13 **Abstract:** Organic aerosol (OA) makes up a substantial fraction of atmospheric
14 particulate matter that exerts tremendous impacts on air quality, climate, and human
15 health. Yet current chemical transport models fail to reproduce both the concentrations
16 and temporal variations of OA, especially the secondary organic aerosol (SOA),
17 hindering the identification of major contribution sources. One possibility is that
18 precursors that are not yet included in the model exist, and intermediate-volatility and
19 semi-volatile organic compounds (I/SVOCs) are advocated to be one of them. Herein,
20 we established a high-resolution emission inventory of I/SVOCs and by incorporating
21 it into the CMAQ model, concentrations, temporal variations, and spatial distributions
22 of POA and SOA originated from different sources in the Yangtze River Delta (YRD)
23 region of China were ~~successfully~~ simulated. Compared with the comprehensive
24 observation data obtained in the region, i.e., volatile organic compounds (VOCs),
25 organic carbon (OC), primary organic aerosol (POA) and SOA, significant model

* Correspondence to C. Huang (huangc@saes.sh.cn)

26 improvements in the simulations of different OA components were demonstrated.
27 Furthermore, spatial and seasonal variations of different source contributions to OA
28 production were identified. We found cooking emissions are predominant sources of
29 POA in the densely populated urban area of the region. I/SVOC emissions from
30 industrial sources are dominant contributors to the SOA formation, followed by those
31 from mobile sources. While the former concentrated in eastern, central, and northern
32 YRD, the latter mainly focused on the urban area. Our results indicate that future control
33 measures should be specifically tailored on intraregional scale based on the different
34 source characteristics to achieve the national goal of continuous improvement in air
35 quality. In addition, local source profiles and emission factors of I/SVOCs as well as
36 SOA formation mechanisms in model framework are urgently needed to be updated to
37 further improve the model performance and thus the accuracy of source identifications.
38 **Key words:** semi-volatile and intermediate volatility organic compounds; secondary
39 organic aerosol; emission inventory; source contribution; model simulation

40 **1. Introduction**

41 Organic aerosol (OA) contributes a large fraction (20 to 90%) of atmospheric
42 submicron aerosol (Zhang et al., 2007; Jimenez et al., 2009) and has negative impacts
43 on air quality, climate (Shrivastava et al., 2017), and human health (Nault et al., 2021).
44 OA is composed of primary organic aerosol (POA) directly emitted from fossil fuel
45 combustion, biomass burning, and other sources, as well as secondary organic aerosol
46 (SOA) formed through the atmospheric oxidation of gas-phase species emitted from a
47 wide range of biogenic and anthropogenic sources (Hallquist et al., 2009).
48 Understanding and identifying the origins of OA is therefore important for elucidating
49 their health and climate effects and establishing effective mitigation policies. However,
50 OA is a dynamic system driven by the gas-particle partitioning of organic vapors and
51 particulate organic material, i.e. POA and SOA, and continuously evolves upon
52 atmospheric oxidation (Robinson et al., 2007; Donahue et al., 2009; Zhao et al., 2013;
53 Jathara et al., 2014). Constraints in their precursors and further source identification

54 have been facing great challenges.

55 Great efforts have been made in the identification of OA sources through source
56 apportionment of the measured OA components, such as positive matrix factorization
57 (PMF), chemical mass balance (CMB) model or multilinear engine (ME-2). The
58 Aerodyne high-resolution time-of-flight aerosol mass spectrometer (AMS), has been
59 proven to be a powerful tool in quantification and chemical characterization of different
60 OA components in real-time. Coupled with PMF analysis, AMS measurements allow
61 for the deconvolution of physically meaningful OA factors. Commonly retrieved factors
62 include three POA sources, i.e. hydrocarbon-like OA (HOA) related to fossil fuel
63 combustion, biomass burning OA (BBOA), and cooking-related OA (COA), as well as
64 two SOA components, i.e. less oxidized oxygenated OA (LO-OOA) and more oxidized
65 oxygenated OA (MO-OOA) (Hayes et al., 2013; Crippa et al., 2014; Sun et al., 2014;
66 Li et al., 2017). Combining offline AMS and radiocarbon (^{14}C) measurements, Huang
67 et al. (2014) also identified the contributions of fossil and non-fossil sources to SOA.
68 Attempts have been made in subsequent studies by coupling the AMS measurement
69 with a suite of comprehensive and collocated SOA tracer measurements to distinguish
70 biogenic and major anthropogenic SOA sources, such as traffic and cooking emission
71 (Xu et al., 2015; Zhang et al., 2018; Zhu et al., 2020; Huang et al., 2021a). However,
72 due to the complex OA composition and variety of emission sources, further
73 deconvolution on the contributions of different sources to OA production is challenging.

