14

15 **Abstract.** Formaldehyde (HCHO) and nitrogen dioxide (NO₂) concentrations and profiles were retrieved
16 from ground-based multi-axis differential optical absorption spectroscopy (MAX-DOAS) observations
17 during January 2017 - December 2018 at three sites in Asia: (1) Phimai (15.18°N, 102.5°E), Thailand;
18 (2) Pantnagar (29°N, 78.90°E) in the Indo Gangetic Plain (IGP), India; and (3) Chiba (35.62°N,
19 140.10°E), Japan. Retrievals were performed using the Japanese MAX-DOAS profile retrieval algorithm
20 ver. 2 (JM2). The observations were used to evaluate the NO₂ and HCHO partial columns and profiles (0
21 - 4 km) simulated using the global chemistry transport model (CTM) CHASER. The NO₂ and HCHO
22 concentrations at all three sites showed consistent seasonal variation throughout the investigated period.
23 Biomass burning affected the HCHO and NO₂ variations at Phimai during the dry season and at Pantnagar
24 during spring (March - May) and post-monsoon (September - November). Results found for the HCHO
25 to NO₂ ratio (R_{FN}), an indicator of high ozone sensitivity, indicate that the transition region (i.e., $1 < R_{FN}$
26 < 2) changes regionally, echoing the recent finding for R_{FN} effectiveness. Moreover, reasonable estimates
27 of transition regions can be derived, accounting for the NO₂ - HCHO chemical feedback.

28 The model was evaluated against global NO₂ and HCHO columns data retrieved from Ozone Monitoring
29 Instrument (OMI) observations before comparison with ground-based datasets. Despite underestimation,
30 the model well simulated the satellite-observed global spatial distribution of NO₂ and HCHO, with
31 respective spatial correlations (*r*) of 0.73 and 0.74. CHASER demonstrated good performance,
32 reproducing the MAX-DOAS retrieved HCHO and NO₂ abundances at Phimai, mainly above 500 m from
33 the surface. Model results agree with the measured variations within the one sigma standard deviation of
34 the observations. Simulations at higher resolution improved the modeled NO₂ estimates for Chiba,
35 reducing the mean bias error (MBE) for the 0 - 2 km height by 35%, but resolution-based improvements
36 were limited to surface layers. Sensitivity studies show that at Phimai, pyrogenic emissions contribute to
37 HCHO and NO₂ concentrations up to 50 and 35%, respectively.

38 **1 Introduction**

39 Formaldehyde (HCHO), the most abundant carbonyl compound in the atmosphere, is a high-yield product
40 of oxidization of all primary volatile organic compounds (VOCs) emitted from natural and anthropogenic
41 sources by hydroxyl radicals (OH). Oxidation of long-lived VOCs such as methane produces a global
42 HCHO background concentration of 0.2 – 1.0 ppbv in remote marine environments (Weller et al., 2000;
43 Burkert et al., 2001; Singh et al., 2004; Sinreich et al., 2005). Aside from oxidation of VOCs, the
44 significant sources of HCHO are direct emissions from biomass burning, industrial processes, fossil fuel
45 combustion (Lee et al., 1997; Hak et al., 2005; Fu et al., 2008), and vegetation (Seco et al., 2007).
46 However, oxidization of non-methane VOCs emitted from biogenic (e.g., isoprene) or anthropogenic (e.g.,
47 butene) sources govern the spatial variation of HCHO on a global scale (Franco et al., 2015). The sinks
48 of HCHO include photolysis at wavelengths shorter than 400 nm, oxidation by OH, and wet deposition,
49 thereby limiting the lifetime of HCHO to a few hours (Arlander et al., 1995).

50 Nitrogen dioxide (NO₂), an important atmospheric constituent, (1) participates in the catalytic
51 formation of tropospheric ozone (O₃), (2) acts as a catalyst for stratospheric ozone (O₃) destruction
52 (Crutzen, 1970), (3) contributes to the formation of aerosols (Jang and Kamens, 2001), (4) acts as a
53 precursor of acid rain (Seinfeld and Pandis, 1998), and (5) strongly affects radiative forcing (Solomon et
54 al. 1999; Lelieveld et al., 2002;). Nitrogen oxides (NO_x = NO (nitric oxide) + NO₂) are emitted from
55 natural and anthropogenic sources. Primary NO_x emission sources include biomass burning, fossil fuel

56 combustion, soil emissions, and lightning (Bond et al., 2001; Zhang et al., 2003). Not only do NO_x
57 emissions degrade air quality; they are leading air pollutant (Ma et al., 2013). Both HCHO and NO_2 are
58 important intermediates in the global VOC– HO_x (hydrogen oxides)– NO_x catalytic cycle, which governs
59 O_3 chemistry in the troposphere (Lee et al., 1997; Houweling et al., 1998; Hak et al., 2005; Kanakidou et
60 al., 2005). Thus, both trace gases play crucially important roles in tropospheric chemistry.

61 The observational sites examined for the present study have different atmospheric characteristics.
62 Thailand is strongly affected by pollution because of rapid economic development and urbanization.
63 Moreover, biomass burning in Southeast Asia is a significant source of O_3 precursors, contributing up to
64 30% of the total concentrations during the peak burning season (Amnuaylorajen et al., 2020; Khodmanee
65 et al. 2021). Because of rapid industrialization, India the second most populous country in the world, is
66 witnessing an increasing O_3 trend along with NO_2 and HCHO concentrations in all major cities (Mahajan
67 et al; 2015; Lu et al, 2018;). The Indo-Gangetic Plain (IGP), which covers ~21% of the Indian
68 subcontinent land area is hotspots of severe air pollution (Giles et al; 2005, Biswas et al; 2019). In contrast,
69 surface O_3 concentrations have shown an increasing trend in Japan, despite decreasing NO_x and VOC
70 concentrations related to emission control measures after 2000 (Irie et al., 2021). Therefore, observational
71 and modeling studies must be conducted to improve our quantitative understanding of the O_3 - NO_x -VOC
72 relation in these regions.

73 Multi-axis differential optical absorption spectroscopy (MAX-DOAS), a well-established, unique, and
74 powerful remote sensing method for measuring trace gases and aerosols, is based on the DOAS technique.
75 Aerosols and trace gases are quantified using selective narrowband (high frequency) absorption features
76 (Platt 1994; Platt and Stutz 2008). Spectral radiance measurements at different elevation angles (ELs) can
77 provide profile information about atmospheric trace gases and aerosols (Hönninger et al., 2004; Wagner
78 et al., 2004; Wittrock et al., 2004; Frieß et al., 2006; Irie et al., 2008a). Many studies have demonstrated
79 the retrieval of aerosol and trace gas concentrations and profiles from MAX-DOAS observations,
80 including NO_2 and HCHO (Clémer et al., 2010; Irie et al., 2011; Hendrick et al., 2014; Wang et al., 2014;
81 Franco et al., 2015; Frieß et al., 2016).

82 The ability of MAX-DOAS to provide information related to surface concentrations, vertical profiles,
83 and column densities makes it a good complement to ground-based in situ and satellite observations.

84 Moreover, the MAX-DOAS method uses narrowband absorption of the target compounds, thereby
85 obviating any need for radiometric calibration of the instrument. Because of these advantages, MAX-
86 DOAS systems are deployed for the assessment of aerosol and trace gases in regional and global
87 observational networks such as BREDOM (Wittrock et al., 2004), BIRA-IASB (Clémer et al., 2010), and
88 MADRAS (Kanaya et al., 2014). Such datasets are used, in but are not limited to, (1) air quality
89 assessment and monitoring, (2) evaluation of chemistry-transport models (CTMS), and (3) validation of
90 satellite data retrievals. Several studies have used MAX-DOAS datasets to validate tropospheric columns
91 retrieved from satellite observations, including NO₂ and HCHO (Irie et al., 2008b; Ma et al., 2013; Chan
92 et al., 2020; Ryan et al., 2020). However, limited MAX-DOAS datasets have been used to evaluate global
93 CTMs. Vigouroux et al. (2009) and Franco et al. (2015) respectively used the MAX-DOAS HCHO
94 datasets from Reunion Island and Jungfraujoch stations to evaluate the Intermediate Model of Annual and
95 Global Evolution of Species (IMAGES) and GEOS-Chem model simulations. Kanaya et al. (2014)
96 validated the Model for Interdisciplinary Research on Climate–Earth System Model – Chemistry
97 (MIROC-ESM-CHEM) simulated NO₂ column densities with MAX-DOAS observations in Cape Hedo
98 and Fukue in Japan. Kumar et al. (2021) used MAX-DOAS observations to evaluate the high-resolution
99 regional model Meco(n)(MESSy-field ECHAM and COSMO model nested n times).

100 For this study, NO₂ and HCHO profiles retrieved from MAX-DOAS observations from the International
101 air quality and sky research remote sensing (A-SKY) (<http://atmos3.cr.chiba-u.jp/a-sky/>) network sites
102 are used to evaluate the global Chemical Atmospheric General Circulation Model for the Study of
103 Atmospheric Environment and Radiative Forcing (CHASER; Sudo et al., 2002). The three A-SKY sites
104 of - (1) Phimai in Thailand (15.18°N, 102.56°E), (2) Pantnagar (29°N, 78.90°E) in the IGP in India, and
105 (3) Chiba (35.62°N, 140.10°E) in Japan, are respectively representative of rural, semi-rural, and urban
106 environments. CHASER has been used mostly for global-scale research (Sudo et al., 2007; Sekiya et al.,
107 2014, 2018; Miyazaki et al., 2017). The study described herein is the first reported attempt to evaluate the
108 CHASER-simulated NO₂ and HCHO profiles using MAX-DOAS observations in three different
109 atmospheric environments. Moreover, few reports of the literature have described the use of MAX-DOAS
110 datasets to evaluate global CTMs in South Asia and South-east Asia. Overall, this study was conducted

111 to provide important insights into model performances and to help reduce model uncertainties related to
112 NO₂ and HCHO simulations in these regions.

113 The paper is structured in the following manner. First, the observation sites, MAX-DOAS
114 instrumentation, and retrieval strategies are described in section 2. Section 2 also includes a short
115 description of the CHASER model and Ozone Monitoring Instrument (OMI) HCHO and NO₂ retrievals.
116 Next, the observations and the evaluation results are described in sections 3. Finally, the sensitivity study
117 results are provided in section 3.4. and the concluding remarks in section 4.

118

119

120 **2 Observations, datasets, and methods**

121

122 **2.1 Site Information**

123 Continuous MAX-DOAS observations at Chiba, Phimai, and Pantnagar started respectively in 2012,
124 2014, and 2017. The measurements from January 2017 to December 2018 at all three sites are discussed
125 herein. Phimai, a rural site, is located ~260 km north-east of the Bangkok metropolitan area and is unlikely
126 to be affected by vehicular and industrial emissions. However, the site is affected by biomass burning
127 during January - April. Two major air streams: the dry, cool north-east monsoon during November – mid-
128 February and the wet, warm south-west monsoon during mid-May – September affect the climate in
129 Phimai. As described by, Hoque et al. (2018), the climate classifications of Phimai are the (a) dry season
130 (January – April), and (b) wet season (June – September).

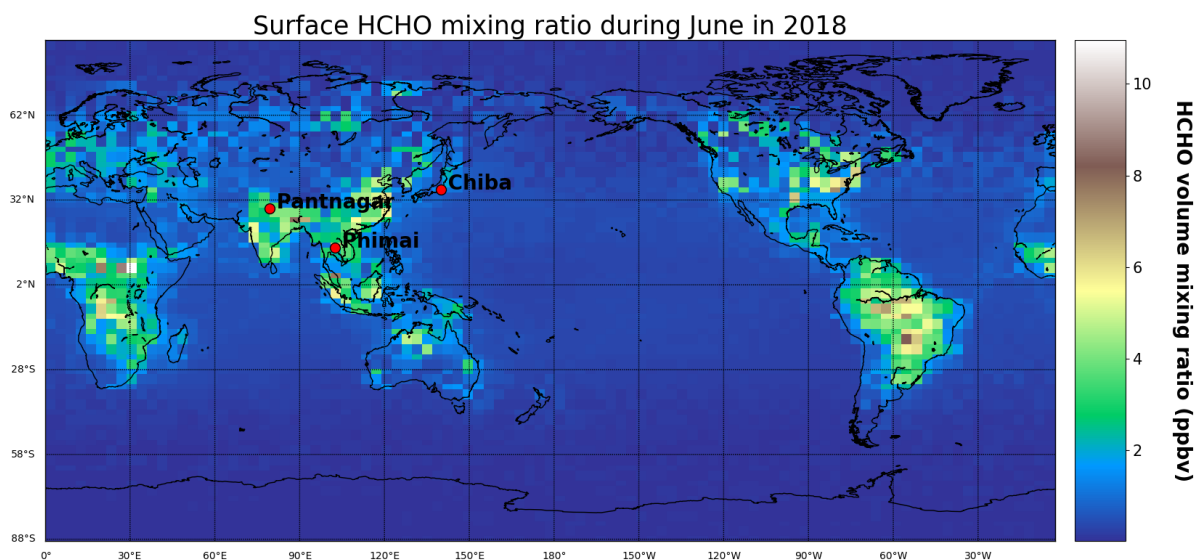

131 Pantnagar, a semi-urban site in India, is located in the IGP. The Indian capital of New Delhi is situated
132 at ~225 km south-west of the site. The low-altitude plains are on the south and west sides of the site. The
133 Himalayan mountains are located to the north and east. An important roadway with moderate traffic
134 volume and a small local airport lies within 3 km of the site. Rudrapur (~12 km south-west of Pantnagar)
135 and Haldwani (~ 25 km north-east of Pantnagar) are the two major cities near Pantnagar, where non-
136 combustible industries are located (Joshi et al., 2016). The climate classification at Pantnagar is the

137 following: (1) winter (December–February), (2) spring (March–May), (3) summer monsoon (June–
138 August), and (4) autumn (September–November).

139 Chiba, an urban site, is located ~40 km south-east of the Tokyo metropolitan region. Tokyo Bay,
140 large-scale industries, and residential areas are located within a 50 km radius. Chiba has four distinct
141 seasons: (1) spring (March–May), (2) summer (June–August), (3) autumn (September–November), and
142 winter (December– February). The locations of the three sites are depicted in Fig. 1.

143

144

145 **Figure 1:** Surface HCHO mixing ratio in June 2018, simulated using the CHASER model. The red points
146 represent the locations of the observation sites, which are part of the A-SKY network.

147

148

149 **2.2 MAX-DOAS retrieval**

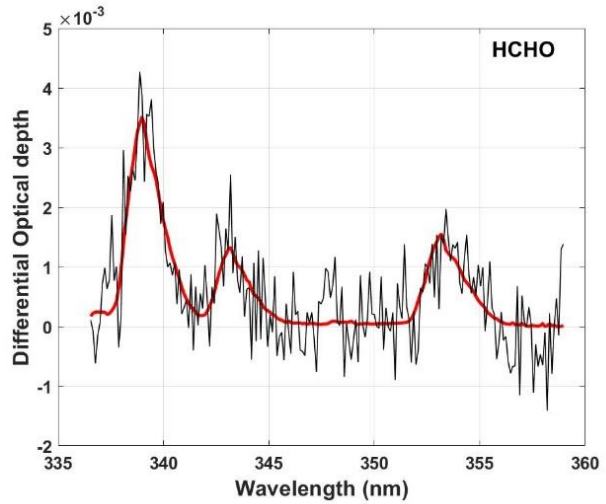

150 The MAX-DOAS systems used for continuous observations at the three sites participated in the Cabauw
151 Intercomparison Campaign of Nitrogen Dioxide measuring Instruments (CINDI) (Roscoe et al., 2010)
152 and CINDI-2 (Kreher et al., 2020) campaigns. The instrumentation setup is described by Irie et al. (2008,
153 2011, 2015). The indoor part of the MAX-DOAS systems consists of an ultraviolet-visible (UV-VIS)
154 spectrometer (Maya2000Pro; Ocean Optics Inc.) embedded in a temperature-controlled box. The outdoor
155 unit consists of a single telescope and a 45° inclined movable mirror on a rotary actuator, used to perform
156 reference and off-axis measurements. The high-resolution spectra from 310–515 nm is recorded at six
157 elevation angles (ELs) of 2°, 3°, 4°, 6°, 8°, and 70° at the Chiba and Phimai sites. At the Pantnagar site,
158 measurements are conducted at ELs of 3°, 4°, 5°, 6°, 8°, and 70°. The sequences of the ELs at all the sites
159 were repeated every 15 min. The reference spectra are recorded at EL of 70° instead of 90° to avoid
160 saturation of intensity. Because all the ELs were considered in the box air mass factor (A_{box}) calculation
161 to retrieve the vertical profile, the choice of reference EL (70° or 90°) is not an important issue for this
162 study. The off-axis ELs are limited to $< 10^\circ$ to reduce the systematic error in the in-oxygen collision
163 complex (O_4) fitting results (Irie et al., 2015), thereby maintaining high sensitivity in the lowest layer of
164 the retrieved aerosol and trace gas profiles. Daily wavelength calibration using the high-resolution solar
165 spectrum from Kurucz et al. (1984) is performed to account for the spectrometer's long-term degradation.
166 The spectral resolution (full width half maximum: FWHM) is about 0.4 nm at 357 and 476 nm. The
167 concentrations and profiles of aerosol and trace gases are retrieved using the Japanese vertical profile
168 retrieval algorithm (JM2 ver. 2) (Irie et al., 2011, 2015). The algorithm works in three steps: (1) DOAS
169 fittings, (2) profile/column retrieval of aerosol, and (3) profile/column retrieval of trace gases. Irie et al.
170 (2008a, 2008b, 2011, 2015) described the retrieval procedures, and the error estimates. Herein we provide
171 a short overview.

172 First, the differential slant column density (Δ SCD) of trace gases is retrieved using the DOAS
173 technique (Platt 1994), which uses the nonlinear least-squares spectral fitting method, according to the
174 following equation :

175
$$\ln I(\lambda) = \ln(I_o(\lambda) - c(\lambda)) - \sum_i^n \sigma_i(\lambda) \Delta SCD_i - p(\lambda) \quad (1)$$

176

177 Therein, $I_o(\lambda)$ represents the reference spectrum measured at time t . $I_o(\lambda)$ is derived by interpolating
178 two reference spectra (i.e., EL=70°) within 15 min before and after the complete sequential scan of the
179 off-axis ELs at time t . ΔSCD represents the difference between the slant column density along the off-
180 axis and reference spectrum. Second- and third-order polynomials are fitted to account, respectively, the
181 wavelength-dependent offset $c(\lambda)$ and the effect of molecular and particle scattering $p(\lambda)$. In addition,
182 $c(\lambda)$ accounts for the influence of stray light. The HCHO ΔSCD and NO₂ ΔSCD are retrieved respectively,
183 from the fitting windows of 340–370 and 460–490 nm. Significant O₄ absorptions in the 338–370 and
184 460–490 nm fitting windows are used to retrieve the O₄ ΔSCD s. The absorption cross-section data sources
185 and the fitted absorbers in the HCHO and NO₂ fitting windows are given in Table 1. Figure 2 presents an
186 example of the fitting results. O₄ fittings in both retrieval windows are shown in Fig S1 (supplementary
187 information).

