerosol show NH_4^+ (49.5 %) as a major cation and Cl^- (29.7 %)
298 as a significant anion followed by NO_3^- (11.7 %) and SO_4^{2-} (9 %). There is also a very high amount of SO_2
299 reaching the site from the nearby industrial area, which is not converted to SO_4^{2-} very quickly (Acharja et al.,
300 2021). In a normally NH_3 -rich atmosphere, gas-phase oxidation of SO_2 is much slower than the aqueous phase
301 oxidation by O_3 , and due to nearby sources, much of the sulfur is present as SO_2 (Li et al., 2007). This appears
302 to be because of the slow rate of gas phase oxidation of SO_2 . Although the atmosphere is rich in NH_3 , in
303 principle favoring aqueous phase oxidation via O_3 , it appears that O_3 concentrations are often insufficient (mean
304 = 36.3, median = 33.8, minimum = 26.5, and maximum = 53.9, $\mu\text{g m}^{-3}$ respectively) at the IGIA site (Fig. S3 in
305 the Supplement). Hence for many periods during the WIFEX campaign, SO_4^{2-} and NO_3^- are very low, with the
306 result that the $\text{NH}_4^+/\text{NH}_x$ ratio does not change appreciably when SO_4^{2-} is neutralized (Table 1).

307 According to thermodynamic equilibrium theory, an aqueous solution maintains charge neutralization
 308 initially by balancing NH₃ uptake with the uptake of sulfuric acid (H₂SO₄) before HNO₃ and HCl can partition
 309 into the aqueous aerosol; hence all SO₄²⁻ in the condensed phase will be fully neutralized before any HNO₃, or
 310 HCl can partition (Behera et al., 2013). Typical Delhi winter conditions of excess NH₃, high RH, and low T
 311 favour gas-to-particle partitioning of NH₃. The principal inorganic chemical reactions that occur in aqueous
 312 atmospheric aerosols form pairs of non-volatile NH₄⁺ and acid anions (SO₄²⁻, NO₃⁻, and Cl⁻) are summarized in
 313 reactions R1 to R3 (Seinfeld et al., 1998).

317

318 NH₄⁺ and Cl⁻ (R3), which are favored by low T and high RH, form a reversible equilibrium with NH₃ and HCl
 319 (Ianniello et al., 2011; Seinfeld and Pandis, 2016), which was the case during WiFEX. It is likely that high Cl⁻ in
 320 Delhi resulted from gas-to-particle partitioning of HCl into aerosol water in the presence of excess NH₃ (R3),
 321 with aqueous phase Cl⁻ stimulating further water uptake and jointly driving aerosol mass composition and
 322 growth through co-condensation (Chen et al., 2022; Gunthe et al., 2021). Hence, to understand the driver of the
 323 measured NH₄⁺ and the role of aqueous chemistry, we plotted the fraction of the ratio of HCl to Cl⁻ (HCl/Cl⁻) as
 324 a function of NH₄⁺ concentration and RH in Fig. 4. The decrease in the fraction of HCl/Cl⁻ is associated with an
 325 increase in NH₄⁺ concentration at high RH between 70-100 %. The HCl/Cl⁻ is highly anticorrelated (r = -0.53)
 326 with NH₄⁺ concentration in the presence of high RH (70-100 %), further supporting the view that HCl promotes
 327 the increase in the particle fraction of NH₄⁺ (49.5 %) with Cl⁻ (29.7 %) the primary anion.