74 Besides field measurements, air quality model is another widespread technique,
75 which advantages in regional-scale OA source apportionment with higher temporal and
76 spatial resolution. However, the model simulated SOA concentration still has large
77 gaps ~~is substantially lower than~~ that measured in the atmosphere. ~~On one hand, this is~~
78 ~~limited by the model treatment, where multiple-generation oxidation of organic vapors~~
79 ~~is not included.~~ The volatility basis set (VBS) scheme is therefore developed, which
80 lumps organic precursors as well as their oxidation products into different volatility bins.
81 Upon atmospheric aging, the volatility of these compounds evolves due to the processes

82 such as functionalization and fragmentation, which can be accounted for in the models
83 by shifting the volatility bins of these compounds (Donahue et al., 2006). It has been
84 widely reported that coupling VBS scheme with air quality models can improve the
85 model performance on SOA simulation (Tsimpidi et al., 2010; Koo et al., 2014; woody
86 et al., 2016; Zhao et al., 2016a; Yang et al., 2019). However, there are still some
87 shortcomings in the modeling of OA with the VBS, for example the lack of
88 representation of the hydrophilic properties of OA, which assumes SOA condenses onto
89 an organic phase, whereas SOA may also condense on an aqueous phase (Kim et al.,
90 2011). Another important constraint is~~On the other hand, the gaps are still not closed~~
91 ~~mainly due to~~ the underestimation ~~missing~~ of intermediate-volatility organic
92 compounds (IVOCs) and semi-volatile organic compounds (SVOCs) emissions in the
93 models, which potentially have substantial contributions to SOA budget owing to their
94 high SOA yields (Presto et al., 2009; Tkacik et al., 2012; Zhao et al., 2014; Liggio et
95 al., 2016). IVOCs refer to organic compounds with effective saturation concentrations
96 (C*) between 10^3 to 10^6 $\mu\text{g}\cdot\text{m}^{-3}$ at 298 K and 1 atm, while SVOCs refer to organic
97 compounds with C* between 10^{-1} to 10^3 $\mu\text{g}\cdot\text{m}^{-3}$ at 298 K and 1 atm (Robinson et al.,
98 2007).

99 I/SVOC emission inventories have been developed and applied into air quality
100 models over the past decade. Most of them were estimated by applying different scaling
101 factors based on their relationship with POA, volatile organic compounds (VOCs), or
102 some proxies like naphthalene (Pye and Seinfeld, 2010; Shrivastava et al., 2011; Jathar
103 et al., 2017; Wu et al., 2019, 2021; Li et al., 2020, 2022; Ling et al., 2022). Yet in
104 practice, a same scaling factor was applied to most of the sources in previous studies
105 due to the lack of measurements on I/SVOC emission factors. For example, except
106 biomass burning (0.75–1.5), Wu et al. (2019) utilized scaling factors of 8–30 for all of
107 the other emission source categories, which was estimated based on the measurements
108 of on-road mobile source. Li et al. (2020) assumed scaling factors of 1.5 for on-road
109 mobile source, and 0.34–1.5 for the other sources, such as industrial and residential

110 sources, which were much lower than the estimations in Wu et al. (2020). Huang et al.
111 (2021) have tried emission factor method to quantify the I/SVOC emissions, yet the
112 results were 60% lower than the scaling factor method, far from catching the measured
113 amount of SOA. Obviously, roughly estimating I/SVOC emissions using one or two
114 emission profiles as surrogates for all emission sources will create large uncertainties.