188 **Figure 2:** Examples of spectral fitting of NO₂ and HCHO, where red and black lines respectively show the scaled
 189 cross-section and the summation of scaled cross-sections and fitting residuals. The example shows the
 190 measurements of 10 April 2017, in Phimai at 10:00 LT at an EL of 2°.

191 In the second step, the aerosol optical depth (AOD) τ and the vertical profiles of the aerosol extinction
 192 coefficient (AEC) k are retrieved using the approach developed by Irie et al, (2008a) which is based on
 193 the optimal estimation method (Rogers, 2000). In this approach, the measurement vector y (representing
 194 the quantities to be fitted) and state vector (representing the retrieved quantities) is defined as

195

$$196 \quad y = (O_4 \Delta SCD(\Omega_1) \dots \dots \Delta SCD(\Omega_n))^T \quad (2) \text{ and}$$

$$197 \quad x = (\tau F_1 F_2 F_3)^T \quad (3),$$

198

200 **Table 1.** Cross-section data references and absorbers fitted in the HCHO and NO₂ windows

201

202

203 where n stands for the number of measurements within one complete scan of an EL sequence. Also, Ω
 204 denotes the viewing geometry and includes three components: solar zenith angle (SZA), EL, and relative
 205 azimuth angle (RAA). The F values determine the profile shape, with values between 0 and 1. The partial
 206 AOD for 0–1, 1–2, 2–3, and above 3 km layers were defined respectively as $AOD \cdot F_1$, $AOD \cdot (1-F_1) F_2$,
 207 and $AOD \cdot (1-F_1) (1-F_2) F_3$, and $AOD \cdot (1-F_1) (1-F_2) (1-F_3)$. The AEC profile from 3 to 100 km is derived

208 assuming a fixed value at 100 km and exponential AEC profile shape with a scaling height of ~1.6 km.
209 The k value at 100 km was estimated from Stratospheric Aerosol and Gas Experiment III (SAGE III)
210 aerosol data ($\lambda=448$ and 521 nm) taken at altitudes of 15–40 km. The negligible influence of such
211 assumptions on the retrievals in the lower troposphere has been demonstrated in sensitivity studies
212 reported by Irie et al (2012). Similarly, the AEC profiles at 2–3, 1–2, and 0–1 km were derived. Such
213 parameterization provides the advantage that the AEC profile can be retrieved using only the apriori
214 knowledge of the F values (profile shape) and little or no information related to the absolute AEC values
215 in the troposphere. Irie et al. (2008a) demonstrated that the relative variability of the profile shape, in
216 terms of 1-km averages, is smaller than that of the absolute AEC values. AEC profile shapes
217 corresponding to different F values is shown in Fig.S2 (supplementary information). However, the
218 vertical resolution and the measurement sensitivity cannot be derived directly with such a
219 parameterization (Irie et al., 2008a; 2009). The retrievals and simulations conducted by other groups for
220 similar geometries (i.e., Frieß et al., 2006) are used to overcome such limitations. The apriori values used
221 for this study were similar to those reported by Irie et al. (2011): $AOD = 0.21 \pm 3.0$, $F_1 = 0.60 \pm 0.05$, F_2
222 $= 0.80 \pm 0.03$, and $F_3 = 0.80 \pm 0.03$.

223 Then, a lookup table (LUT) of the box air mass factor (A_{box}) vertical profile at 357 and 476 nm is
224 constructed using the radiative transfer model JACOSPAR (Irie et al., 2015), which is based on the Monte
225 Carlo Atmospheric Radiative Transfer Simulator (MCARaTS) (Iwabuchi, 2006). The values of the single-
226 scattering albedo (s), asymmetry parameter (g), and surface albedo were, respectively, 0.95, 0.65 (under
227 the Henyey-Greenstein approximation), and 0.10. The U.S. standard atmosphere temperature and pressure
228 profiles were used for radiative transfer calculations. Uncertainty of less than 8% related to the usage of
229 fixed values of s , g , and a were estimated from sensitivity studies (i.e., Irie et al 2012). Results obtained
230 from JACOSPAR are validated in the study reported by Wagner et al. (2007). The optimal aerosol load
231 and the A_{box} profiles are derived using the A_{box} LUT and the O_4 Δ SCD at all ELs.

232 In the third step, the A_{box} profiles, HCHO and NO_2 Δ SCDs, and the nonlinear iterative inversion
233 method are used to retrieve the HCHO and NO_2 vertical column densities (VCDs) and profiles. Here the
234 NO_2 retrieval is explained.

235

236 For trace gas retrieval, the measurement vector and state vector are defined as

$$237 \quad y = (NO_2 \Delta SCD(\Omega_1) \dots \dots \dots NO_2 \Delta SCD(\Omega_n))^T \quad (4) \text{ and}$$

238

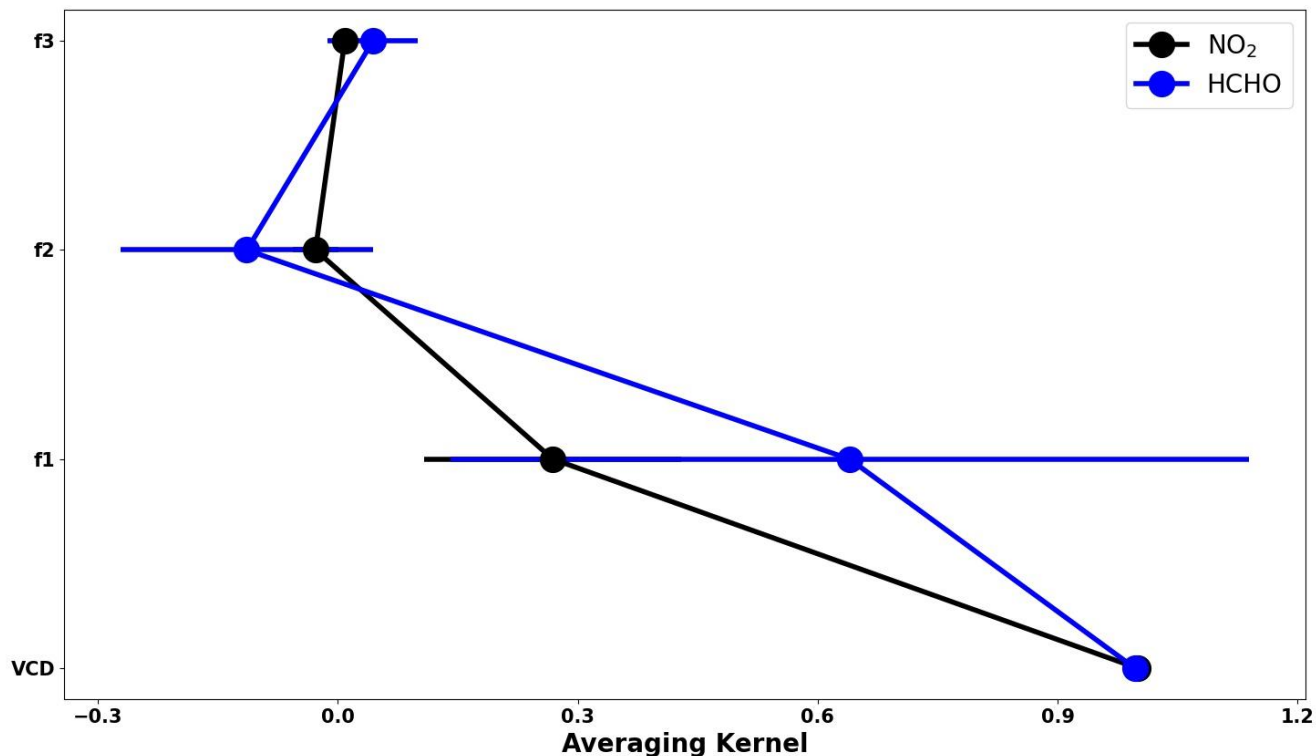

$$239 \quad x = (VCD f_1 f_2 f_3)^T \quad (5)$$

240 VCD represents the vertical column density below 5 km. The f values are the profile shape factors.
241 Above the 5 km layer, fixed profiles are assumed. Similarly, to aerosol retrieval, the partial VCD values
242 for the 0–1, 1–2, 2–3, and 3–5 km is defined respectively as $VCD \cdot f_1$, $VCD \cdot (1-f_1) f_2$, $VCD \cdot (1-f_1) (1-f_2)$
243 f_3 , and $VCD \cdot (1-f_1) (1-f_2) (1-f_3)$. Finally, the volume mixing ratio (VMR) is calculated using the partial
244 VCD, and U.S. standard atmosphere temperature and pressure data scaled to the respective surface
245 measurements.

246 The calculated vertical profile is converted to $NO_2 \Delta SCDs$ using the A_{box} LUT constructed for aerosol
247 retrieval. However, the trace gas wavelengths differed from the representative wavelengths of A_{box} LUT
248 (357 and 476 nm). Therefore, the AOD at the trace gas wavelength is estimated, converting the retrieved
249 AOD to the closer aerosol wavelength of 357 or 476 nm, assuming the Angstrom exponent value of 1.00.
250 The choice of the Angstrom exponent value can induce uncertainty in the retrieved VCDs. However, such
251 uncertainty was found to be non-significant compared to that of A_{box} profiles. Uncertainty in the A_{box}
252 profiles are assumed to as high as 30 to 50%. Such values are derived empirically from comparison with
253 sky radiometer and LIDAR observations (i.e., Irie et al., 2008b). Then, the A_{box} profiles from the LUT
254 corresponding to the recalculated AOD values are selected. The dependence of the A_{box} profiles on the
255 concentration profiles is expected to be low because both HCHO and NO_2 are optically thin absorbers
256 (Wagner et al., 2007; Irie et al., 2011). For every 15 min (time necessary for one complete scan of ELs),
257 20% (the mean ratio of the retrieved VCD to maximum ΔSCD) of the maximum trace gas $\Delta SCDs$ is used
258 as a priori information for the VCD retrievals. The a priori error is set to 100% of the maximum trace gas
259 ΔSCD . Figure 3 presents the mean averaging kernel (AK) of the HCHO and NO_2 retrievals during the dry
260 season at Phimai. The area (Rodgers, 2000) provides an estimate of the measurement contribution to the
261 retrieval. The total area is the sum of all the elements in the AK and weighted by the a priori error (Irie et
262 al. 2008a). The areas for VCD and f_1 of NO_2 retrieval are 1 and 0.6, respectively. The f_2 and f_3 values
263 are much smaller. Consequently, at first, the a priori profiles were scaled, and later f values determined

264 the profile shape. The VCD area is close to unity, and therefore, the retrieved VCD is independent of the
 265 a priori values. Irie et al (2008) conducted sensitivity studies of choice of the f values and reported
 266 negligible effect on the retrievals.

267

268

269 **Figure 3:** Mean averaging kernel of the NO₂ and HCHO retrievals from observations at Phimai during 2017. The
 270 error bars represent the 1-sigma standard deviation of the mean values.

271

272 The total error of the retrieval consists of random and systematic errors. The measurement error
 273 covariance matrix constructed from the residuals of the respective trace gas Δ SCDs is used to estimate
 274 the random error. The systematic error is calculated while assuming uncertainties as high as 30 and 50%
 275 in the retrieved AOD (or the corresponding A_{box} values). Table 2 shows the total estimated error. Aside
 276 from the random and systematic error, more sources of error might exist. For instance, the bias in the ELs

277 can induce uncertainties in the retrieved products. However, Hoque et al. (2018) demonstrated that such
278 biases had a non-significant effect on the final retrieved products, mostly less than 5%.

279 The cloud screening procedure is similar to that described by Irie et al. (2011) and by Hoque et al.
280 (2018a, 2018b). During the retrieval steps, retrieved AOD values greater than 3 are excluded, because
281 optically thick clouds are primarily responsible for such large optical depth. Filtering based on the
282 residuals of O₄ and the trace gas Δ SCDs is also used to screen clouds. Larger residuals likely occur due
283 to two reasons: (1) when the constructed profile is too simple to represent the true profile, particularly
284 with a steep vertical gradient of extinction due to clouds, and (2) rapid changes in optical depth within 30
285 min (time for one complete scan) (Irie et al, 2011). The screening criteria are: respective residuals of O₄,
286 HCHO, and NO₂ Δ SCDs < 10%, < 50%, and <20%, and the degrees of freedom of retrievals greater than
287 1.02. The threshold values were determined statistically corresponding to the mode plus one sigma (1 σ)
288 in the logarithmic histogram of relative residuals.

289

290 **Table 2.** Estimated Errors (%) for the NO₂ and HCHO concentration in 0-1 km layer, retrieved using the
291 JM2 algorithm

Retrieved Product	Random error	Systematic error	Error related to instrumentation	Total error
NO₂	10	12	5	16
HCHO	16	25	5	30

292

293

294 **2.3 CHASER simulations**

295 CHASER 4.0 (Version 4) (Sudo et al., 2002; Sudo and Akimoto, 2007; Sekiya and Sudo, 2014), coupled
296 online with the MIROC-AGCM atmospheric general circulation model (AGCM) (K-1 model developers,
297 2004) and the SPRINTARS aerosol transport model (Takemura et al., 2005, 2009), is a global chemistry
298 transport model used to study the atmospheric environment and radiative forcing. In addition, several

299 updates, including the introduction of aerosol species (sulfate, nitrate, etc.) and related chemistry,
 300 radiation, and cloud processes, have been implemented in the latest version of CHASER.

301 CHASER can calculate the concentrations of 92 species through 263 chemical reactions (gaseous,
 302 aqueous, and heterogeneous chemical reactions) considering the chemical cycle of O_3 – HO_x – NO_x – CH_4 –
 303 CO along with oxidation of non-methane volatile organic compounds (NMVOCs)(Miyazaki et al., 2017).
 304 The chemical mechanism is largely based on the master chemical mechanism (MCM,
 305 <http://mcm.york.ac.uk>)(Jenkin et al., 2015). CHASER simulates the stratospheric O_3 chemistry
 306 considering the Chapman mechanisms, catalytic reactions related to halogen oxides (HO_x , NO_x , ClO_x ,
 307 and BrO_x), and polar stratospheric clouds (PSCs). Resistance-based parameterization (Wesely, 1989),
 308 cumulus convection, and large-scale condensation parameterizations are used to calculate dry and wet
 309 depositions. The piecewise parabolic method (Colella and Woodward, 1984)

310

311 **Table 3:** Settings of the CHASER simulations used in this study

Simulation	Anthropogenic emissions	Pyrogenic emissions	Biogenic emissions	Soil NO_x emission	Other physical and chemical processes
Standard	ON	ON	ON	ON	ON
L1_HCHO	ON	Pyrogenic VOCs switched	ON	ON	ON
L1_opt	ON	OFF	Reduced by 50%	ON	ON
L1_NO₂	ON	ON	ON	OFF	ON

L2	Anthropogenic VOC emissions switched OFF	ON	ON	ON	ON
-----------	--	----	----	----	----

312

313 and the flux-form semi-Lagrangian schemes (Lin and Rood, 1996) calculate advective tracer transport.
314 CHASER simulates tracer transport on a sub-grid scale in the framework of the prognostic Arakawa–
315 Schubert cumulus convection scheme (Emori et al., 2001) and the vertical diffusion scheme (Mellor and
316 Yamada, 1974). In this study, CHASER simulations were conducted at a horizontal resolution of $2.8^\circ \times$
317 2.8° , with 36 vertical layers from the surface to ~ 50 km altitude and a typical time step of 20 min. The
318 meteorological fields simulated by MIROC-AGCM were nudged toward the six-hourly NCEP FNL
319 reanalysis data at every model time step.

320 The anthropogenic, biomass burning, lightning, and soil emissions of NO_x were incorporated into
321 CHASER simulations. Anthropogenic emissions were based on HTAP_v2.2 for 2008. Biomass burning
322 and soil emissions from the ECMWF/MAC (Global Fire Assimilation System (GFAS)) reanalysis were
323 used. The biogenic emissions for VOCs are based on the process-based biogeochemical model the
324 Vegetation Integrative Simulator for Trace gases (VISIT) (Ito and Inatomi, 2012) simulations. The NO_x
325 production from lightning is calculated based on the parameterization of Price and Rind (1992) linked to
326 the convection scheme of the AGCM (Sudo et al., 2002). Isoprene, terpene, acetone, and ONMV
327 emissions estimates in the VISIT inventory during July were 2.14×10^{-11} , 4.43×10^{-12} , 1.60×10^{-12} , and
328 $9.93 \times 10^{-13} \text{ kgCm}^{-2}\text{s}^{-1}$. Global NO_x emissions of 43.80 TgNyr^{-1} are used in the simulations, considering
329 industries (23.10 TgNyr^{-1}), biomass burning (9.65 TgNyr^{-1}), soil (5.50 TgNyr^{-1}), lightning (5 TgNyr^{-1}),
330 and aircrafts (0.55 TgNyr^{-1}) as significant sources. Global isoprene emissions from vegetation were set to
331 400 TgCyr^{-1} .

332 NO_x emissions in India were estimated as 14 Tg/yr in 2016, almost two-fold increase since 2005 (~8
333 Tg/yr), with the energy and transportation sector being the largest contributor (Sadavarte et al 2014).
334 Indian anthropogenic non-methane VOCs (NMVOCs) emissions in 2010 were estimated ~ 10 Tg/yr ,
335 with respective contributions of 60, 16, and 12% from residential, solvents, and the transport sector(
336 Sharma et al 2015). In Japan, vehicular exhausts (14 - 25%), gasoline vapor (9 - 16%), liquefied natural
337 gas (7 - 10%), and liquefied petroleum gas (49 - 71%) contribute to the total VOC concentrations (Morino
338 et al., 2011), with annual NMVOC emission of ~2 Tg (Kannari et al., 2007). Annual NO_x emissions in
339 Japan and Thailand in 2000 was estimated as ~2000 and 591 kt/yr, with the largest contribution from
340 transport-oil use, followed by the energy and industrial sector (Ohara et al., 2007). Annual anthropogenic
341 VOC emissions in Thailand are approximately 0.9 Tg, with 43, 38, and 20% contributed, respectively,
342 from industrial, residential and transportation sectors (Woo et al; 2020).
343 Multiple CHASER simulations with different settings used for sensitivity studies are presented in Table
344 3.