328 We investigated the directions of local emission sources associated with concentration increases of
 329 NH₃, NH₄⁺, Cl⁻ and NH_x through bivariate polar graphs using the OpenAir software (Carslaw and Ropkins,
 330 2012) at the IGIA site. Figure 5 shows the bivariate polar plots of mean NH₃ (Fig. 5a), NH₄⁺ (Fig. 5b), Cl⁻ (Fig.
 331 5c), and total NH_x (Fig. 5d) concentration for the observation period in relation to wind speed and wind
 332 direction. The 270-300° sector dominated the wind direction at IGIA (Acharja et al., 2021). Figure 5a shows that
 333 the highest NH₃ concentration was associated with the winds coming from the east and southeast of the site,
 334 where it could have been emitted from dairy farms, including animal houses, yards, and manure storage, as well
 335 as by the application to the farmland of urea and other ammoniacal fertilizers, ammoniacal wastes and ruminant
 336 urine located at this region (Hindustan Times, 2021; Leytem et al., 2018; Sherlock et al., 1994). Such sources of
 337 NH₃ volatilization (Hristov et al., 2011; Laubach et al., 2013) can also explain the higher concentrations of total
 338 NH₄⁺ (and, by definition NH_x) for air coming from the southeast of the measurement site (Fig. 5b and d). This
 339 enhancement in the southeast region is not only affected by emissions but also by meteorology and chemistry.
 340 Thus higher NH₃ concentration may also be due to the lack of turbulent mixing, which restricts the dilution of
 341 plumes from local point sources at lower wind speeds (Ianniello et al., 2010). The bivariate polar plots of
 342 NH₄⁺ (Fig. 5b) and Cl⁻ (Fig. 5c) concentration point to the west direction as a principal source for
 343 thermodynamic partitioning of NH₃ and HCl to the condensed phase to form NH₄⁺ and Cl⁻. Two industrial
 344 sources are located in this direction: the site is impacted by a cluster in northwest Delhi of industrial processes,
 345 such as steel pickling industries, and others include metal finishing and electroplating, which are known to be
 346 vital HCl emitters (Acharja et al., 2021; Jaiprakash et al., 2017). Near the source, abundant quantities of NH₃

347 may drive the partitioning of HCl to the condensed phase resulting in high concentrations of NH_4^+ and Cl^-
348 towards the west at lower wind speeds. Thus, high NH_4^+ and Cl^- correspond to the lowest NH_3 concentration
349 region (inverse relation), which can be observed in Fig. 5a, b, and c, highlighting the importance of nearby HCl
350 industrial sources in driving the particle fraction of NH_4^+ and Cl^- .

351 To gain insight into the role of NH_4^+ in the neutralization of anions (SO_4^{2-} , NO_3^- and Cl^-), the aerosol
352 neutralization ratio (ANR) was calculated using the observed data. The ANR is defined as the equivalent ratio of
353 NH_4^+ to the sum of SO_4^{2-} , NO_3^- and Cl^- because these species represent the dominant cations and anions in
354 $\text{PM}_{2.5}$, respectively. Figure 6 demonstrates, on average, how well the charge balance works between Cl^- , NO_3^-
355 and SO_4^{2-} (in $\mu\text{eq m}^{-3}$) as the anions and NH_4^+ as the major cation (ANR close to unity), with Cl^- as the most
356 significant anion followed by NO_3^- and SO_4^{2-} . The mean $\pm 1\sigma$ ANR value for $\text{PM}_{2.5}$ during the observed period
357 was 0.96 ± 0.14 . It ranges from a minimum of 0.35 ± 0.04 to a maximum of 2.31 ± 0.08 . Higher values than
358 unity may indicate the presence of organic acids in the aerosol, which MARGA does not measure (Acharja et
359 al., 2020). Also, high standard error in Fig.6 indicates the possibility of uncertainties associated with the
360 breakthrough of NH_3 spikes on the denuder at high concentration ($\sim 1\%$) (Stieger et al., 2019). However, the
361 good charge balance indicates this wasn't a major issue. There also were certain periods where low
362 concentrations were observed of Cl^- and NO_3^- (03-06 January 2018 and 16-17 January 2018) in Fig.6.
363 Comparing the model/obs for NH_3 , NH_4^+ and total NH_x during these periods provides some degree of validation
364 of the model where sulfur chemistry dominates the reaction with NH_3 . Figure S4 (in the supplement) shows that
365 model/obs indicates substantial variability which appears to be overestimating NH_3 (model/obs >1) while
366 underestimating total NH_4^+ (model/obs <1) on average in the model.