115 ~~However, due to the vast number of different I/SVOC components with low~~
116 ~~volatility (C^* of 10^{-1} to $10^6 \mu\text{g}\cdot\text{m}^{-3}$) and concentrations, qualitative and quantitative~~
117 ~~characterization of I/SVOCs in molecular level are difficult.~~ Recent studies have
118 successively determined the volatility distribution, chemical composition, and emission
119 factors of I/SVOCs from mobile sources, including gasoline and diesel vehicles, non-
120 road diesel machinery, marine vessel, and aircraft (Presto et al., 2011; Cross et al., 2013;
121 Zhao et al., 2015, 2016b; Huang et al., 2018; Qi et al., 2019; Drozd et al., 2019). I/SVOC
122 emission profiles have been reported for nonmobile-sources as well, including coal
123 combustion, wood-burning, cooking, fuel evaporation, and industrial and residential
124 volatile chemical products (Huffman et al., 2009; Gentner et al., 2012; May et al., 2013;
125 Koss et al., 2018; McDonald et al., 2018; Cai et al., 2019; Drozd et al., 2021). ~~Most of~~
126 ~~these reported emission profiles have been released in SPECIATE 5.1 (US EPA, 2021),~~
127 making the quantification of I/SVOC emissions and their involvement in air quality
128 models possible.

129 In China, SOA has been emerging as an important contributor to air pollution.
130 Field observations reveal that OA ~~contributes significantly~~ dominates (30%) the $\text{PM}_{2.5}$
131 concentrations in most parts of China (Tao et al., 2017; Liu et al., 2018), among which
132 the SOA contributes up to 80% of OA during haze pollution (Huang et al., 2014; Ming
133 et al., 2017; Li et al., 2021). SOA formation in China has already been examined in
134 several modeling studies. They found that by considering the POA aging and I/SVOCs
135 oxidation in the models, which is realized by the coupling of VBS scheme, the
136 formation and evolution of SOA can be much better simulated compared to the results
137 of the two-product SOA modeling framework (Zhao et al., 2016a; Wu et al., 2019; Li

138 et al., 2020; Yao et al., 2020; Huang et al., 2021). Chang et al. (2022) developed a full-
139 volatility organic emission inventory with source-specific I/SVOC emission profiles for
140 China, which have greatly improved the model performance on SOA concentrations.
141 However, large gaps still exist between the observed and modeled SOA. Studies on
142 high-resolution I/SVOC emission inventory for more specific sources are highly
143 needed.~~large uncertainties still exist in the estimation of I/SVOC emissions used in~~
144 ~~previous modeling studies, which has essential impacts on model performance.~~
145 ~~Theoretically, the I/SVOC emissions can be obtained quantitatively by applying~~
146 ~~different scaling factors to POA emissions from different sources. Yet in practice, a~~
147 ~~same scaling factor was applied to most of the sources in previous studies due to the~~
148 ~~lack of measurements on I/SVOC emission factors. For example, except biomass~~
149 ~~burning (0.75–1.5), Wu et al. (2019) utilized scaling factors of 8–30 for all of the other~~
150 ~~emission source categories, which was estimated based on the measurements of on-road~~
151 ~~mobile source. Li et al. (2020) assumed scaling factors of 1.5 for on-road mobile source,~~
152 ~~and 0.34–1.5 for the other sources, such as industrial and residential sources, which~~
153 ~~were much lower than the estimations in Wu et al. (2020). Huang et al. (2021) have~~
154 ~~tried emission factor method to quantify the I/SVOC emissions, yet the results were 60%~~
155 ~~lower than the scaling factor method, far from catching the measured amount of SOA.~~

156 ~~Beyond the aforementioned uncertainties, another obstacle is that I/SVOC~~
157 ~~emission profiles have not been taken into account in previous studies. It should be~~
158 ~~noted that volatility and chemical composition of I/SVOC emissions vary by source~~
159 ~~category (Lu et al., 2018), which matters in model simulation because different I/SVOC~~
160 ~~components are of different SOA yields. For example, the SOA yields of *n* alkanes~~
161 ~~increase with increasing carbon number (Presto et al., 2010) and for a given volatility~~
162 ~~bin, the aromatics usually have higher SOA yields than the alkanes (Lim and Ziemann,~~
163 ~~2009; Tkacik et al., 2012). In a recent study, Lu et al. (2020) compiled new emission~~
164 ~~profiles for I/SVOCs based on the existing mobile source emission data and~~
165 ~~incorporated them into an updated version of the Community Multiscale Air Quality~~

~~model version 5.3 (CMAQ v5.3) to investigate their contributions to SOA formation. Their results indicated that mobile source related I/SVOC emissions produced almost as much SOA as traditional precursors such as single ring aromatics in southern California and suggested that the potential contributions of nonmobile source I/SVOC emissions were nonnegligible to SOA formation (Lu et al., 2020).~~

In this study, taking the Yangtze River Delta (YRD) region, including Jiangsu, Zhejiang, Anhui provinces and Shanghai city, as a pilot, we established a high-resolution source specific I/SVOC emission inventory. We then applied the **newly** established inventory into CMAQ v5.3 to evaluate the contributions of I/SVOC emissions to SOA formation by comparing the results with the observation data collected in the region. Furthermore, we also run the model in different scenarios to quantify the seasonal contributions of different sources to POA and SOA formation in the YRD region.