345

346 **2.4 Satellite observations**

347 Tropospheric NO₂ and HCHO retrievals from the Ozone monitoring Instrument (OMI) were also used to
348 evaluate the model simulations. The ultra-violet nadir-viewing spectrometer OMI, on board the Aura
349 satellite measures backscattering solar radiation covering the spectral range of 270 – 500 nm (Levelt et
350 al., 2006). In an ascending sun-synchronous polar-orbit, OMI crosses the equator at 13:40 LT (local time
351 (Zara et al., 2018). OMI measures at a spatial resolution of 13 × 24 km² and provides daily global coverage
352 of various trace gases including NO₂ and HCHO. The NO₂ and HCHO datasets were obtained respectively
353 from the TEMIS (www.temis.nl, last accessed on 2022/04/23) and aeronomie
354 (<https://h2co.aeronomie.be/>, last accessed 2022/05/03) websites. NO₂ tropospheric columns retrieved
355 using the DOMINO version 2.0 (Boersma et al., 2011) algorithm were used for the analysis. Data meeting
356 the following criteria were selected: cloud fraction < 0.5, SZA < 70°, surface albedo < 0.3, quality flags
357 =0, and cross-track quality flags= 0. For HCHO, we used the BIRA-IASB v14 (De Smedt et al 2015)

358 retrieved products. The data filtering criteria was the following: cloud fraction < 0.4, SZA<70°, AMF >
359 0.2, quality flag=0, and cross-track quality flag =0.

360

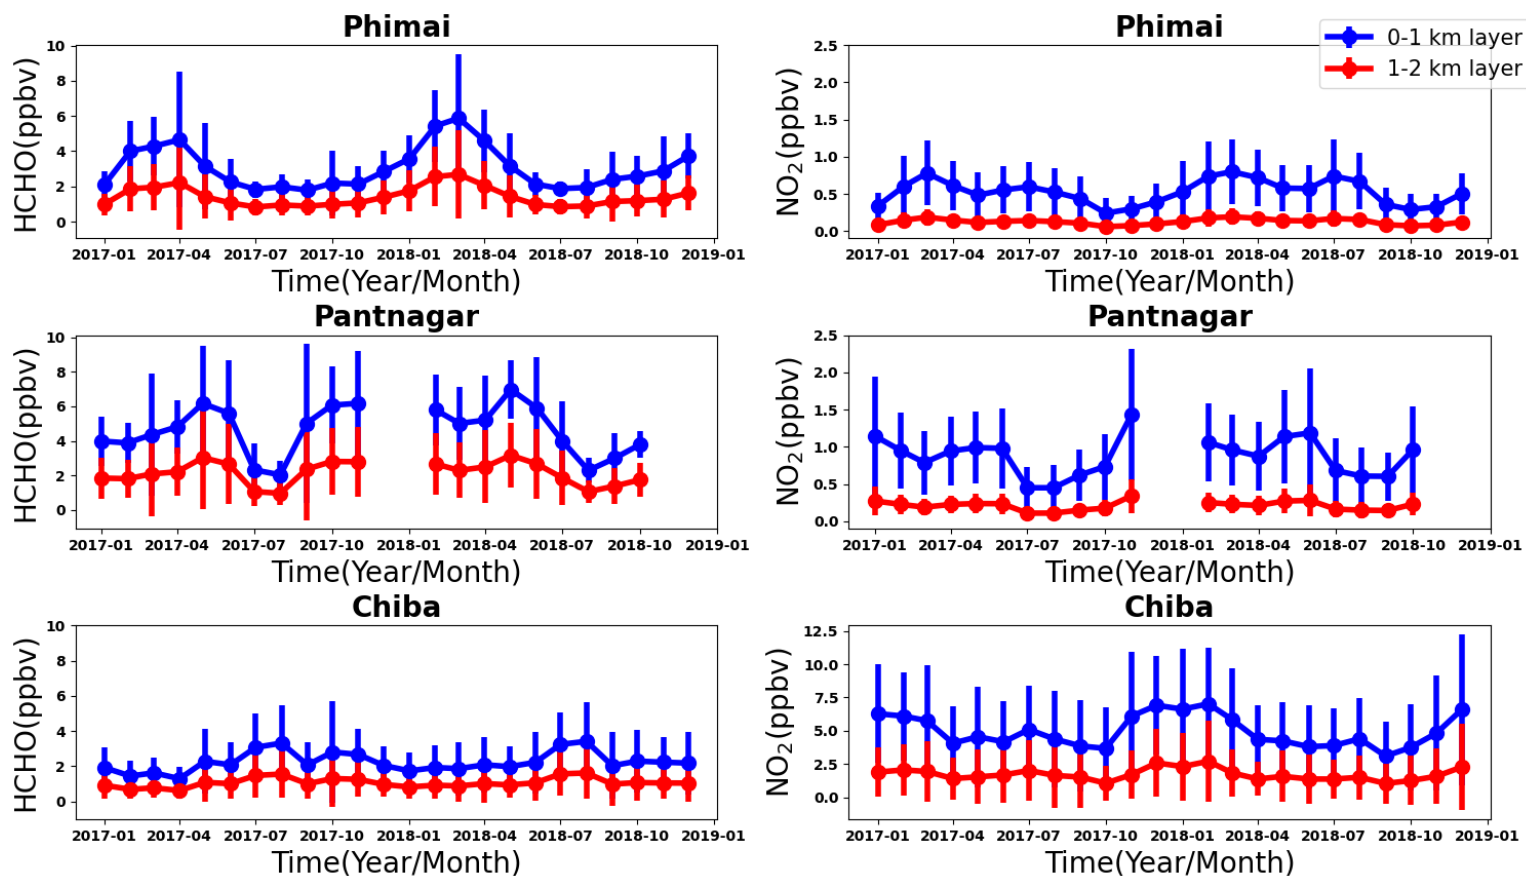

361

362 **3 Results and discussion**

363 **3.1 Results from MAX-DOAS observations**

364 **3.1.1 HCHO seasonal variation**

365 The monthly mean HCHO mixing ratios in the 0–1 and 0–2 km layers from January 2017 – December
366 2018 and the corresponding one sigma (1σ) standard deviations indicating the variation ranges for the
367 three sites are presented in Fig. 4. The HCHO levels at the Phimai site show a consistent seasonal cycle,
368 characterized by high VMRs during the dry season. Such enhancement is related to the influence of
369 biomass burning during the dry season, which has been well documented in the work of Hoque et al.
370 (2018). The HCHO mixing ratio at Phimai reach a peak in March or April, with a maximum of 4 – 6
371 ppbv. The variation in the peak concentration and timing depends mainly on the intensity of biomass
372 burning activities. During the wet season, the HCHO concentrations are mostly within 2–3 ppbv,
373 indicating a two-fold increase in HCHO abundances during the dry season. The daily mean HCHO
374 amounts (0 –1 km) are 0.78 - 9.84 ppbv, representing seasonal modulation of 134%.

376 **Figure 4:** Seasonal variations in the HCHO (left panel) and NO₂ (right panel) mixing ratios in the 0 - 1 (blue) and
 377 1 - 2 (red) km layers at Phimai, Pantnagar, and Chiba. The error bars represent the one sigma standard deviation of
 378 the mean values. The gaps in the plots for the Pantnagar site indicate the unavailability of observations during the
 379 investigated period.

380

381

382 Seasonal variation of HCHO in the 0–1 km layer at the Pantnagar site has been elucidated by Hoque
 383 et al. (2018b). Here, the results are replotted to verify the consistency of the seasonal variations.
 384 Observations made during autumn 2018 were not available because of problem with the spectrometer.
 385 Consistent seasonal variation of HCHO abundances is observed at the Pantnagar site, with enhanced
 386 concentrations during the spring. The Pantnagar site is affected by biomass burning during spring and
 387 autumn (Hoque et al., 2018b), explaining the high mixing ratios found during spring. In both years, the

388 maximum HCHO mixing ratios are ~ 6 ppbv. The springtime peak occurred in May. The HCHO
389 concentrations during the monsoon are $\sim 35\%$ lower than in the spring, indicating a strong effect of the
390 monsoon on the HCHO concentrations found for Pantnagar. The seasonal modulation of HCHO at
391 Pantnagar estimated from the daily mean concentrations is 107%. The peak HCHO mixing ratio at
392 Pantnagar is almost twice that of in Pune city (~ 3 ppbv) (Biswas and Mahajan, 2021), a site in the IGP
393 region. The HCHO seasonality at the two sites are found to be dissimilar, because of differences in the
394 VOC sources, however, lower mixing ratios during the monsoon is consistent. From another site in the
395 IGP region (i.e., Mohali), Kumar et al., (2020) reported lowest HCHO VCDs during March 2014 and
396 2015, attributing them to lower biogenic and anthropogenic VOC emissions. At Pantnagar, the lowest
397 HCHO mixing ratios are observed during the monsoon. The rainfall events in the IGP region shows strong
398 annual variability (Fukushima et al. 2019). Discrepancies between the sites might be related to the rainfall
399 pattern.

400 Under the influence of biomass burning, the maximum monthly HCHO mixing ratios at Phimai and
401 Pantnagar are similar (~ 6 ppb). The maximum instantaneous HCHO VMR during biomass burning
402 influence in Phimai and Pantnagar are, respectively, 26 and 30 ppbv. Zarzana et al. (2017) reported HCHO
403 abundances of ~ 60 ppbv in fresh biomass plumes in the US. The lower values obtained from our
404 measurements might be attributable to (1) more aged plumes intercepted by the MAX-DOAS instruments
405 and (2) differences in the types of biomass fuel used. Comparison to reports of literature indicates that the
406 retrieval of HCHO under biomass burning is reasonable.

407 The summertime maximum and wintertime minimum characterize the seasonal variations of HCHO at
408 the Chiba site, with a peak at ~ 3 ppbv. The HCHO concentrations are ~ 2 ppbv during other seasons,
409 which are similar to the HCHO concentrations in Phimai during the wet season. The seasonal variation
410 amplitudes of HCHO at Chiba is $\sim 94\%$. For a site with similar seasonal variation (i.e., summertime
411 maximum and wintertime minimum), Franco et al. (2015) reported HCHO seasonal modulation of 88%.

412 The HCHO VMRs in the 1–2 km layers at all three sites are lower, almost 50% the value of the
413 concentrations in the 0–1 km layer. The HCHO seasonal variation amplitudes at Phimai, Pantnagar, and
414 Chiba sites are, respectively, 131%, 102%, and 90% when calculated based on the HCHO concentration
415 in the 1–2 km layers. The modulation was even lower when retrieved values for the 2–3 km layer is used.

416 3.1.2 NO₂ seasonal variation at the three sites

417 Figure 4 also shows the seasonal variation of NO₂ in the 0–1 and 1–2 km layers at the three sites. The
418 error bars represent the 1 σ standard deviation of the mean values. The NO₂ seasonal variations at Phimai
419 and Pantnagar sites are similar to those of HCHO. Pronounced peaks attributable to biomass burning
420 influence is observed during the dry season at Phimai (~0.8 ppbv) and during spring (1.2 ppbv), and post-
421 monsoon (1.4 ppbv) at Pantnagar. The lowest NO₂ mixing ratios at Phimai and Pantnagar are, respectively,
422 ~0.2 and 0.5 ppbv. The NO₂ VMRs at Chiba is higher (~7 ppbv) during winter. The longer lifetime of
423 NO_x and lower NO/NO₂ ratio because of lower photochemical activity in winter lead to high NO₂ mixing
424 ratios at Chiba (Irie et al., 2021).

425 At Phimai, the NO₂ mixing ratios in both seasons are similar. However, when Hoque et al. (2018a)
426 reported the seasonal variations in NO₂ at Phimai during 2015 – 2018, the dry season mixing ratios were
427 higher. Table 4 shows the number of fire events during the dry seasons during 2015 - 2018. The fire data
428 are extracted from the MODIS Active Fire Detections database (<https://firms.modaps.eosdis.nasa.gov>,
429 last accessed on 2021/12/15). Data fulfilling the following criteria were chosen – (a) data points located
430 within 100 km of the Phimai site, (b) confidence of the data greater than 70%, and (c) observations during
431 the daytime. The lower fire counts during 2017 - 2018 compared to those of 2015 - 2016 period coincide
432 with the lower NO₂ levels in the former. Fire counts varied between 2017 and 2018 but did not affect the
433 NO₂ levels. However, HCHO levels changed with the number of fire occurrences between 2015 – 2018
434 (i.e., Figure 4 and Hoque et al., 2018a).

435 At such low NO₂ levels at Phimai, soil NO_x emissions are likely to make a greater contribution to
436 NO₂. Although NO₂ is not emitted directly from soils, biological processes emit NO, which is rapidly
437 converted to NO₂ (Hall et al., 1996). In addition, many studies have established a relation between soil
438 moisture and NO emissions (Carden et al., 1993; Zheng et al., 2000; Schindlbacher et al., 2004; Huber et
439 al., 2020). The potential contribution of soil NO_x emissions, as inferred from CHASER simulations, is
440 discussed in section 3.4.2.

441 **Table 4:** Number of fire events occurring during the dry season (January - April) at Phimai from 2015
442 - 2018. Selection criteria of the data are the following: (1) situated within 100 km of the site, (2)
443 confidence level > 70%, and (c) daytime measurements.

Dry season years	Number of fire events
2015	84
2016	98
2017	62
2018	77

444

445

446 3.1.3.1 The HCHO to NO₂ ratio (R_{FN}):

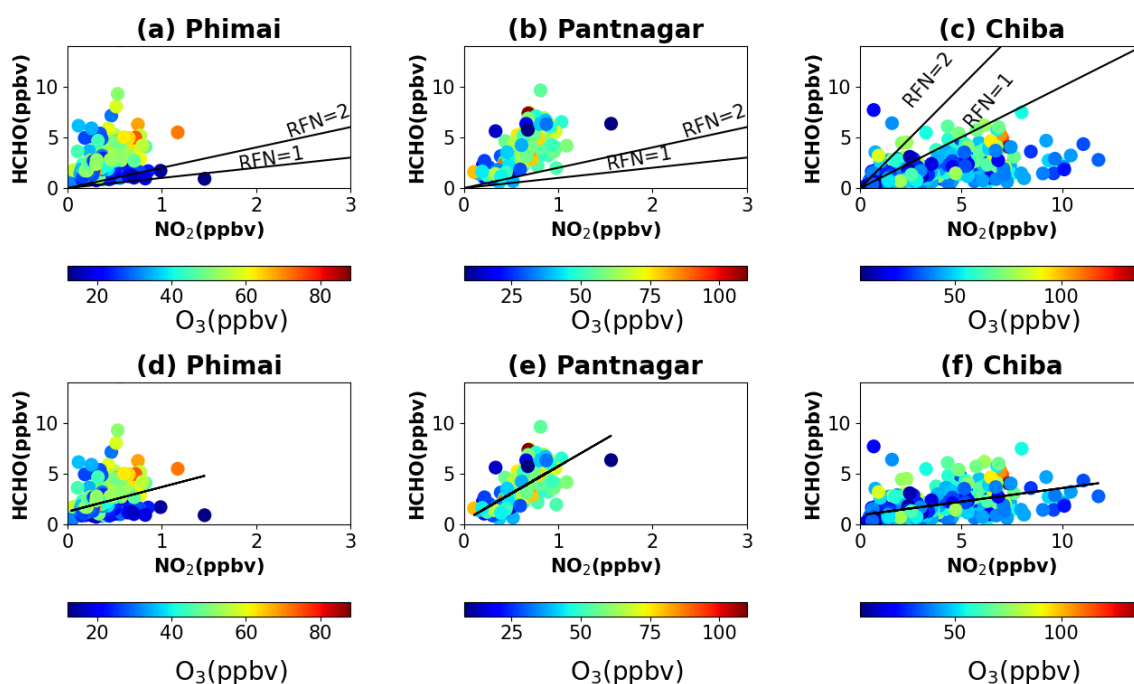

447 The HCHO to NO₂ (R_{FN}) ratio is regarded as an indicator of high ozone O₃ sensitivity (Martin et al., 2004;
448 Duncan et al., 2010). The O₃ production regime is characterized as VOC-limited for $R_{FN} < 1$ and NO_x-
449 limited when $R_{FN} > 2$, and the values in the range 1-2 are said to be in the transition/ambiguous region
450 (Duncan et al., 2010; Ryan et al., 2020). Subsequent to a report of Tonnesen and Dennis (2000), several
451 studies used R_{FN} estimated from satellite and ground-based observations to infer O₃ sensitivity to NO_x
452 and VOCs (Martian et al., 2004; Duncan et al., 2010; Jin and Holloway et al., 2015; Mahajan et al., 2015;
453 Irie et al., 2021; etc.). However, the effectiveness of R_{FN} is still under discussion primarily based on two-
454 points- (1) the range of the transition region to categorize the VOC and NO_x -limited region, and (2) the
455 altitude dependence of R_{FN} (Jin et al., 2017). Most of the studies described above used the transition range
456 ($1 < R_{FN} < 2$) proposed by Duncan et al. (2010). Schroeder et al. (2017) reported that a common transition
457 (i.e., $1 < R_{FN} < 2$) range might not be valid globally. Instead, it should be calculated based on the region.
458 First, the results based on the standard transition range are discussed herein, and then its applicability to
459 the study regions is assessed.

460 Figure 5 shows scatter plots of the daily mean NO₂ and HCHO concentrations in the 0 - 2 km layer at the
461 three sites, color-coded with the respective O₃ concentrations (0-2 km). Retrieval of the JM2 O₃ product
462 is explained by Irie et al. (2011). The O₃ concentrations for SZA < 50° are used to minimize stratospheric
463 effects. This criterion on the SZA is also applied for the selection of the NO₂ and HCHO concentrations.
464 Although not checked here, the JM2 O₃ product showed good agreement with ozonesonde measurements
465 in Tsukuba (Irie et al., 2021). Most of the high O₃ occurrences fall in the $R_{FN} > 2$ region at Phimai and
466 Pantnagar and in $R_{FN} < 1$ at Chiba. The common transition range classifies the O₃ production regime as

467 NO_x-limited at Phimai and Pantnagar and VOC-limited at Chiba. At all sites, the R_{FN} values tend to be
 468 biased to a particular regime (i.e., NO_x - or VOC-limited), with only 4 and 2% of the ratios in the range
 469 0 - 2, at Phimai and Pantnagar, respectively. This finding suggests that the transition occurs at a higher or
 470 lower ratio than the common definition. Recent report by Souri et al. (2020) found that the NO₂-HCHO
 471 relation plays an important role in determining the transition region and derived a formulation from
 472 accounting for the NO₂-HCHO chemical feedback in the ratios as

$$HCHO = m * (NO_2 - b) \quad (6)$$

473 where m and b respectively denote the slope and intercept. Equation (6) is based on observations, which
 474 means that the regionally adjusted fitting coefficients will reflect the local NO₂ - HCHO relation. Solving
 475 equation (6), the transition line estimated from the observations in the 0 - 2 km layer, is shown in Fig 5
 476 (bottom panel). Rather than a range, the method calculates a single transition line, which corresponds to
 477 the NO₂- HCHO feedback. The regions above and below the transition line are characterized, respectively
 478 as VOC- and NO_x -limited or other.