367 **3.3 Influence of HCl/Cl⁻ chemistry in WRF-Chem**

368 We further conducted three scenario simulations for the period 7-16 January 2018 (10 days) to explore the
369 potential impacts of the addition of anthropogenic chloride (HCl/Cl⁻) emissions in the concentrations of NH_3 ,
370 NH_4^+ and total NH_x . We employ the HCl emissions from trash-burning activities in Delhi, as predicted by
371 Sharma et al. (2019) in our model set-up. We tested the three sensitivity experiments named: No HCl (0 mol km^{-2}
372 h^{-1}), Base Case HCl ($3 \times$ Sharma et al., 2019; $24.8 \text{ mol km}^{-2} \text{ h}^{-1}$), and $3 \times$ Base HCl ($74 \text{ mol km}^{-2} \text{ h}^{-1}$) scenario,
373 reflecting adjustments which are consistent with the more recent upward adjustments in the amount of waste
374 burned in landfills by Chaudhary et al. (2021) and also to reflect additional industrial HCl sources not accounted
375 for in the inventory. Figure 7 presents the box-whiskers plots for secondary inorganic aerosols and trace gases
376 from the observations (MARGA), and those simulated by the model for the three sensitivity experiments. Daily
377 mean $\pm 1\sigma$ values are summarized in Table 2 for three different model scenarios. As can be observed from Fig.
378 7(a-c), increasing the HCl emissions (Fig. 7g) in the model partitions more NH_3 to the condensed phase due to
379 its high concentrations, reaching maximum mass loadings of NH_4^+ and Cl^- of 70 and $110 \mu\text{g m}^{-3}$, respectively, in
380 the $3 \times$ Base HCl scenario, while increasing the total mean NH_x concentration by $15 \mu\text{g m}^{-3}$ compared to the No
381 HCl run presumably reflecting the longer residence time of NH_4^+ for near-surface air measurements.

382 The simulated NO_3^- concentration (Fig. 7e) generally exceeds the measurements in all three
383 experiments; since the main neutralizing species for NO_3^- is NH_4^+ , it is controlled via the equilibrium between
384 NO_3^- , HNO_3 , and NH_3 , but also the competition with HCl for free NH_3 . Simulated HNO_3 is significantly
385 underestimated (by $\sim 3 \mu\text{g m}^{-3}$) (Fig. 7h) by the model compared to the observations. As a consequence, the

386 model suggests that NO_3^- formation from gaseous NH_3 and HNO_3 cannot occur. The gas fraction of observed
387 HNO_3 will be determined by aerosol pH and liquid water content based on NH_3 and NO_3^- availability (Nenes et
388 al., 2020). The over-prediction of NH_3 concentration in the model compared with the observations generates
389 more NO_3^- (and simultaneously reduces HNO_3), with the total fraction of $\text{HNO}_3 + \text{NO}_3^-$ (THNO_3) concentration
390 in the model also exceeding the observed THNO_3 , which is more strongly affected by reducing the NH_3
391 emissions in the model (Fig. S5 in the Supplement). On average, THNO_3 reduced by only $0.38 \mu\text{g m}^{-3}$ in 3×Base
392 HCl compared to the No HCl run. But reducing NH_3 emissions by a factor of 3 ($-3\times\text{NH}_3\text{_EMI}$) in the 3×Base
393 HCl scenario reduced mean THNO_3 by a further $4.71 \mu\text{g m}^{-3}$. The extent of partitioning and accumulation of
394 NH_4NO_3 depends on T, aerosol water, pH, as well as NH_3 availability (Nenes et al., 2020). Our model
395 simulations find that the presence of HCl/Cl^- does not significantly alter THNO_3 but that the excess NH_3 with
396 missing chloride chemistry is a major contributor and will lead to mismatches in the model between measured
397 simulated gas and particulate matter concentrations.