480

481 **Figure 5.** Scatter plots of HCHO and NO₂ concentrations in the 0-2 km layer at (a, d) Phimai, (b, e) Pantnagar, and
482 (c, f) Chiba, coloured with the O₃ concentrations in the 0-2 km layer at the respective sites. The solid lines in the
483 top panel represent $R_{FN} = 2$ and $R_{FN} = 1$ benchmarks. The black lines in the bottom panel are calculated according
484 to equation (1).

485

486 The revised transition line at Phimai and Pantnagar is apparently more reasonable than the earlier method.
487 At Phimai, the transition line almost clearly distinguishes between the high and low O₃ occurrences. It is
488 perceptible that when the HCHO concentrations are higher than NO₂, the transition of the regimes is likely
489 to occur at higher R_{FN} values. The minimum and mean R_{FN} value along the transition line are 3.62 and
490 6.78, respectively. Because Phimai is a VOC-rich environment, the regime transition occurs at higher R_{FN}
491 values than by the conventional definition. This finding echoes the results reported by Schroeder et al.
492 (2017) for a regionally variable transition region. The definition of $R_{FN} < 1$ as a VOC -limited regime might
493 not be valid in this case. Considering the mean R_{FN} ratio along the transition line (i.e., 6.78), the VOC-
494 and NO_x -limited (and other) regimes are defined, respectively as $R_{FN} < 6.78$ and $R_{FN} > 6.78$. Based on this
495 definition, around 34% (65%) of the ratios are higher (lower) than 6.78, classifying Phimai as a dominant
496 VOC-limited region, which contradicts earlier results. Biomass burning affects Phimai during January -
497 April and is a significant emission source in addition to biogenic emissions. Thus, high O₃ occurrences
498 likely occur only 30% of the time during a year. Such events mostly lie above the transition line.

499 At Pantnagar, high O₃ occurrences lie below (42%) and above (57%) the transition line, indicating that
500 O₃ production is sensitive to both HCHO and NO₂ which contradicts results reported by Biswas et al.
501 (2019). Based on satellite and ground-based observations, the study estimated the R_{FN} values at a site in
502 the IGP as > 4 and > 2 respectively, and regarded the O₃ regime as NO_x-limited. Mahajan et al. (2015)
503 reported R_{FN} values of less than 1 over the IGP region signifying as a VOC-limited region. Pantnagar is
504 a sub-urban site situated beside a busy road. Therefore, effects of anthropogenic emissions are expected
505 year-round, especially with pyrogenic emissions during the spring and post-monsoon period. O₃
506 sensitivity to both NO_x and VOCs in the north-west IGP region has also been reported by Kumar and
507 Sinha (2021). Therefore, the balance between the VOC and NO_x-limited region in the IGP is reasonable.
508 The mean and minimum R_{FN} value along the transition line are, respectively, 5.59 and 6.09. The minimum

509 value (i.e., 5.59) is higher than Phimai (3.26), suggesting higher VOC levels at Pantnagar, consistent with
510 the observations.

511 At Chiba, 60% of the R_{FN} values lie below the transition line, suggesting a dominant VOC-limited
512 region, which is consistent with the results reported by Irie et al. (2021). The minimum and the mean R_{FN}
513 along the transition line are, respectively, 0.33 and 0.72. The transition occurs at a low R_{FN} value because
514 of higher NO_2 levels. The fact that, 40% of the R_{FN} values are above the transition region suggests a
515 moderate effect of HCHO on the O_3 sensitivity at Chiba.

516 Although the new classification results are apparently reasonable, they should be interpreted with
517 care. Our current understanding of R_{FN} contradicts the classification of rural sites as VOC-limited. Despite
518 the theoretical and observational evidence (i.e., Souri et al.,2020), the classification of regimes based on
519 a single transition line is not yet well-established. Schroder et al. (2017) used regionally varying transition
520 ranges. Moreover, (a) the number of observations and (b) the systematic and retrieval errors can affect
521 the estimations and classifications. These findings are expected to contribute to the ongoing discussion
522 about the effectiveness of R_{FN} . However, the results support the idea of a regionally varying transition
523 range.

524

525 **3.1.3.2 R_{FN} profiles**

526 Figure 6 shows the seasonal mean R_{FN} profiles at the three sites. Only the profiles during the high O_3
527 concentrations at the sites (i.e., March at Phimai, May at Pantnagar, and February at Chiba) are shown.
528 The R_{FN} values are likely increase with height because of the lower vertical gradient of NO_2 , than that of
529 HCHO (Fig.4). It is particularly interesting that, the R_{FN} values are similar in the 1-2 km height under
530 biomass burning conditions, suggesting a small variation in the HCHO loss rate in the particular layer. At
531 both sites, the HCHO concentration at 1.5 km is about 3 ppbv. At Chiba, a considerable amount of NO_2
532 in the higher layers increases the ratio up to 2 km height. Beyond 2 km, the ratio variation at all sites is
533 opposite that found for the surface. The gradient issue of R_{FN} has been discussed explicitly by Jin et al.
534 (2017). They proposed a conversion factor to account for gradient differences in the surface and column-
535 derived R_{FN} values, estimating the conversion factor from the model simulated surface and column

536 abundances of NO₂ and HCHO. We adopt the method reported by Jin et al. (2017) for this study using
537 the CHASER simulated NO₂ and HCHO concentrations and vertical columns.

538 First, CHASER simulated near-surface NO₂ and HCHO concentrations were converted to number
539 density. The effective boundary layer height (E) (Halla et al., 2011; Jin et al., 2017) was estimated.

540

$$541 \quad E_{NO_2} = \frac{NO_2 \text{ total column}}{NO_2 \text{ near-surface number density}} \quad (7)$$

542

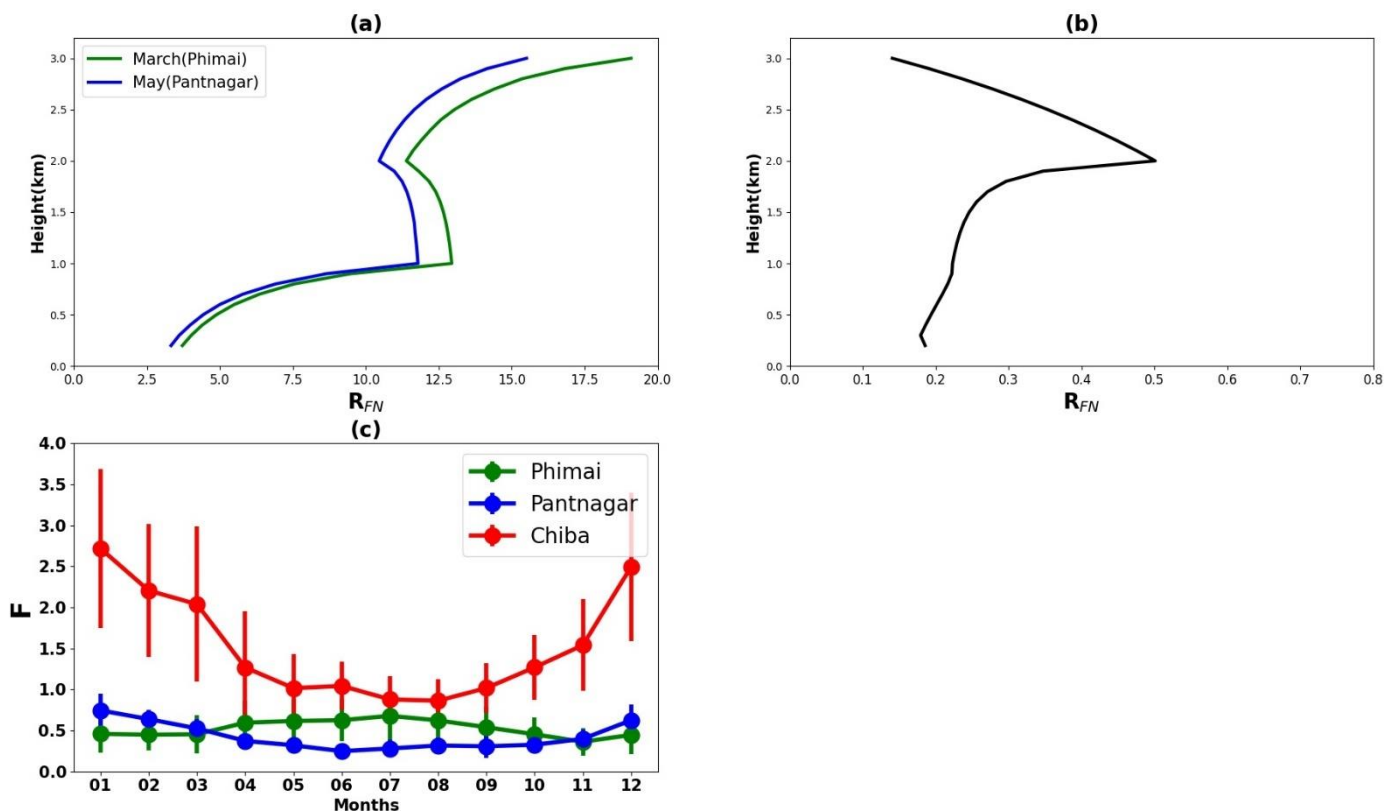

$$543 \quad E_{HCHO} = \frac{HCHO \text{ total column}}{HCHO \text{ near-surface number density}} \quad (8)$$

544 Therein, E_{NO₂} and E_{HCHO} respectively denote the effective boundary layer heights of NO₂ and HCHO.

545 In the second step, the column to surface conversion factor (F) was calculated according to the following
546 equation:

$$547 \quad F = \frac{E_{HCHO}}{E_{NO_2}} \quad (9)$$

548 The seasonal variation of F for the three A-SKY sites and the associated 1σ standard deviation of the
549 mean values are depicted in Fig. 7(c). The F values over East Asia reported by Jin et al. (2017) were ~2,
550 without marked seasonal variation. CHASER estimated F values over Chiba range between 1–2.5, which
551 is apparently reasonable, when compared with literature values. Values reported in literature for polluted
552 regions (NO₂ > 2.5 molecules cm⁻²) considered simulation data for 1–2 PM, but the estimates for this
553 study used daytime (07:00 – 18:00) simulations.

554

555 **Figure 6:** Seasonal mean R_{FN} profiles during (a) March and May at Phimai and Pantnagar, respectively, and (b)
 556 February at Chiba. (c) Seasonal variations in the column to surface conversion factor (F) for the Phimai, Pantnagar,
 557 and Chiba sites, estimated from the CHASER simulated HCHO and NO₂ surface concentrations and VCD. The
 558 simulated data from 07:00 – 18:00 in 2017 were used to estimate the F values. The error bars represent the one
 559 sigma standard deviation of the mean values.

560

561 The F values for Pantnagar are mostly less than 1, with no distinctive seasonal variation. Mahajan et
 562 al. (2015) reported OMI-derived R_{FN} values < 1 over the IGP region. When this estimated conversion
 563 factor is used with the values reported by Mahajan et al. (2015), the discrepancy in the satellite and
 564 ground-based observation derived R_{FN} values in the IGP region are reduced indicating that the estimated
 565 F values for the Pantnagar site can be representative for the IGP region. The F values at the Phimai site

566 range were 0.5–1. Our estimated F values for the Phimai and Pantnagar sites are useful as representative
567 values for these respective regions, which can be improved further based on the results.

568

569 **3.2 Global Evaluation of the CHASER model**

570 This section describes the evaluation of CHASER NO₂ and HCHO columns for 2017 against OMI
571 observations. The OMI AKs were applied to the CHASER outputs to account for the altitude-dependence
572 of the retrievals. First, 2-hourly simulated profiles (NO₂ and HCHO) were sampled closest to the
573 observation time. Secondly, AKs were applied to the sampled profiles and the mean profile was
574 calculated. Thirdly, both the simulations and observations were averaged on a 2.8° bin grid. The month
575 of July and December were discarded from the NO₂ comparison because few coincident days (only five
576 days) were available after filtering. It should be noted that simulations based on old NO_x emission
577 inventory will likely affect the model-satellite comparison results. However, the current study has not
578 assessed such impact due to technical issues related to using an updated emission inventory. All these
579 issues will be addressed in a separate study.

580 **3.2.1 Comparison between CHASER and OMI NO₂**

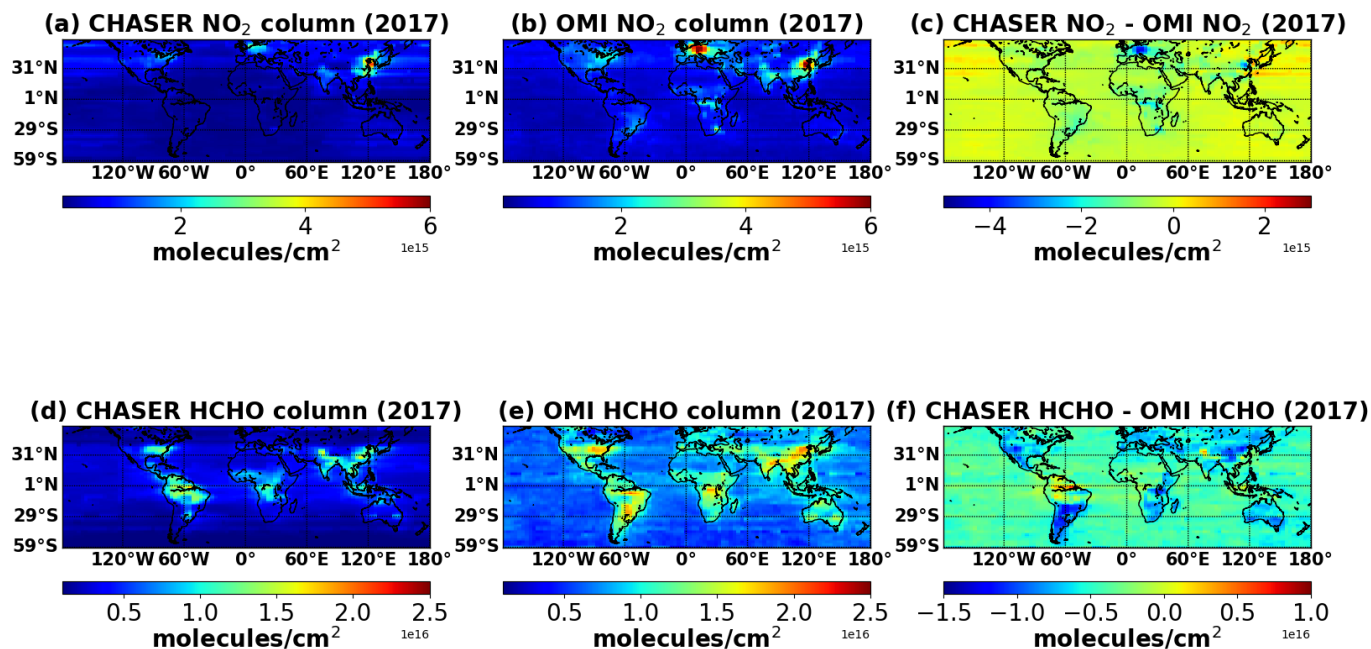

581 Figure 7 compares the simulated and observed annual mean tropospheric NO₂ columns. The statistics for
582 the comparison are given in Table 5. The model captured the global spatial variation well with a spatial
583 correlation (*r*) of 0.70. The mean bias error (MBE) and the root mean square error (RMSE) are
584 respectively, 3×10^{14} and 5.4×10^{14} molecules cm⁻². On a global scale, CHASER estimations are
585 negatively biased by 38% compared to OMI. Actually, studies evaluating global NO₂ simulations with
586 satellite observations have reported similar negative biases (Miyazaki et al., 2012, Sekiya et al., 2018).
587 The differences in the spatial representativeness between the model and observations is one potential
588 reason for such negative biases. CHASER simulations at 1.1° improved the MBE and RMSE by 5 and
589 15%, respectively, compared to simulations at 2.8° (Sekiya et al. 2018). Moreover, Sekiya et al (2018)
590 used NO₂ simulations with an updated inventory and compared the results with OMI observations from
591 2014. Although they reported a better global spatial correlation (*r* > 0.90), the MBE (2.5×10^{14} molecules
592 cm⁻²) and RMSE (4.4×10^{14} molecules cm⁻²) values at 2.8° resolution are comparable to those obtained
593 from this study.

594 OMI retrievals show the highest NO₂ columns over eastern China (E-China) and Western Europe. Annual
595 mean NO₂ columns over the remainder of the land areas are between 7×10^{14} and 4×10^{15} molecules cm⁻².
596 Over the land areas the differences between the datasets are mostly between -2×10^{15} and 5×10^{14} molecules
597 cm⁻². Although CHASER also underestimates NO₂ columns over the ocean, the differences are lower than
598 that of over lands. CHASER estimates are higher by $\sim 5 \times 10^{14}$ molecules cm⁻² than OMI over Japan. Since
599 2012, the NO₂ columns have shown a declining trend over Japan, mainly because of emission controls in
600 China (Irie et al 2016). Probably because of simulations with an emission inventory earlier than 2012, the
601 simulated values tend to be higher than observations.

602 Figure 8 compares the seasonal variations in the monthly mean NO₂ columns in some selected region.
603 The error bars represent the 2-sigma standard deviation of the observed mean values. The numbers in
604 each subplot signify the regional spatial correlation between the datasets. Over eastern China (E-China),
605 CHASER values are negatively biased by 24%; the *r*-value is 0.68. The model captured the seasonality
606 well within variation range of the observations. Over E- and W-USA (eastern and western USA), the
607 respective *r*-values are 0.85 and 0.49 respectively. Simulated NO₂ columns are higher over E-USA than
608 over W-USA, consistent with the observations. Although, in both regions model estimates are biased by
609 $\sim 23\%$ in the lower side compared to OMI observations, the RMSE in E-USA are $\sim 40\%$ higher than in W-
610 USA.

611 Over Europe, CHASER estimates are negatively biased by 54%, with an *r*-value and RMSE of 0.80 and
612 1.28×10^{15} molecules cm⁻², respectively. The observed NO₂ levels over Europe are almost twice those of
613 the W-USA. The model was unable to capture the regional differences. Model underestimations in Europe
614 can be attributed to the older anthropogenic emission inventory used for the study. In fact, using the HTAP
615 2010 inventory the MBE (-0.53×10^{15} molecules cm⁻²) between OMI and CHASER NO₂ column

616

618 **Figure 7:** (top panel) Annual mean tropospheric NO_2 ($\times 10^{15}$ molecules cm^{-2}) columns (a) simulated by CHASER
 619 and (b) retrieved from OMI observations. Limited NO_2 data in July and December met the filtering criteria, thus
 620 discarded from the calculation. (c) The differences between the simulated and observed NO_2 columns. (bottom
 621 panel) Annual mean HCHO ($\times 10^{16}$ molecules cm^{-2}) columns (d) simulated by CHASER and (e) retrieved from
 622 OMI observations. (f) The differences between the simulated and observed HCHO columns. The data for 2017 are
 623 plotted only. All the datasets are mapped onto a 2.8° bin grid.

624

625 simulations at 2.8° over Europe (Sekiya et al. 2018) was $\sim 50\%$ lower than in the current study, although
 626 their RMSE value is similar.

627 Over India, MBE and RMSE for the annual mean NO₂ column are -4.3×10^{14} and 4.4×10^{14} molecules
 628 cm⁻², respectively, and the *r*-value is moderate (0.65). Although CHASER estimates are negatively biased
 629 by

630

631

632

633 **Table 5:** Statistics of comparison of annual mean NO₂ and HCHO columns between CHASER and OMI. MBE1
 634 and MBE2 are the respective mean bias error. RMSE1 and RMSE2 are the respective root mean square errors. *r*₁
 635 and *r*₂ signifies the respective spatial correlation coefficient. The units of MBE1 and RMSE1 are $\times 10^{15}$ molecules
 636 cm⁻². MBE2 and RMSE2 values are in the unit of $\times 10^{16}$ molecules cm⁻².

Region	r ₁ (CHASER vs OMI NO ₂)	MBE1 (CHASER - OMI NO ₂)	RMSE1 (CHASER - OMI NO ₂)	r ₂ (CHASER vs OMI HCHO)	MBE2 (CHASER - OMI HCHO)	RMSE2 (CHASER - OMI HCHO)
Global	0.73	-0.30	0.54	0.74	-0.45	0.49
E-China	0.68	-1.84	2.47	0.57	-0.63	0.64
E-USA	0.85	-0.62	0.63	0.91	-0.56	0.56
W-USA	0.49	-0.33	0.37	0.63	-0.71	0.71
Europe	0.80	-1.20	1.28	0.51	-0.67	0.68
India	0.65	-0.43	0.44	0.73	-0.56	0.57
N-Africa	0.58	-0.88	0.90	0.65	-0.29	0.32
S-Africa	0.80	-1.25	1.40	0.22	-0.66	0.70
S-America	0.87	-0.80	0.88	0.47	-0.31	0.40
SE Asia	0.57	-0.61	0.64	0.48	-0.41	0.44

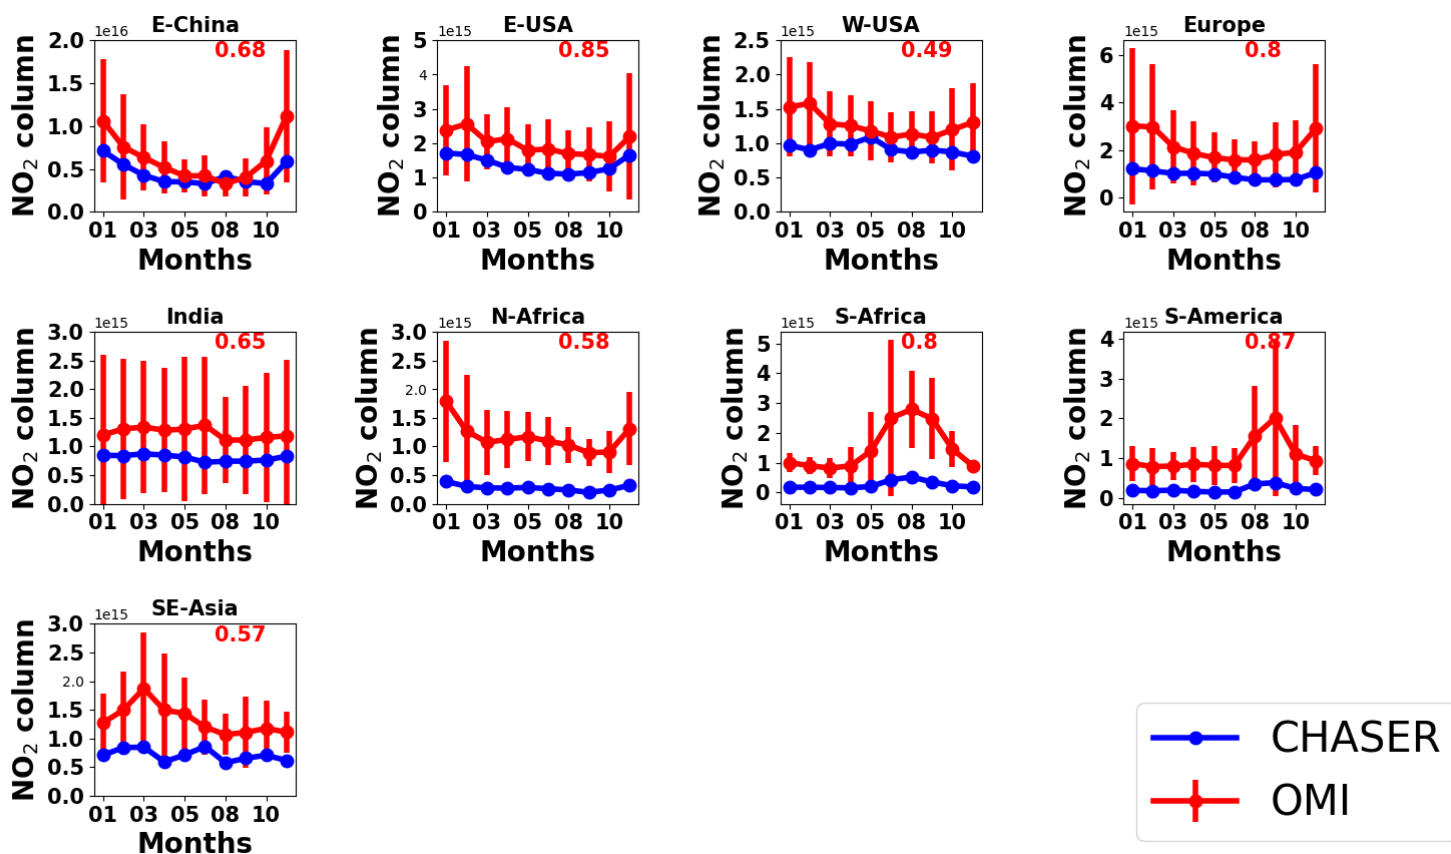

637

638

639 32%, the values lie within the 2-sigma range of the observations. Sekiya et al. (2018) found no significant
640 effect of higher model resolution on the MBE and RMSE in the Indian region.

641 Over N- and S-Africa (North and South Africa), the model values are biased low by more than 75%
642 compared to the observations. Prominent biomass burning occurs in both regions, which explains the
643 enhanced NO₂ levels in the OMI retrievals. High negative biases in the model values indicates that
644 biomass burning NO_x emissions for the African regions are likely underestimated. Similarly, CHASER
645 underestimates NO₂ columns by 80% in South America, where pyrogenic emissions contributions are
646 significant. CHASER estimates are lower than OMI in these regions, but model captured the spatial
647 distribution well.

648 Over the SE-Asian (Southeast) region, OMI columns are enhanced during the dry season (i.e., January -
649 April. Burning agricultural wastes is a common practice in many countries in Southeast Asia during the
650 dry season, explaining the enhanced columns. The MBE ($- 6 \times 10^{14}$ molecules cm⁻²) and RMSE ($6.4 \times$
651 10^{14} molecules cm⁻²) in the SE-Asia region are lower than the African regions (i.e., N-Africa, S-Africa,
652 and S-America), where biomass burning is prominent.

654

655 **Figure 8:** Seasonal variations in tropospheric NO₂ columns in E-China (110° -123° E, 30° - 40° N), E-USA (32°
 656 - 43° N, 71° - 95° W), W-USA(32° - 43° N, 100° - 125° W), Europe (35° - 60° N, 0° - 30° E), India (7.5° - 54° N,
 657 68° - 97° E), N-Africa (5° - 15° N, 10° W - 30° E), S-Africa (5° -15° S, 10° -30° E), S-America (0° -20° S, 50° -
 658 70° W), and SE-Asia (10° - 20° N, 9° - 145° E). CHASER simulations and OMI retrievals are plotted in blue and
 659 red colors respectively. The error bars indicate the 2-sigma variation of the observed mean values. The number in
 660 the insets signifies the regional spatial correlation between CHASER and OMI NO₂ columns.

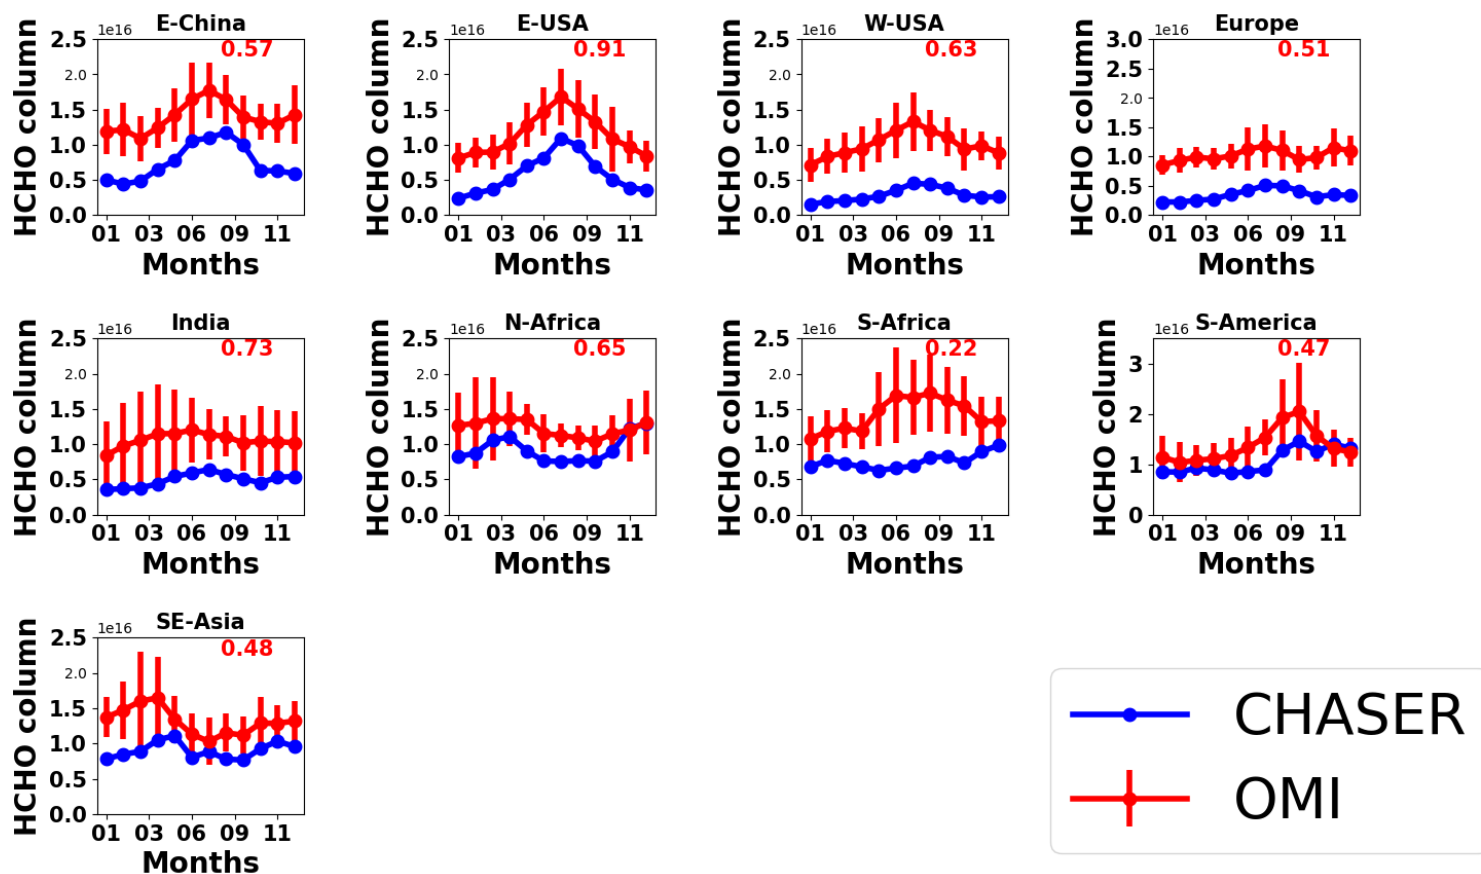

661

662 3.2.2 Comparison between CHASER and OMI HCHO

663 Figure 9 presents a comparison between the simulated and observed global annual mean HCHO columns.
 664 The statistics of the comparison are given in Table 5. CHASER is able to reproduce the observed global
 665 spatial variation well with $r = 0.73$. The global MBE and the RMSE are respectively, -4.5×10^{15} and 4.9

666 $\times 10^{15}$ molecules cm^{-2} . MBE and RMSE for monthly mean fields show no distinctive seasonal variation
667 (Table S2). High HCHO columns are observed over China, Australia, Europe, India, Central Africa, South
668 America, and the United States. The model mostly underestimated the HCHO abundances in the higher
669 latitudes and Australia. Absolute differences between the model and observations in the higher latitudes
670 vary between 5×10^{15} and 1×10^{16} molecules cm^{-2} . Figure 9 compares the seasonal variations in the monthly
671 mean HCHO columns in some selected region. Therein error bars represent the 2-sigma standard
672 deviation of the observed mean values. The numbers in the respective subplots signify the regional spatial
673 correlation between the datasets.

674 Over E-China, CHASER HCHO estimates are negatively biased by 45% compared to OMI and the r -
675 value is greater than 0.50. The model reproduced the observed HCHO seasonality well including
676 enhanced peaks during the summer. The greatest differences between the datasets are observed during
677 the winter. Over E-USA, the spatial correlation between the datasets is greater than 0.90. Also, the
678 CHASER estimates are biased by 49% in the lower side. Simulations show that the peak in the HCHO
679 abundances occurs in July, which is consistent with the observations. The observed and simulated
680 magnitude of the seasonal modulation is 51 and 78%, respectively. The seasonality in the HCHO columns
681 in E-China and E-USA signifies a strong contribution from biogenic emissions. In both regions, the
682 observed peak HCHO column is $\sim 1.75 \times 10^{16}$ molecules cm^{-2} . The simulated peak HCHO values are also
683 similar in both regions, despite the underestimation. Over W-USA and Europe, the negative biases in the
684 simulation are greater than 60%. However, the simulated peaks during summer are consistent with the
685 observations. The OMI retrievals show that the HCHO abundances in both regions are almost similar,
686 which has been well captured by CHASER, although the magnitude is underestimated.

688

689 **Figure 9:** Seasonal variations in HCHO columns in E-China (110° - 123° E, 30° - 40° N), E-USA (32° - 43° N,
 690 71° - 95° W), W-USA (32° - 43° N, 100° - 125° W), Europe (35° - 60° N, 0° - 30° E), India (7.5° - 54° N, 68° -
 691 97° E), N-Africa (5° - 15° N, 10° W - 30° E), S-Africa (5° - 15° S, 10° - 30° E), S-America (0° - 20° S, 50° - 70° W),
 692 and SE-Asia (10° - 20° N, 9° - 145° E). CHASER simulations and OMI retrievals are plotted in blue and red colors
 693 respectively. The error bars indicate the 2-sigma variation of the observed mean values. The number in the insets
 694 signifies the regional spatial correlation between CHASER and OMI HCHO columns.

695

696 Over India, the model estimates mostly lie outside of the observational variation ranges, although,
 697 CHASER captured the spatial distribution well ($r = 0.73$). Magnitudes of the seasonal variation in both
 698 OMI and CHASER are around 32%. Between the two African regions, CHASER demonstrated better
 699 capability for reproducing HCHO distribution in N-Africa ($r = 0.65$). Negative model bias in N-Africa is

700 almost half (22%) that of S-Africa (46%). Observed N-African HCHO columns are mostly higher than
701 1.2×10^{16} molecules cm^{-2} during the biomass burning period (November - April). Although the modeled
702 values are lower than the observed values, the year-end columns (November - December) are similar.
703 Both datasets show low HCHO variation during May - September. Over the S-African region, the model
704 capabilities were limited.

705 Over S-America, the negative bias (~22%) in the model estimates compared to the observations is similar
706 to that of N-Africa. In addition to consistency in the year-end (November to December) columns,
707 CHASER well reproduced the biomass burning-led enhancements. The observed and simulated
708 magnitudes of seasonal modulation are 49 and 43%, respectively.

709 Over SE-Asia, CHASER reproduced the observed biomass burning-led enhanced HCHO columns during
710 the dry season (January - April), however, the occurrence of the peak is inconsistent. As discussed in
711 section 3.1, observed HCHO peaks related to biomass burning can vary depending on the fire numbers.
712 The r -value (0.48) is moderate and model is biased by 30% in the lower side. The model negative biases
713 in the biomass prone regions are lowest (<30%) among the discussed regions.

714 De Smedt et al. (2021) reported that cloud corrections can positively bias OMI HCHO columns up to
715 30% compared to Tropospheric Ozone Monitoring Instrument (TROPOMI) columns. Consequently,
716 uncertainties in the observations are also likely to contribute to the observed negative biases. Comparison
717 among CHASER, TROPOMI, and OMI HCHO columns is beyond the scope of this study. However, the
718 effects of uncertainties in the satellite retrievals on the negative biases is discussed qualitatively and
719 briefly. To demonstrate such effects, CHASER and TROPOMI HCHO columns for 2019 are compared
720 in Fig S3. The simulation settings and emission inventories are similar to those explained in section 3.2.3.
721 The comparison results are presented in Table S2. TROPOMI data has been processed following De
722 Smedt et al. (2021). The CHASER and TROPOMI HCHO spatial distribution correlates strongly with r -
723 value of 0.78. The values for MBE and RMSE are respectively, -2.3×10^{15} and 2.8×10^{15} molecules cm^{-2} .
724 Compared to OMI and TROPOMI, CHASER HCHO columns are negatively biased, respectively, by
725 61 and 38%. The model biases are lower when compared to TROPOMI observations. Because of temporal
726 differences in the two comparisons, the biases cannot be compared quantitatively. However, the
727 differences in the biases signify that the observational uncertainties can strongly affect discrepancies

728 between the simulated and observed HCHO abundances. Moreover, using different cloud products may
729 introduce inconsistencies in the OMI BIRA-IASB retrievals (De Smedt et al., 2021), affecting the
730 comparison results. De Smedt et al. (2021) proposed to recalculate the OMI HCHO VCDS based on the
731 AMF information to minimize cloud-induced uncertainties. Such a detailed method will be evaluated in
732 our future studies.