398 The simulated SO_4^{2-} concentration (Fig. 7f) was underestimated (by $\sim 7.5 \mu\text{g m}^{-3}$), while gas-phase SO_2
399 (Fig. 7i) was found to be overestimated by about $16 \mu\text{g m}^{-3}$ in all three experiments compared with the
400 observations. This may be caused by the fact that the drivers for typical sulfate production via OH or aqueous
401 H_2O_2 oxidation pathway are likely to be wrong in the model. The missing chemistry may underly this mismatch
402 and requires further sensitivity studies considering different SO_2 oxidation pathways. This requires further
403 study, such as scenario evaluation of altered SO_2 emissions in the model, to examine the main pathway(s) for
404 SO_2 to SO_4^{2-} conversion. Measurements of OH and other radicals in Delhi are currently lacking, making it
405 difficult to constrain the associated chemical schemes. To investigate the further impact of 3×Base HCl in the
406 model, uptake of gaseous NH_3 to form NH_4^+ and Cl^- was analyzed via a strong correlation coefficient values of r
407 = 0.84 for $\text{NH}_4^+/\text{NH}_x$ with Cl^- concentration, indicating a fraction of gas-to-particle conversion in the model
408 correlates well with the Cl^- concentration and was reasonably well simulated in the 3×Base HCl run.

409 **3.4 Comparison of the temporal variation in NH_3 , NH_4^+ , and NH_x using WRF-Chem (HCl/Cl⁻) and** 410 **MARGA**

411 **3.4.1 Diurnal variation**

412 Here, diurnal variations of monitored aerosol compounds and gases were analysed to investigate the gas-to-
413 particle conversion of NH_3 in the model. We analyzed the simulation results of the 3×Base HCl run. The diurnal
414 variations for NH_3 and NH_4^+ are controlled mainly by thermodynamic gas-to-particle partitioning, boundary
415 layer mixing, emission and deposition processes, along with vertical and horizontal advection (Meng et al.,
416 2018). Figure 8 (top) presents the diurnal variations of NH_3 and NH_4^+ (in $\mu\text{g m}^{-3}$) along with particulate NH_4^+ ,
417 Cl^- , NO_3^- , SO_4^{2-} , SO_2 , HCl, and HNO_3 concentrations (in $\mu\text{eq m}^{-3}$) measured (Fig. 8a (top)) and modeled (Fig. 8b
418 (top)) along with its meteorological parameters such as T and RH (Fig. 8 (bottom)). We adopted diurnal
419 variation in emissions from Jena et al. (2021) based on boundary layer mixing. It can be seen in Fig. 8a (top and
420 bottom) that a much bigger peak in NH_3 concentration is observed in the daytime than the modeled (despite
421 turbulence differences), indeed suggesting a much stronger NH_3 in the middle of the day (11:00-01:00 h). As
422 evaporation proceeds mainly in the morning (08:00-12:00) getting warmer, the peak is near midday (11:00-
423 13:00 h), rather than in the afternoon (13:00-14:00 h) when warmest, similar to what was also observed in
424 Sutton et al. (1998). Indeed, the decreasing NH_4^+ and Cl^- during the late morning (10:00 h) corresponds to the