733

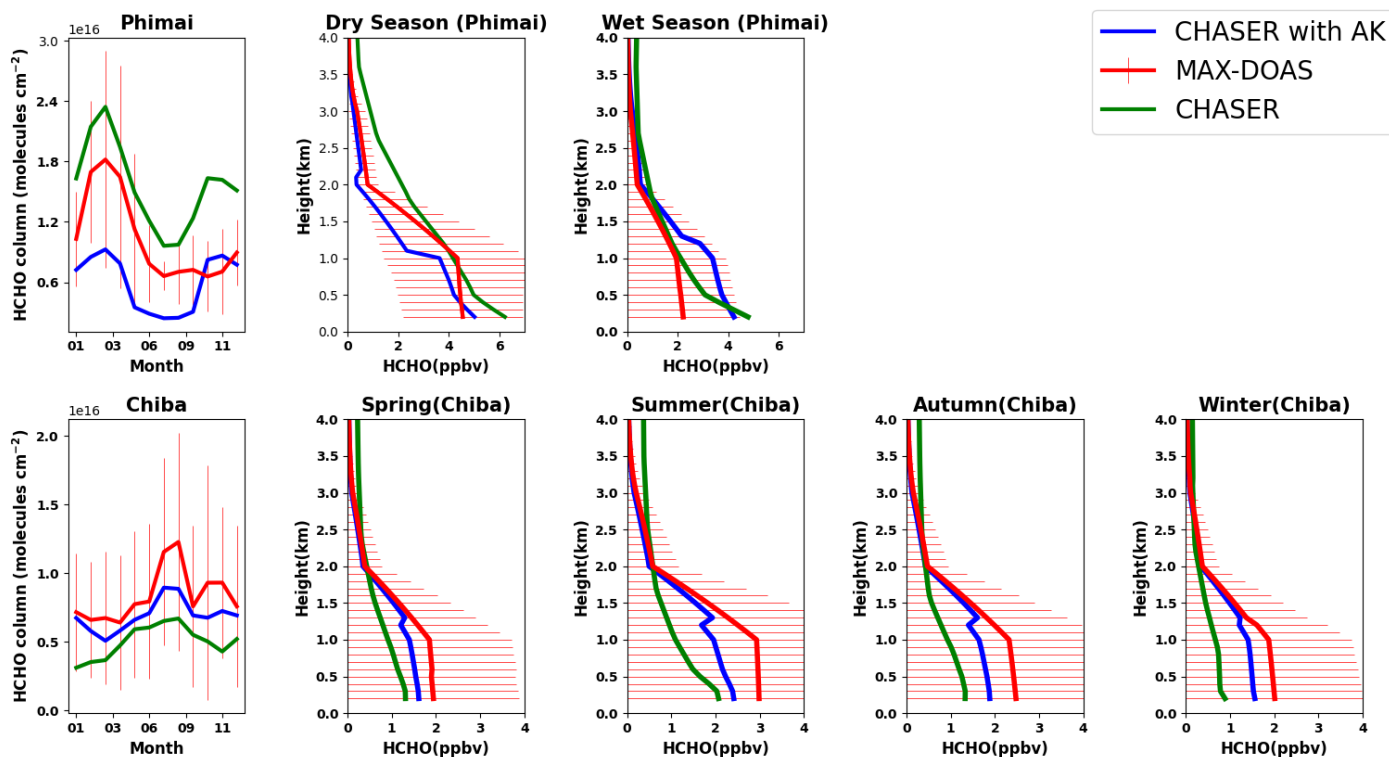

734

735 **3.3 Evaluation of CHASER simulations at the three sites**

736 **3.3.1 Evaluation of CHASER HCHO at Phimai and Chiba**

737 The seasonally averaged observed and modeled HCHO profiles and partial columns in the 0 - 4 km
738 altitude range at Phimai and Chiba are presented in Fig. 10. The CHASER outputs smoothed with MAX-
739 DOAS averaging kernels (AK) are also depicted. The AK is applied following Franco et al. (2015). First,
740 the CHASER HCHO profiles are interpolated to the MAX-DOAS vertical grids. Next, the MAX-DOAS
741 AK information from individual retrieved profiles is seasonally averaged according to the climate
742 classifications of each site. Finally, the CHASER outputs on the coincident days are selected, and the
743 seasonally averaged AK is applied to the daily mean interpolated profile. Applying individual AKs to the
744 model outputs yielded similar results. The seasonally averaged AKs for both sites are shown in Fig S4.
745 The coincident days at Phimai and Chiba were respectively, 690 and 668.

746 At Phimai, CHASER predicted the increase in the HCHO partial columns during the dry season and
747 well-reproduced the HCHO seasonality. The simulated and observed seasonality correlates strongly with
748 *R*-value of 0.96. The modeled monthly mean values during the dry season are found to be within the 1σ
749 standard deviation of the observed values, indicating that the pyrogenic emissions estimates used for the
750 simulations are reasonable. CHASER predicted a 41% increase in the HCHO column during January -
751 March, consistent with the observations (41%). CHASER overestimates the HCHO columns in both
752 seasons, and the mean bias error (MBE) (CHASER – MAX-DOAS) is lower (3.7×10^{15} molecules cm^{-2})
753 (Table 6) during the wet season. Although underestimated, the dry season smoothed column values are
754 within the 1σ range.

755 **Figure 10.** Seasonal variations in the HCHO partial columns at 0 - 4 km and vertical profiles during all seasons at
 756 Phimai and Chiba, as inferred from the MAX-DOAS observations (red) and CHASER simulation (green). The
 757 CHASER HCHO partial column and vertical profile smoothed with the MAX-DOAS AK are coloured blue. The
 758 AK information of all the screened (as explained in section 2.2) retrievals were averaged based on the seasonal
 759 classification of the respective sites. The coincident time and date between the model and observations are selected
 760 only. Error bars indicate the one sigma standard deviation of mean values of the MAX-DOAS observations.

761

762 The modeled and observed HCHO mixing ratios in the 1- 2km layers during the wet season are almost
 763 identical, whereas VMR near the surface (i.e., 0 - 1 km) differ by 30%. The absolute mean difference in
 764 the 0-4 km layer is ~0.45ppbv, with the maximum difference of 2.58 ppbv below 200 m. CHASER has
 765 demonstrated good capabilities for reproducing the HCHO profile in the 0.5 – 4 km layer during the wet
 766 season. The significance of AK information is low for the wet season. However, smoothing the model
 767 profiles reduces the overall MBE by 43%.

768

769 **Table 6:** Comparison of the seasonal mean HCHO partial columns and profiles (0-4 km) between MAX-DOAS
 770 and CHASER at Phimai and Chiba. MBE (CHASER – MAX-DOAS) is the mean bias error. The partial column
 771 and profile MBE units are respectively, $\times 10^{16}$ molecules cm^{-2} and ppbv, respectively.

Site	Season	Partial column MBE	Smoothed Partial column MBE	Profile MBE	Smoothed Profile MBE
Phimai	Overall	0.28	-0.07	0.35	0.01
Phimai	Dry	0.37	-0.28	0.58	-0.38
Phimai	Wet	0.21	0.07	0.45	0.33
Chiba	Overall	-0.12	-0.05	-0.37	-0.11
Chiba	Spring	-0.07	-0.04	-0.22	-0.12
Chiba	Summer	-0.16	-0.08	-0.45	-0.26
Chiba	Autumn	-0.10	-0.04	-0.40	-0.19
Chiba	Winter	-0.09	-0.01	-0.42	0.11

772

773

774 During the dry season, the respective absolute mean and maximum difference in the datasets in the 0
 775 -1 km layers is ~ 1 and ~ 2 ppbv. The observed and simulated seasonal differences in the 0-1 km are 50 and
 776 34%, respectively. Simulated dry season profile values at the heights greater than ~ 2 km is out of the 1σ
 777 variation range. The two-potential reasons for such differences are lower measurement sensitivity in the
 778 free troposphere and the overestimated Southeast Asian biogenic emissions in the model. Despite the
 779 measurement limitations, CHASER and MAX-DOAS wet season profiles up to 3 km are consistent.
 780 Consequently, it is likely that the biogenic emissions for this region in the model are overestimated. The
 781 Southeast Asian isoprene emissions in CHASER is 128 Tgyr^{-1} , higher than the CMAS-GLO-BIO
 782 (Sindelarova et al., 2022) inventory (78 Tgyr^{-1}). However, the dry season HCHO profiles in 0 - 2 km are
 783 well simulated. Smoothing underestimates the dry season profile within the 1σ variation range but
 784 improved simulations below 200 m. At heights greater than 3 km, the smoothed values mostly reproduce
 785 the a priori because of reduced measurement sensitivity (i.e., low AK value, indicating limited
 786 information was retrievable).

787

788 Moderate correlation ($R=0.58$) can be observed between the modeled and observed HCHO partial
789 columns at Chiba. CHASER was able to reproduce the peak in the partial columns in August. The model
790 predicts a 41% increase in the HCHO columns during January - August, whereas the observed increase
791 is 54%. Although Chiba is an urban site, the HCHO and temperature seasonal variations show a tight
792 correlation ($R\sim 0.70$) (Fig S5), suggesting that changes in biogenic emissions modulate HCHO
793 seasonality. Similarly, the modeled seasonality is consistent with temperature variation (Fig. S4). Thus,
794 the simulated HCHO seasonality in Chiba is reasonable, despite underestimation of absolute values.
795 Smoothing the simulations improve the correlation, and the MBE is reduced by 54% (Table 6).

796 The CHASER HCHO profiles in the 0 - 4 km layers are lower than the observations, with an MBE
797 of 0.39 ppbv. The absolute differences in the modeled and retrieved HCHO profiles in the 0-2 km layer
798 during all seasons are higher than at Phimai. Absolute mean differences of ~ 1 ppbv and higher are mainly
799 observed for 0 to 2 km. In addition, the vertical gradients of the simulated profiles are low compared to
800 those at Phimai. The modeled profiles at Chiba resemble the HCHO profiles measured over the ocean
801 during the INTEX-B (Intercontinental Chemical Transport Experiment: Phase B) (Boeke et al., 2011).
802 The Chiba site is near the sea, and coarse CHASER resolution includes the ocean pixels. Moreover, urban
803 surfaces are not homogeneous. Thus, a significant part of the profile discrepancies is likely related to the
804 systematic differences, in addition to emission estimates. However, the model estimates lie within the
805 standard deviation range of the measurements. Because of the low gradients in the simulated profiles, the
806 smoothed profiles mostly imitated the a priori values even below 2 km. Overall, given the large
807 uncertainty on the MAX-DOAS profiles (Fig. 10), the differences between the observations and smoothed
808 profile are statistically insignificant. Effects of the horizontal resolution on the simulated HCHO levels is
809 discussed in section 3.3.4.

810

811

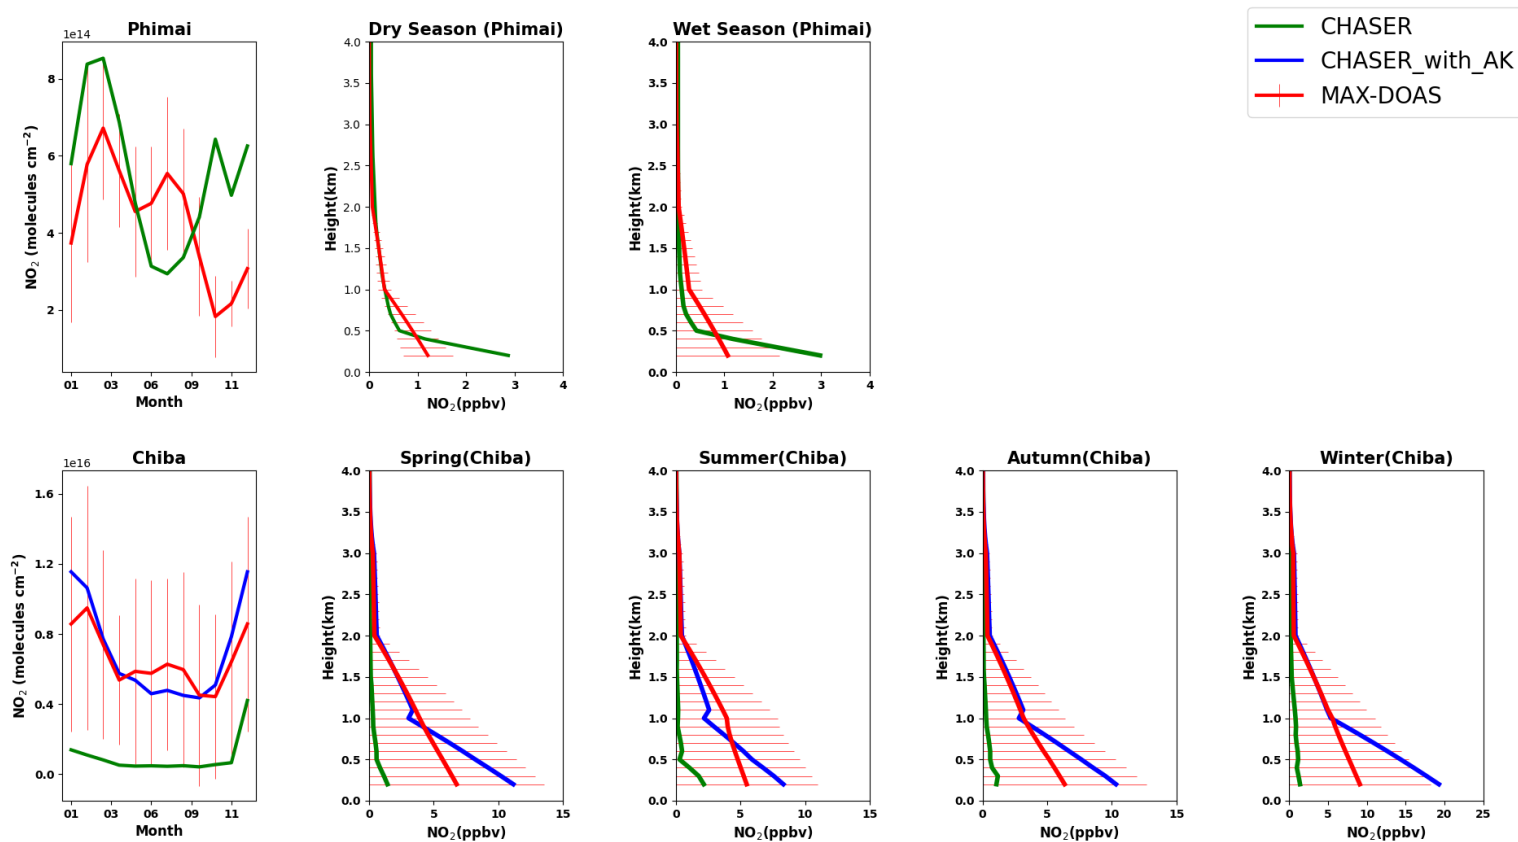

812 **3.3.2 Evaluation of CHASER NO₂ in Phimai and Chiba**

813 Figure 11 presents the seasonal averages of the MAX-DOAS and CHASER NO₂ profiles and partial
814 columns (0 - 4 km) at Phimai and Chiba. The AK is applied to the modeled outputs for the Chiba site
815 only.

816 Figure S5 of the supplementary information presents a comparison of the observations, model, and
817 smoothed model profiles averaged within the 0 - 2 km layer at Phimai. Smoothing with different a priori
818 values is depicted to demonstrate the effects of the a priori values. The smoothed NO₂ concentrations,
819 calculated using the original a priori values, show a seasonal variation shift. The mean smoothed profile
820 resembles the observations when a priori values are reduced by 50%; however, the dry season values are
821 similar in both cases. Two test cases of smoothing profiles using a priori values above 500 and 800 m
822 shows good agreement with the observations; however, the results are sensitive to the a priori values.
823 Because smoothed profiles are strongly biased to the a priori choice, the smoothing results obtained for
824 the Phimai site are discarded.

825 The modeled NO₂ partial column at Phimai shows good agreement with observations made during the
826 dry season. CHASER well reproduces the enhanced NO₂ columns attributable to biomass burning within
827 the standard deviation of the observations. The peak in the NO₂ levels during March is consistent in both
828 datasets. Although the seasonality does not agree in other months, the overall MBE is 8×10^{13} molecule
829 cm⁻² (Table 7). Above 500 m, the datasets shows excellent agreement. The absolute mean differences in
830 the 0 - 1km layer are 0.22 ppbv, and the maximum difference of ~1.9 ppbv is observed near the surface.
831 Amidst the biomass burning influence, the NO₂ concentrations at Phimai are mostly < 1 ppbv. Thus, the
832 results of comparisons demonstrate CHASER's good capabilities in regions characterized by low NO₂
833 concentrations. Moreover, when NO₂ concentrations are less than < 1 ppbv, the AK information seems
834 less significant if the model can capture low-concentration scenarios.

835

837

838 **Figure 11.** Seasonal variation in NO_2 partial columns from 0 - 4 km and vertical profiles during all seasons at
 839 Phimai and Chiba, as inferred from the MAX-DOAS observations (red) and CHASER simulation (green). The
 840 CHASER NO_2 partial column and vertical profile smoothed with the MAX-DOAS AK are coloured in blue. The
 841 coincident time and date between the model and observations are selected only. The error bars represent the one
 842 sigma standard deviation of mean values of the MAX-DOAS observations.

843

844

845

846

847

848 **Table 7:** Comparison of the seasonal mean NO₂ partial columns and profiles (0-4 km) between MAX-DOAS and
 849 CHASER at Phimai and Chiba. MBE (CHASER – MAX-DOAS) is the mean bias error. The partial column and
 850 profile MBE units are $\times 10^{15}$ molecules cm⁻² and ppbv, respectively.