425 increasing NH_3 peak, which reflects the fact that warming promotes the shift of aerosols to the gas phase.
426 Ammonium decreases more than NH_3 during the day, as this also evaporates to form NH_3 . Similarly, Cl^-
427 evaporates during the day since the HCl concentration increases. However, it can be seen that NO_3^- and SO_4^{2-}
428 are slightly changed diurnally, inferring longer range transport perhaps, whereas HCl and Cl^- are from more local
429 sources. The diurnal variability in gases and aerosols in 3×Base HCl simulations in Fig. 8b (top) is primarily
430 controlled by the planetary boundary layer mixing, meteorology/dispersion, environment (T and RH in Fig. 8b
431 (bottom)), and transport. So presumably, maximum NH_3 at 08:00 h is due to limited turbulence/boundary layer,
432 with dilution by mixing after 08:00 h. However, the model is able to represent well the diurnal variation of NH_4^+
433 and Cl^- both in terms of amount and pattern, which was not the case in the No HCl run where NH_4^+ was
434 observed to be flat in Section 1. During the hours of 09:00 and 11:00 h, when measured NH_3 rises, the model
435 predicts a large decrease in NH_3 , while during 19:00-23:00 h, when measured NH_3 decreases, the model predicts
436 a large increase. Furthermore, the modeled HCl and HNO_3 are very low compared to the measurements,
437 whereas SO_2 concentration matches well with the observations. It can be seen that NO_3^- and SO_4^{2-} are flat in the
438 model. This highlights the need to develop accurate diurnal variability in NH_3 emissions over this region.

439 Figure 9 presents the differences in diurnal variation of mean NH_3 (Fig. 9a), NH_4^+ (Fig. 9b), and total
440 NH_x (Fig. 9c) concentration for the three sensitivity experiments. While the simulated NH_3 concentrations
441 decrease in the 3×Base HCl compared to the No HCl and Base Case HCl run (Table 2), none of the model
442 experiments capture the diurnal cycle of NH_3 . Higher levels of observed NH_3 during daytime and modeled NH_3
443 during night-time highlight the need to improve diurnal variability in NH_3 emissions over this region based on
444 the nature and strength of the actual sources. Between the No HCl and the 3xBase HCl run, the NMB for NH_3
445 reduced from 1.38 to 1.13, and NMB for NH_4^+ systematically improved from -0.61 to -0.03. In contrast, NMB
446 for total NH_x increased from 0.12 to 0.39. Table 3 summarizes the statistical indicators for the three sensitivity
447 experiments. An increase in HCl emissions in the 3×Base HCl leads to a higher mass concentration of NH_4^+ and
448 Cl^- , which also increases total mean NH_x concentration by $22.4 \mu\text{g m}^{-3}$, presumably reflecting the longer
449 atmospheric lifetime of NH_4^+ compared with NH_3 . We find consistent high bias in all the simulations for NH_3 ,
450 which is highest during the early morning and at night-time. In order to better understand the relationship
451 between NH_3 , NH_4^+ and NH_x concentrations in the diurnal profile of model, one sensitivity study is conducted
452 in the best case HCl experiment to simulate the response of NH_x concentrations by changing NH_3 emissions. In
453 these simulations, only NH_3 emissions were reduced further by a factor of 3 (-3× NH_3 _EMI) in the 3×Base HCl
454 experiment, while all other processes and chemical schemes were unchanged. Figure S6 in the Supplement
455 shows the diel profile of model/obs ratio for NH_3 (Fig. S6a), NH_4^+ (Fig. S6b), and total NH_x (Fig. S6c)
456 concentration simulated with the 3×Base HCl and -3× NH_3 _EMI scenario. Reducing NH_3 emissions in the model
457 (-3× NH_3 _EMI) significantly improves model-measurement agreement for NH_3 (mean model/obs = 1.9), NH_4^+
458 (mean model/obs = 0.9), and total NH_x concentration (mean model/obs = 1.2) compared to the 3×Base HCl run,
459 further suggesting that the longer lifetime of NH_4^+ may be the controlling driver for the total NH_x concentration
460 in the model.