Site	Season	Partial column MBE	Smoothed Partial column MBE	Profile MBE	Smoothed Profile MBE
Phimai	Overall	0.08		0.11	
Phimai	Dry	0.18		0.09	
Phimai	Wet	-0.14		0.02	
Chiba	Overall	-5.58	-1.90	-3.27	-1.66
Chiba	Spring	-5.56	-2.00	-3.19	-1.74
Chiba	Summer	-5.52	-2.87	-2.85	-1.86
Chiba	Autumn	-4.57	-1.24	-2.74	-1.40
Chiba	Winter	-6.64	-1.50	-4.30	-1.63

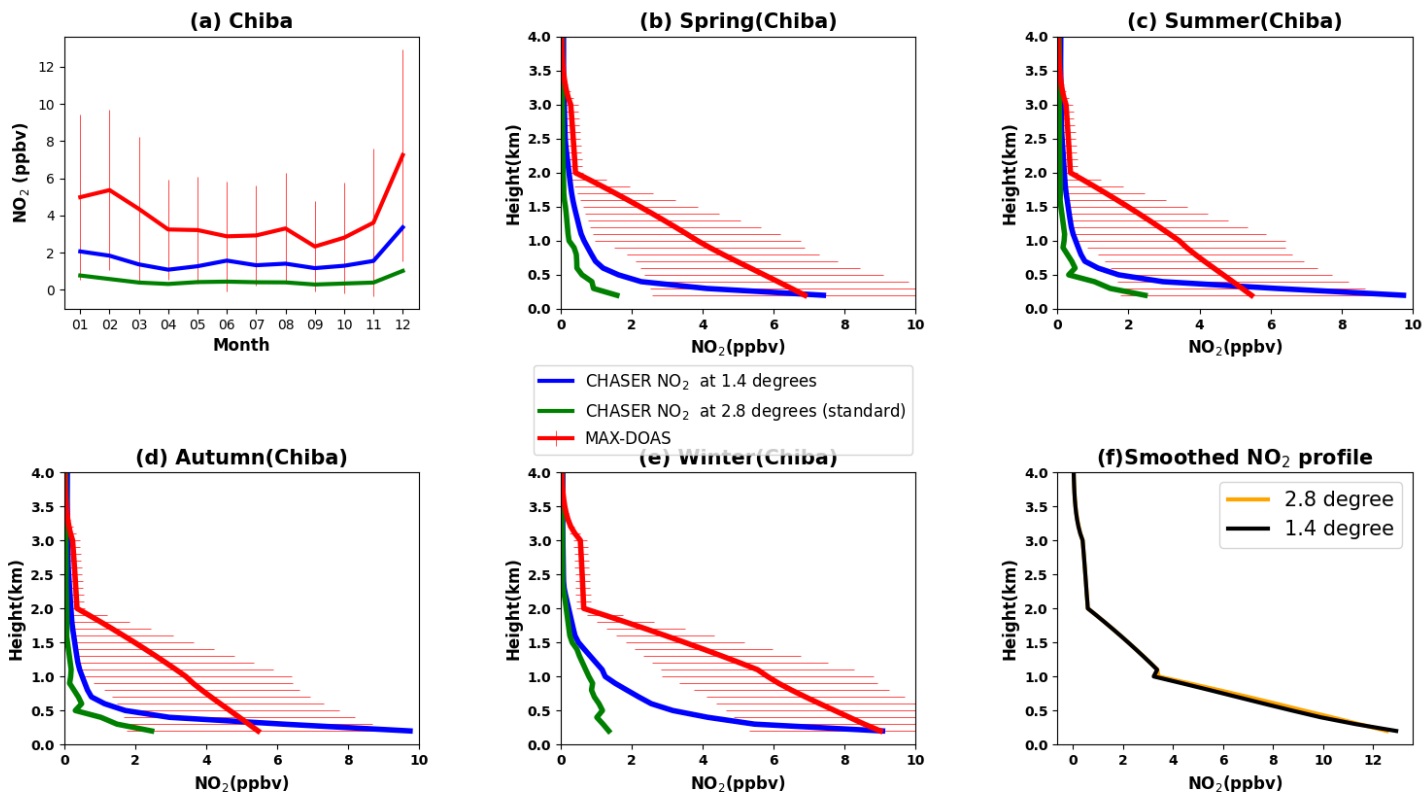

851
 852 Although the datasets are moderately correlated ($R=0.59$) at Chiba, the model largely underestimates the
 853 NO₂ partial column with MBE of $\sim 5 \times 10^{15}$ molecules cm⁻². The model predicts almost constant NO₂
 854 profiles and columns throughout the year. Therefore, the respective seasonal biases are almost similar.
 855 The vertical gradient of the modeled NO₂ profiles is also low, too, similarly to the HCHO profiles. The
 856 model resolution can be a potential cause for such significant underestimation. The AKs improved the
 857 partial column and profiles significantly, reducing the MBE by more than 50%. However, the smoothed
 858 profiles and partial columns between the 0 - 2 km layer, differ significantly from the simulations,
 859 suggesting that the a priori values strongly affect the smoothed profiles. Consequently, the smoothed NO₂
 860 profiles at Chiba (Fig.S7) are biased to the a priori values, similar to that of Phimai (Fig. S6). NO₂
 861 smoothed profile sensitivity to a priori values might be attributable to our retrieval procedure. The a priori
 862 data are taken from the measured SCD and retrieved VCD values. As a result, the values are sensitive in
 863 the 0 - 2 km layer, similarly to the observations. Using a priori values other than those obtained from
 864 observations can affect such sensitivity. The smoothing sensitivity to a priori values is stronger for NO₂
 865 than HCHO. The NO₂ profile gradient is higher than that of HCHO (Figs. 10 and 11), which means that,

866 within 10 km (MAX-DOAS horizontal resolution), the NO₂ mixing ratio and a priori variability (sources
867 and sinks) is higher than those of HCHO, leading to a stronger a priori effect on the smoothed profiles.

868

869 The mean NO₂ mixing ratios in the 0 - 2 km layer in 2018, simulated at spatial resolutions of 2.8° × 2.8°
870 (standard) and 1.4° × 1.4°, are compared with observations at Chiba, as depicted in Fig.12. The error bars
871 are the 1σ standard deviation of the observations. Higher resolution simulations reduced the overall MBE
872 by 35% (Table 8). NO₂ concentrations at 1.4° are now within the variation range of the observations. The
873 1.4° simulation captured the NO₂ seasonal variability better than at 2.8°. Despite improved resolution, the
874 model values are underestimated, with the highest MBE during the winter. According to Miyazaki et al.
875 (2020), the seasonality in the anthropogenic emissions, primarily wintertime heating, is not well
876 represented in the emission inventories, which could likely underestimate winter NO₂ levels. The best
877 agreement between the datasets is observed during summer and spring, with an MBE of ~1 ppbv on a
878 seasonal scale.

879

880 **Figure 12:** (a) Seasonal variations in the NO₂ mixing ratios in the 0 - 2 km layer at Chiba, as inferred from the
 881 MAX-DOAS observations (red) and two CHASER simulations at 2.8°(green) and 1.4°(blue) resolutions. The
 882 simulated NO₂ profiles at 2.8°(green) and 1.4°(blue) resolutions during (b) spring, (c) summer, (d) autumn, and (e)
 883 winter are shown with the observed seasonal profiles at Chiba. Only data (both observed and simulated) for 2018
 884 are plotted. The coincident time and date between the model and observations are selected only. The error bars in
 885 (a), (b), (c), and (d) represent the one sigma standard deviation of mean values of the MAX-DOAS observations.

886

887

888 NO₂ profiles at 2.8° and 1.4° resolution are shown in Figs. 12(b - e). A strong effect of the increased
 889 resolution is observed below 500 m, reducing the negative bias by 70% near the surface. Above 500 m,
 890 the effects of higher resolution are limited, with an MBE reduction of 12% in the 0.6 – 2 km. Although
 891 the near-surface NO₂ concentrations at 1.4° resolution are overestimated, the values are within the
 892 standard deviation of the observations. At around 200m, winter mean NO₂ concentrations at 1.4°

893 resolution are identical to the observations (~9 ppbv), and the summer mean is overestimated. Moreover,
 894 the NO₂ levels above 2 km are similar at both resolutions. The resolution effects on NO₂ profiles vary
 895 with the location and season (Williams et al., 2017). For example, CHASER NO₂ at 1.1° resolution
 896 improved the agreement with aircraft observations below 650 hPa significantly over the Denver
 897 metropolitan area (Sekiya et al. 2018), whereas, at Chiba, the 1.4° resolution improved the surface
 898 estimates. Consequently, the horizontal resolution is not the only reason for the model underestimation.
 899 Other factors such as the vertical resolution, uncertainties in emission inventories, and chemical kinetics,
 900 can also affect the simulated NO₂ estimates. Effects of the emission inventory is discussed in section
 901 3.3.4.

902 Figure 12(f) shows the smoothed NO₂ profiles at both resolutions. Although the profile shapes are
 903 different, the smoothed profiles are almost identical, which demonstrates that, smoothed NO₂ profile
 904 sensitivity to a priori choice is mostly independent of the model resolution.

905

906 **Table 8:** Comparison of the seasonal mean NO₂ profiles (0-2 km) among MAX-DOAS and CHASER simulations
 907 at 2.8° and 1.4° resolutions at Chiba. MBE at (CHASER – MAX-DOAS) 1.4° and 2.8° are the mean bias error at
 908 the respective resolutions. The MBE unit is ppbv.

Season	MBE at 1.4°	MBE at 2.8°
Overall	-2.24	-3.37
Spring	-2.26	-3.23
Summer	-1.50	-2.47
Autumn	-1.57	-2.57
Winter	-3.44	-5.07

909

910

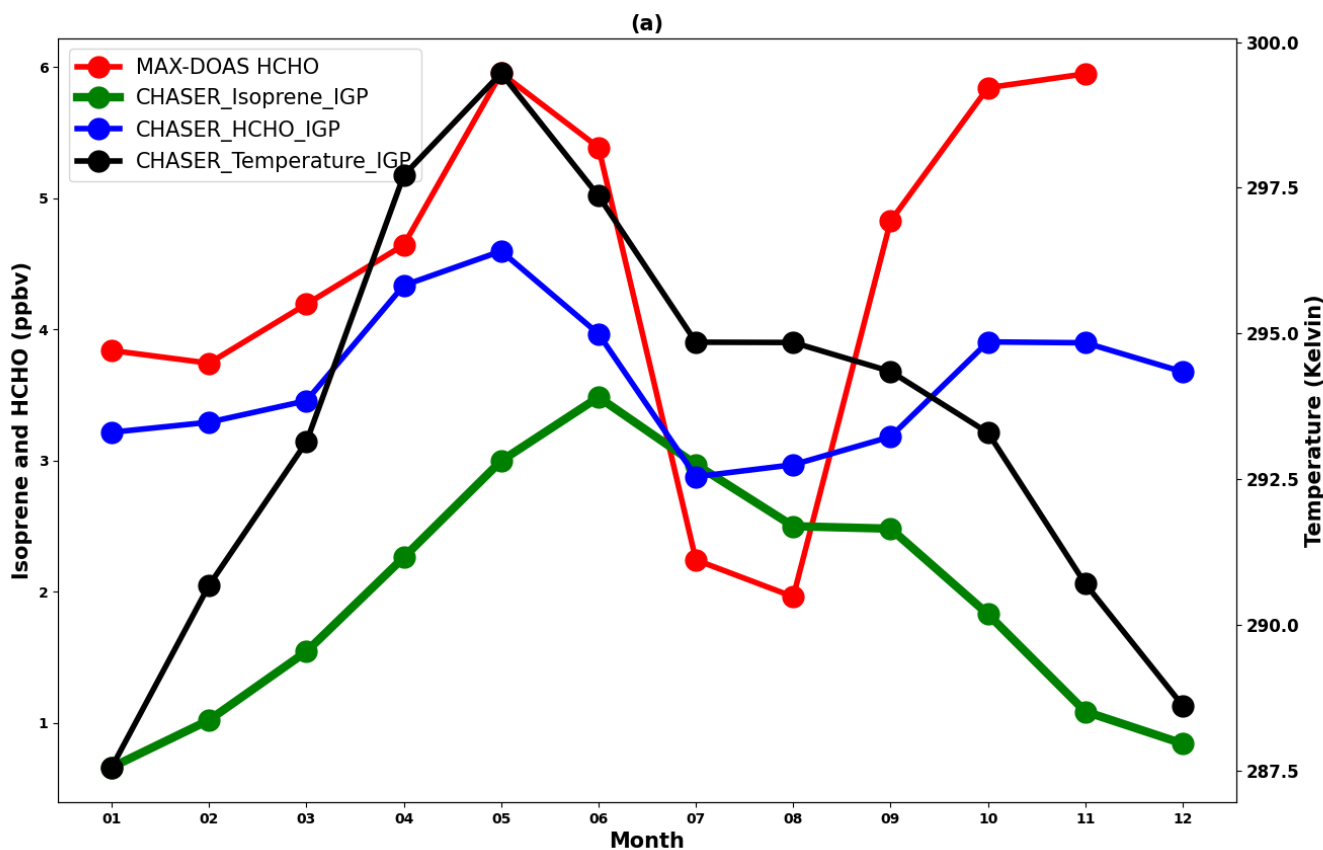

911

912

913

914 **3.3.3 Evaluation of CHASER HCHO in the IGP region**

915 The IGP is the most fertile region in South Asia, which accounts for approximately 50% of the total
916 agricultural production of India and is one of the significant contributing regions to the global greening
917 based on leaf area index (Sarmah et al., 2021). Moreover, IGP is one of the regional HCHO hotspots in
918 India (Chutia et al., 2019). The observed HCHO seasonality at Pantnagar is consistent with that reported
919 by Mahajan et al. (2015) for the entire IGP region. Consequently, comparison with the HCHO retrievals
920 in Pantnagar can assess the model capability in the IGP region. The spatial representiveness is a
921 limitation for comparison between a point measurement and regional simulations. Thus, the results are
922 interpreted qualitatively. Because of the availability of a dataset with continuous observations, only the
923 comparison for 2017 is shown in Fig. 13.

924

925 **Figure 13.** Seasonal variations in the MAX-DOAS (red) and CHASER (blue) HCHO concentrations at Pantnagar
926 and the IGP region, respectively, in 2017. The coincident dates between the observations and model are plotted

927 only. The CHASER simulated isoprene and temperature seasonality are shown respectively, in green and black
928 colours. Only the daytime simulated values were considered for the plot.

929

930 The modeled HCHO seasonal variations in the IGP region correlate well with the observations at
931 Pantnagar ($R \sim 0.80$). The enhancement in the HCHO concentrations during the spring and post-monsoon
932 season is well reproduced by CHASER, which indicates that CHASER can capture HCHO variation in
933 complex terrain region such as IGP. Figure 13 also depicts the isoprene concentrations and temperature
934 in the IGP region, in addition to the HCHO concentrations. Oxidization of precursor hydrocarbons and
935 photochemical reactions are the most dominant sources of HCHO. Also, isoprene is the most abundant
936 hydrocarbon in the atmosphere. The average ambient isoprene concentrations during July, August, and
937 September in the IGP region are 1.4 ± 0.3 ppbv (Mishra et al., 2020). Therefore, the CHASER isoprene
938 concentration range of $1.5 - 2$ ppbv during the monsoon season seems reasonable. The HCHO
939 concentrations in the IGP region reach a peak during the spring and post-monsoon seasons. A strong
940 correlation between HCHO, isoprene, and temperature variation ($R \sim 0.90$) during the first half of the year
941 indicates that the change in biogenic emissions strongly drives the HCHO seasonal modulation. The
942 observed enhancement in the HCHO levels during spring at Pantnagar is related to biomass burning. The
943 biomass burning events are primarily concentrated in the northwest IGP region (Kumar and Sinha, 2021),
944 where the site is located. On a regional scale, the biomass burning effects is expected to smear. Thus, the
945 strong effect of the biogenic emission on the regional HCHO modulation is reasonable. HCHO
946 modulation differs from isoprene and temperature during the post-monsoon period, suggesting a greater
947 role of biomass burning and anthropogenic emissions. Consequently, the physical processes driving the
948 HCHO seasonality in the IGP region are well reflected in the CHASER simulations.

949

950 **3.3.4 Effects of the model resolution and emission inventories on results**

951 Effects of the spatial resolution on the evaluation results is assessed by comparing the results of CHASER
952 simulations at 2.8° and 1.4° resolutions with the surface observations, as shown in Fig. 14. Only, the
953 simulated surface HCHO and NO_2 concentrations during 2017 are shown only. The statistics are provided
954 in Table 9. For the Pantnagar site, only the simulations are presented. At Phimai, the HCHO simulations

955 differ by 3%. The standard simulation shows better agreement with the observations. The higher MBE at
956 1.4° occurred mostly because of the model overestimation during the wet season. The NO₂ mixing ratios
957 at the two resolution differ by 9%. The MBEs for both trace gases at Phimai are less than 1 ppbv. Thus,
958 the HCHO and NO₂ standard simulations at 2.8° can be regarded as reasonable for regions characterized
959 by low NO₂ levels (<1 ppbv). At Chiba, surface NO₂ and HCHO mixing ratios at 1.4° resolution differ
960 respectively, by 61 and 19%. The NO₂ MBE at 1.4° resolution improved significantly, indicating a strong
961 effect of the model resolution. However, discussion in section 3.2.2 showed limited resolution-based
962 improvement in the overall profile. Results for MBE in the HCHO mixing ratios at 1.4° mostly improved
963 during summer. The wintertime HCHO estimates at both resolutions are similar. In contrast to Chiba and
964 Phimai, differences in the HCHO simulations (30%) at Pantnagar are greater than those of NO₂ (3%).
965 The effect of model resolution varying with location and season was also reported by Sekiya et al. (2018).
966 Compared to the other two sites, differences in the NO₂ simulations at Chiba are larger. This finding is
967 consistent with the results by William et al (2017), which found larger differences with changing model
968 resolution over urban areas.

969 Although the NO_x estimates for the low NO₂ regions seem reasonable, global NO_x emissions have
970 changed since 2008(i.e., EDGAR-HTAP (2008) emissions used for this study). A recent study by Miyazaki
971 et al. (2020) reported changes in global NO_x emissions from 2005 to 2018. They found a continuous 30%
972 increase in NO_x emissions in India since 2005. REAS v3 (Regional Emission inventory in Asia version
973 3) inventory estimated a 23% increase in NO_x emissions in India between 2010 - 2015, and power plants
974 were the most significant contributor. Many power plants are clustered along the IGP region (Nair et al.,
975 2007). Thus, the current simulation settings are likely to underestimate the NO₂ mixing ratios and columns
976 in the IGP region. Figure S8 presents comparison of CHASER and OMI NO₂ columns for 2017 over the
977 IGP region. Although the modeled columns are biased by 32% in the lower side, the spatial correlation
978 between the datasets is high ($r=0.78$). CHASER values lie within the range of variation of the
979 observations. Although underestimated, NO₂ estimates in the IGP based on the current inventory are yet
980 reasonable. Sekiya et al., (2018) used higher model resolution and updated emission inventory (HTAP
981 2010 for simulations in 2014) and reported ~30% lower MBE over India. However, the RMSE values of
982 both studies are comparable.

983 NO_x emissions in Japan have shown continuous decline since the execution of pollution control policies
984 in 1970 (Ohara et al., 2020). Irie et al. (2021) reported a declining trend in NO₂ levels in Chiba since
985 2012, echoing results obtained by Miyazaki et al. (2020) throughout Japan. The bias between CHASER
986 and OMI NO₂ column over Japan is non-significant (Fig. S8 and Table S3). Thus, an updated inventory
987 will not substantially affect the comparison results at the Chiba site. NO_x emissions increased
988 considerably in Southeast Asia. CHASER NO₂ estimates for Thailand based on HTAP 2008 inventory
989 are biased by 45% in the lower side compared to OMI (Fig. S8). However, Phimai being a rural site, the
990 NO_x levels are expected to be low. Changes in biomass burning NO_x estimates are likely to affect the
991 model estimates. Because, the NO₂ levels at Phimai are mostly less than 1 ppbv, the effect of updated
992 inventory on the comparison results is expected to be minimal.