461 3.4.2 Variation of daily means

462 Figure S7 in the Supplement illustrates a time-series graph that compares daily mean NH_3 (Fig. S7a), NH_4^+ (Fig.
463 S7b), and total NH_x concentrations (Fig. S7c) for the three sensitivity experiments, and Table 2 shows the mean

464 $\pm 1\sigma$ of these variables. The results show that compared to the No HCl run, NH_3 mean concentrations decreased
465 by $2 \mu\text{g m}^{-3}$ in the Base Case HCl and decreased by a further $3.2 \mu\text{g m}^{-3}$ in the 3×Base HCl run. On the contrary,
466 NH_4^+ mean concentration increases in the Base Case HCl by $7.5 \mu\text{g m}^{-3}$ and further increases by $13.1 \mu\text{g m}^{-3}$
467 (3×Base HCl). This decrease in NH_3 is associated with the enhanced gas-to-particle conversion of NH_3 to NH_4^+ .
468 Associated with these changes, total mean NH_x also increased by 5.5 and $9.8 \mu\text{g m}^{-3}$ in the Base Case HCl and
469 3×Base HCl, respectively, compared to the No HCl. This is likely due to associated increases in the atmospheric
470 lifetime of NH_x with respect to deposition as the partitioning shifted from the faster depositing gas phase to the
471 aerosol phase. The lifetime of NH_3 is very short, a few hours, while that of NH_4^+ is 1 to 15 days (Aneja et al.,
472 1998; Nair and Yu, 2020; Pawar et al., 2021; Wang et al., 2020a).

473 To understand further the overestimation of total NH_x in the daily mean variation by the model, we
474 compared 3×Base HCl and -3× NH_3 _EMI sensitivity experiment. Figure 10 shows the ratio of model/obs for
475 NH_3 (Fig. 10a), NH_4^+ (Fig. 10b) and total NH_x (Fig. 10c) concentration. It can be seen that the model-
476 measurement agreement improves significantly (model/obs closer to 1) after reducing NH_3 emissions for all
477 three metrics. -3× NH_3 _EMI would reduce the mean NH_3 , NH_4^+ , and total NH_x concentration by $\sim 8.1 \mu\text{g m}^{-3}$,
478 $3.2 \mu\text{g m}^{-3}$, and $11.3 \mu\text{g m}^{-3}$, respectively, compared to the 3×Base HCl run. Even though reducing NH_3
479 emissions, it is still sufficient to react rapidly with the varying HCl in the sensitivity experiments contributing to
480 an increase in NH_4^+ . As can be seen in Fig. 10b, initially, NH_4^+ is somewhat lower, but it increases later and
481 matches the 3×Base HCl run. This suggests that NH_4^+ formation in the model is more sensitive to changes in
482 HCl than changes in NH_3 emission, while total NH_x agrees well by reducing the NH_3 emissions. In general,
483 CTMs have higher NH_3 concentration than observations, further supporting models having too much NH_3 . A
484 few factors might contribute to the model discrepancies for NH_3 : there are uncertainties in the emission
485 inventory of the bottom-up approach of NH_3 , and the model does not currently include the bidirectional
486 exchange of NH_3 with surfaces, such as dew and fog water. Also, model does not have accurate industrial
487 sources of HCl emission. Diurnal emission profiles are uncertainty for both NH_3 and HCl. Furthermore, gas-to-
488 particle partitioning associated with SO_2 oxidation pathways in the model is not correct at present.

489 4. Conclusions

490 In this study, we have evaluated for the first time in South Asia the performance of a chemical transport model
491 (WRF-Chem) in modeling NH_3 , NH_4^+ , and total NH_x , by comparing against the WIFEX measurements
492 (MARGA). In daily means, we find NH_3 is significantly overestimated by the model, NH_4^+ was underestimated
493 while simulated total NH_x agreed well with the measurement, indicating incorrect gas-to-particle partitioning
494 along with missing chemical process may impact this mismatch in the model. The ability of the model to
495 accurately describe the gas-to-particle partitioning of the MARGA was evaluated by the fraction of total NH_x (= NH_3 + NH_4^+)
496 in the particulate phase ($\text{NH}_4^+/\text{NH}_x$). A strong relation of MARGA $\text{NH}_4^+/\text{NH}_x$ was observed with
497 dominant anion (Cl^-) ($r = 0.79$), whereas the standard model showed a strong correlation between $\text{NH}_4^+/\text{NH}_x$
498 with dominant anion (SO_4^{2-}) ($r = 0.77$), pointing to the missing chloride (HCl/Cl^-) chemistry in the model.

499 We incorporated HCl/ Cl^- emissions in the model and conducted three sensitivity experiments of
500 varying HCl emissions, named as No HCl ($0 \text{ mol km}^{-2} \text{ h}^{-1}$), Base Case HCl ($3 \times$ Sharma et al., 2019; 24.8 mol
501 $\text{km}^{-2} \text{ h}^{-1}$) and 3×Base HCl ($74 \text{ mol km}^{-2} \text{ h}^{-1}$) run. The revised model shows that by adding HCl emissions more
502 NH_x was partitioned to the condensed phase improving agreement with the observations. 3×Base HCl was able

503 to represent well the diurnal variation of NH_4^+ and Cl^- both in terms of amount and pattern with improved NMB
504 for NH_3 . Additional sensitivities tests in changing NH_3 emissions (reduction by a factor of 3) in the 3×Base HCl
505 also improved NH_3 , NH_4^+ , and NH_x concentrations. We find excess NH_3 along with longer lifetime of NH_4^+ may
506 act as a controlling driver for NH_x overestimation in the model. These results highlight the need to include
507 correct industrial sources of HCl emissions along with appropriate emissions of NH_3 to reduce biases in NH_x .
508 Developing the appropriate NH_3 emissions using country-specific emission inventories, which are currently
509 under development as part of the Global Challenges Research Fund (GCRF), South Asian Nitrogen Hub
510 (SANH). Also, there is potential to develop top-down constraints on NH_3 emissions by taking inference from
511 the satellite, model, and ground-based observations. Challenges remain in simulating NH_3 as a contributor to
512 particulate matter due to temporal factors in ammonia peaks including the role of fog and dew where more work
513 is needed. This work also suggests model improvements to SO_2 oxidation pathways could improve NH_x
514 partitioning.

515 **Data availability**

516 The $0.1^\circ \times 0.1^\circ$ emission grid maps can be downloaded from the EDGAR website on
517 https://edgar.jrc.ec.europa.eu/htap_v2/index.php?SECURE=_123 per year per sector. Gridded emissions in t y^{-1}
518 on a $0.1^\circ \times 0.1^\circ$ for HCl emissions can be downloaded from Mendeley data: <http://dx.doi.org/10.17632/546t9249bv.1>. The model data is available at Aditya, Indian Institute of Tropical Meteorology
520 (IITM) super-computer and can be provided upon request to the corresponding author. The observational and
521 meteorological data of WiFEX are available by contacting the corresponding author.

522 **Author contributions**

523 SDG designed the research; PVP performed the WRF-Chem model simulations and led the analysis; PA and RK
524 contributed to data collection and its quality control and assurance; GG, RK, and PG helped with the model set
525 up; PVP and SDG wrote the paper with contributions from all co-authors.

526 **Competing interests**

527 The authors declare that they have no conflict of interest.

528 **Acknowledgments**

529 We thank the Director, IITM, for his continuous support and encouragement. IITM is funded by the Ministry of
530 Earth Sciences (MoES), Government of India. We wish to thank the MoES for supporting the WiFEX
531 campaign. The lead author's fellowship was supported by the National Supercomputing Mission (NSM)
532 program grant at C-DAC, and Ph.D. fees are covered by the Natural Environment Research Council (NERC) of
533 UK Research and Innovation (UKRI)-Global Challenges Research Fund (GCRF), South Asian Nitrogen Hub
534 (SANH), and we are grateful to the Executive Director and the Director-General of C-DAC and the SANH

535 Director and Chair of the Executive Board. We acknowledge the availability of CPCB-NO_x, NO₂, and O₃ data
536 from the CPCB web portal (<https://app.cpcbcr.com/ccr>, last access: 1 December 2021). We wish to
537 acknowledge the National Center for Atmospheric Research is sponsored by the National Science Foundation.