993 CHASER HCHO columns over Japan, the IGP region, and Thailand are negatively biased respectively,
994 by 60, 36, and 32% compared to OMI observations, with *r*-values of 0.5 – 0.7 (Fig. S8). Surl et al. (2018)
995 reported spatial correlation of ~0.5 between GEOS-CHEM and OMI over the IGP region. Anthropogenic
996 VOC emissions in India and other Asian cities have increased since 2005, whereas a negative trend has
997 been observed over Japan (Bauwens et al., 2022). The REAS inventory estimated a 5% increase in
998 NMVOCS in India since 2005. Moreover, anthropogenic emission contributes strongly to the HCHO
999 abundances in the IGP region (Kumar and Sinha 2021). Thus, updated anthropogenic VOC emission
1000 inventory is likely to improve the model HCHO estimates in the study regions. However, the formation
1001 pathway of HCHO from isoprene emissions is a non-linear function of NO_x chemistry. Consequently, the
1002 effects of NO_x emissions changes on the overall HCHO simulations cannot be assessed based on current
1003 analyses explained herein.

1027

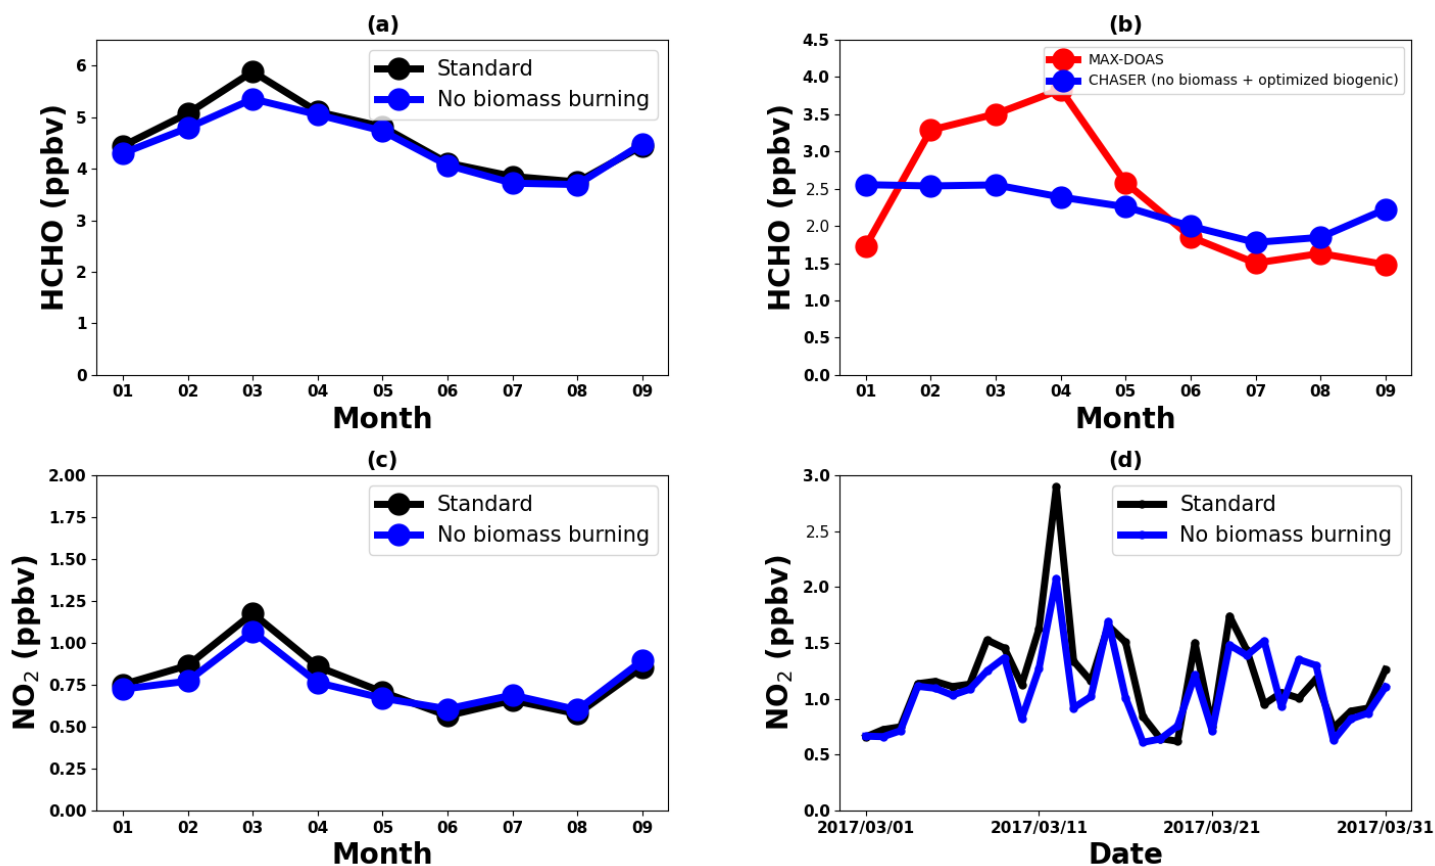

1028 **3.4 Contribution estimates**

1029 **3.4.1 Contribution from biomass burning to the HCHO and NO₂ abundances at Phimai**

1030 Good agreement between the datasets in the 0 - 1 km layer at Phimai can quantify biomass burning
1031 contributions to the HCHO and NO₂ concentrations. Figure 15 presents results of simulations L1_HCHO,
1032 L1_opt, and L1_NO₂. The simulation settings are presented in Table 3. For better readability, the
1033 switched-off emissions criterion is described in the legends of Fig.15. The plots present mean mixing
1034 ratios in the 0 – 1 km layer. Biomass burning contributes ~10% to the HCHO concentrations at Phimai
1035 during the dry season. However, based on the observations, a greater effect of biomass burning is
1036 expected. During the wet season, the MAX-DOAS and CHASER HCHO surface mixing ratios are,
1037 respectively, ~2 and ~4 ppbv (Fig. 10), indicating overestimation of the biogenic emissions in CHASER.
1038 Figure 15(b) shows the HCHO concentration obtained from simulation L1_opt and MAX-DOAS

1039 observations in 2017. In the L1_opt simulation setting, the biomass burning emissions are switched off;
 1040 the biogenic emissions are optimized to reproduce results analogous to those obtained from observations
 1041 during the wet season. In the absence of biomass burning, the surface HCHO concentrations at Phimai
 1042 would be ~2 ppbv, indicating a biomass burning contribution of ~20–50% during the dry season. The
 1043 observed interseason difference in the HCHO concentration at Phimai is ~60%. Consequently, the revised
 1044 biomass burning contribution estimate is more reasonable. Pyrogenic emissions contributions to the NO₂
 1045 concentrations at Phimai are ~10% during the dry season (Fig. 15(c)). Because the NO₂ concentrations
 1046 are low at Phimai, the simulation results obtained for March, when the influence of biomass burning is
 1047 highest, are used to derive a better contribution estimate. In the absence of biomass burning, the NO₂
 1048 concentration during March would be about 0.84 ppbv (Fig.15(d)), indicating a contribution as high as
 1049 35% to the NO₂ concentrations at Phimai.

1050

1051

1052 **Figure 15.** (top panel) (a) Seasonal variations in the HCHO concentrations in the 0 - 1 km layer at Phimai, as
1053 obtained from the standard and L1_HCHO simulations. Pyrogenic emissions of VOCs are switched off in
1054 L1_HCHO. (b) The HCHO seasonal variation in Phimai in 2017, as obtained from the MAX-DOAS observations
1055 (red) and L1_opt simulations. The pyrogenic VOC emissions were switched off, and the biogenic emissions were
1056 reduced by 50% in L1_opt. The coincident dates between the observation and the simulations are shown only.
1057 (bottom panel) (c) Seasonal variations in the NO₂ surface concentrations at Phimai in 2017, as obtained from the
1058 standard and L1_NO₂ simulations. (d) Standard and L1_NO₂ simulation outputs of the daily mean NO₂ surface
1059 concentrations during March 2017. The pyrogenic NO₂ emissions were switched off in the L1_NO₂ simulation.
1060 Only the daytime values from 09:00 – 15:00 LT are used to calculate the seasonal mean.

1061

1062

1063 **3.4.2 Contribution of soil NO_x emissions at Phimai**

1064 Because soil NO_x emissions are included in CHASER simulations, the NO₂ contributions from soil
1065 emissions are quantified. Figure 16 presents the monthly mean surface NO₂ concentrations at Phimai in
1066 2017, simulated including (standard) and switching off (L1_NO₂) the soil NO_x emissions. The NO₂
1067 concentrations between 09 and 12 hr. were used to calculate the monthly mean concentrations. Soil
1068 emissions contribute ~20% of the overall NO₂ concentrations at Phimai, with higher contributions during
1069 the wet season. The highest soil contribution of about 25% occurs in July.

1070

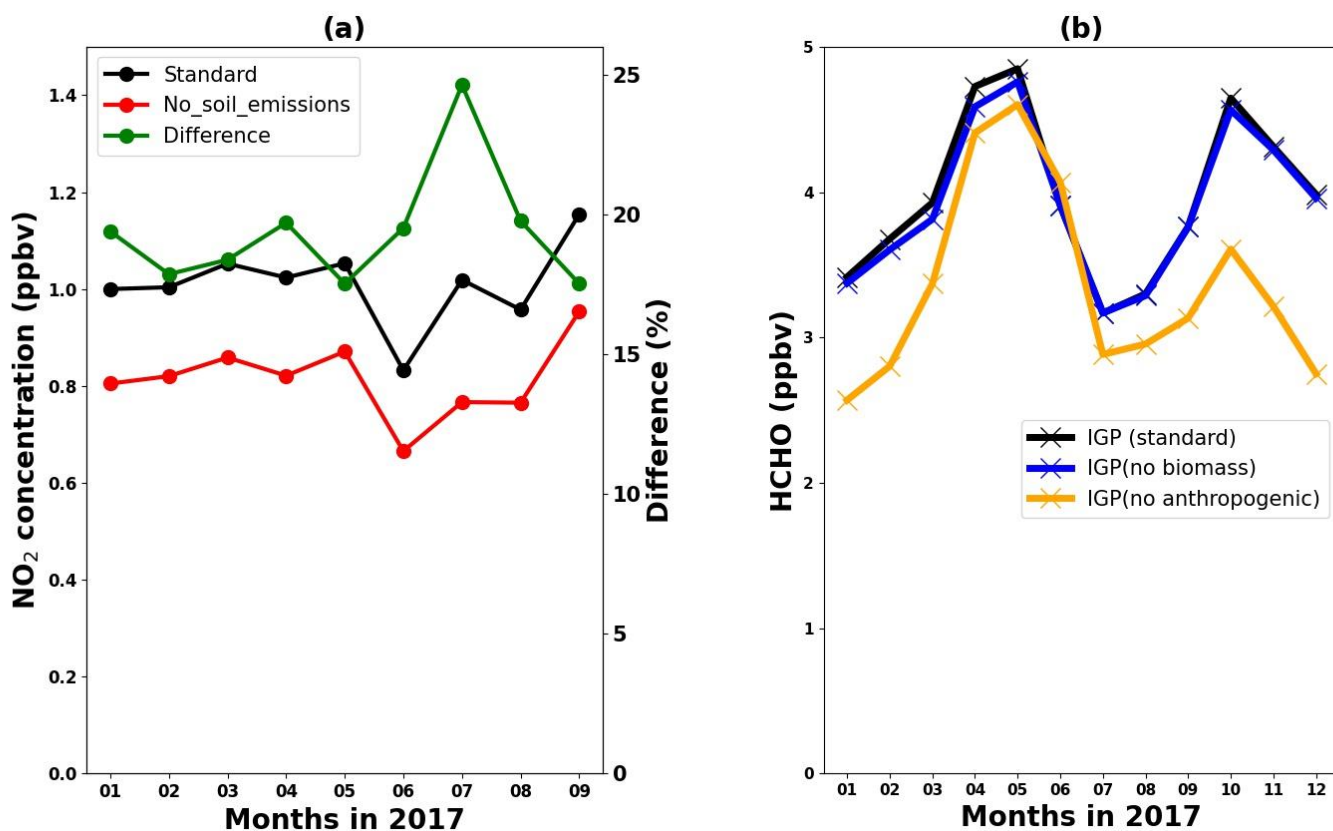

1071 **3.4.3 Contribution from pyrogenic and anthropogenic emissions to the HCHO abundances in the** 1072 **IGP region**

1073 Figure 16(b) presents the standard, L1_HCHO (pyrogenic VOC emissions switched off), and L2
1074 (anthropogenic VOC emissions switched off) HCHO simulations in the IGP region. According to
1075 L1_HCHO simulation results, effects of biomass burning emissions on the regional HCHO modulation
1076 are small (~12%). The HCHO concentrations in India have biogenic, anthropogenic, and pyrogenic VOC
1077 sources. However, biogenic VOCs are the primary driver of the over HCHO variation (Surl et al., 2018).
1078 Consequently, two reasons might be responsible for the small effects of pyrogenic emissions on HCHO
1079 concentrations: (1) Overestimation of the biogenic emission or underestimation of pyrogenic emissions

1080 in the model. (2) Stronger effects of anthropogenic VOC emissions than of pyrogenic VOCs. The L2
 1081 simulations show that anthropogenic emissions contribute up to 30% of the HCHO concentration in the
 1082 IGP region, with a maximum contributed during the post-monsoon season, which coincides with the
 1083 lower isoprene concentration (i.e., biogenic emissions) and temperature (Fig. 14). Moreover, Kumar and
 1084 Sinha (2021) reported high acetaldehyde concentrations from anthropogenic emissions in the IGP region
 1085 throughout the year. Consequently, anthropogenic emissions are likely to be a significant driver of HCHO
 1086 concentrations in the IGP region after biogenic emissions.

1087

1088

1089

1090 **Figure 16.** (a) Monthly mean NO₂ concentrations at Phimai were estimated from the standard (black) and L1_NO₂
 1091 (red) simulations. The soil NO_x emissions are switched off in the LI_NO₂ simulation. The green line represents the
 1092 percentage difference between the two simulations. (b) Seasonal variations in the HCHO concentrations in the IGP

1093 region, obtained from the standard, L1_HCHO (pyrogenic VOC emission switched off), and L2 simulations
1094 (anthropogenic VOC emissions switched off). The simulations for 2017 are shown and analysed. Daytime values
1095 from 09:00-12:00 and 09:00 – 15:00 LT were selected respectively, for Phimai and IGP.

1096

1097 **4 Conclusions**

1098 Using the JM2 algorithm, NO₂ and HCHO concentrations and profiles were retrieved from MAX-DOAS
1099 observations at three A-SKY sites during January 2017 - December 2018. The retrieved products were
1100 used to evaluate the global chemistry transport model CHASER simulations at the three sites. At all three
1101 locations, the seasonal variation of both trace gases was consistent throughout the investigated period. At
1102 Phimai and Pantnagar, biomass burning led to enhanced HCHO and NO₂ concentrations, respectively,
1103 during the dry season and spring and post-monsoon season. At Chiba, the HCHO variation was consistent
1104 with the temperature-led seasonal changes in biogenic emissions. The changes in the dry season HCHO
1105 and NO₂ levels at Phimai during 2015 - 2018 were consistent with the number of fire events.

1106 The R_{FN} values were biased towards a particular regime when the standard transition range $1 < R_{FN} < 2$
1107 (Duncan et al., 2010) was used. The parameterization of Souri et al. (2020) provides a better estimate of
1108 the transition region. The classification results of the revised transition region at Phimai and Pantnagar
1109 contradicted the results based on the standard transition range. However, they were more reasonable. Such
1110 a method based on observations, is therefore influenced by measurement constraints. More observational
1111 evidence must be accumulated to standardize this method. Overall, the results further indicated that that
1112 the standard transition region is not valid globally.

1113 Despite the use of an old NO_x emission inventory the simulated NO₂ and HCHO spatial distributions
1114 agreed reasonably well with those observed from satellite- observations. The modeled regional NO₂
1115 columns estimates were within the 2-sigma variability range of OMI NO₂ retrievals. Although the
1116 negative bias in HCHO comparison was higher than that of NO₂, the model demonstrated good
1117 capabilities for simulating the HCHO seasonal variation in different regions.

1118 CHASER showed good capabilities at Phimai, characterized as a VOC-rich and low NO₂ (<1 ppbv)
1119 region. In both seasons, the observed and modeled profiles (HCHO and NO₂) agreed within the one sigma

1120 standard deviation of the measurements, despite general overestimation of the model. Furthermore, both
1121 wet season HCHO profiles were almost identical in the 0.5 – 4 km layer in both datasets.
1122 CHASER demonstrated limited performances at Chiba. NO₂ at higher resolution (i.e., 1.4°) mainly
1123 improved the surface estimates, reducing the overall MBE in the 0 - 2 km layer by 35%. Finer resolution
1124 would improve the HCHO estimates in Chiba by 10%; however, it still is underestimated.
1125 Sensitivity studies for the Phimai site estimated biomass burning contributions to the respective HCHO
1126 and NO₂ concentrations of up to ~50 and ~ 35%, respectively. On average, 20% of the NO₂ level
1127 originates from soil NO_x emissions, increasing to 25% in July. Anthropogenic emissions (contribution of
1128 up to 30%) have a larger impact on VOC variation in the IGP region than biomass burning, which is
1129 consistent with earlier reports in the literature.

1130

1131 *Code availability.* The CHASER and JM2 source codes are not available publicly. Dr. Kengo Sudo
1132 (kengo@nagoya-u.jp) is the contact person for readers and researchers interested in the CHASER model.
1133 In addition, Dr. Hitoshi Irie (hitoshi.irie@chiba-u.jp) will answer queries related to the JM2 codes.

1134

1135 *Data availability:* The MAX-DOAS data used in the study are publicly accessible on the A-SKY network
1136 website (<http://atmos3.cr.chiba-u.jp/a-sky/data.html>). Upon request, the corresponding author can
1137 provide the CHASER simulations and MAX-DOAS averaging kernel data.

1138

1139 *Author contributions:* HMSH conceptualized the study, conducted the model simulations, analysed the
1140 observational and simulation data, and drafted the manuscript. AMF helped with the data processing. HI
1141 developed the JM2 code and maintained the A-SKY network. KS developed the CHASER model and
1142 supervised the study. MN is the PI of the Pantnagar site. AD and MN shared their experience to explain
1143 the results. HI, KS, AD, MN, and AMF commented and provided feedback on the final results and
1144 manuscript.

1145

1146 *Conflict of Interest:* The authors declare that they have no conflict of Interest

1147

1148 *Acknowledgments:* This research is supported by the Global Environmental Research fund (S-12 and S-
1149 20) of the Ministry of the Environment (MOE), Japan, and JSPS KAKENHI Grants: JP20H04320,
1150 JP19HO5669, and JP19H04235. The CHASER model simulations are partly performed with the
1151 supercomputer (NEC SX-Aurora TSUBASA) at the National Institute for environmental studies (NIES),
1152 Tsukuba, Japan. The authors are grateful to the OMI and TROPOMI data providers. Support from ISRO-
1153 ATCTM project for Pantnagar site is also acknowledged.