2. Materials and methods

2.1 I/SVOC emission inventory estimates

I/SVOCs commonly exist in both gas- and particle-phase in the atmosphere. Previous studies usually used POA scaling factors to estimate the I/SVOC emissions, which may lead to large uncertainties in the estimation of gas-phase organic compound-dominated sources, like oil refinery, chemical production, and industrial solvent-use. Herein, we compiled both gas-phase I/SVOCs (I/SVOCs-G) and particle-phase I/SVOCs (I/SVOCs-P) emission inventories and incorporate them into the model. Detailed process of the inventories is as follows.

~~I/SVOCs-G emissions for each specific source were estimated by the ratios of total I/SVOC components to VOC components (I/SVOCs to VOCs). Similarly, I/SVOCs-P emissions were estimated by the ratios of total particle-phase I/SVOC components to POA (I/SVOCs to POA). On this basis, we further determined the source profiles of I/SVOCs for each source. The I/SVOCs-G emissions were distributed into four lumped aliphatic IVOC bins across the volatility basis set from $C^*=10^3$ to $10^6 \mu\text{g}\cdot\text{m}^{-3}$, two~~

194 aromatic IVOC bins with the $C^*=10^5$ and $10^6 \mu\text{g}\cdot\text{m}^{-3}$, and four lumped SVOC bins with
195 C^* from 10^{-1} and $10^2 \mu\text{g}\cdot\text{m}^{-3}$. The I/SVOCs-P emissions were distributed into five bins
196 spanning C^* from 10^{-1} and $10^3 \mu\text{g}\cdot\text{m}^{-3}$.

197 (1) Source classification: To refine the I/SVOC emissions from different sources,
198 we divided the sources into five major categories and then further grouped them into
199 21 sub-categories. The major categories include In this study, we first divided the
200 sources into five categories, including industrial process sources, industrial solvent-use
201 sources, mobile sources, residential sources, and agricultural sources. As shown in
202 Table S1, the , and then further grouped them into 21 sub-categories. For example,
203 industrial process sources include the sectors such as oil refinery, chemical production,
204 and pulp and paper production; Industrial solvent-use sources include textile, leather
205 tanning, timber processing, and various industrial volatile chemical products use;
206 Mobile sources include gasoline and diesel vehicle emissions, fuel evaporation, diesel
207 machinery, marine vessel, and aircraft; Residential sources include coal combustion,
208 residential solvent-use, and cooking emissions; Agricultural source is specifically
209 referred to biomass burning in household stoves, and open burning was not included in
210 this study.

211 (2) Emission estimation: I/SVOCs-G emissions for each specific source were
212 estimated by the ratios of total I/SVOC components to anthropogenic VOC (AVOC)
213 components (I/SVOCs-to-VOCs). Similarly, I/SVOCs-P emissions were estimated by
214 the ratios of total particle-phase I/SVOC components to POA (I/SVOCs-to-POA). The
215 I/SVOCs-G-to-VOCs and I/SVOCs-P-to-POA ratios for each source were determined
216 according to their fractions of total I/SVOC species in VOC and POA emissions. Then
217 we grouped different I/SVOC species into lumped I/SVOC bins based on their C^* to
218 determine the volatility distributions of each source. The I/SVOCs-G emissions were
219 distributed into four lumped aliphatic IVOC bins across the volatility basis set from
220 $C^*=10^3$ to $10^6 \mu\text{g}\cdot\text{m}^{-3}$, two aromatic IVOC bins with the $C^*=10^5$ and $10^6 \mu\text{g}\cdot\text{m}^{-3}$, and
221 four lumped SVOC bins with C^* from 10^{-1} and $10^2 \mu\text{g}\cdot\text{m}^{-3}$. The I/SVOCs-P emissions

222 were distributed into five bins spanning C^* from 10^{-1} and $10^3 \mu\text{g}\cdot\text{m}^{-3}$. Source profiles
223 of I/SVOC species for different sources were referenced from the results in previous
224 studies. Table S1 and S2 show the I/SVOCs-G-to-VOCs and I/SVOCs-P-to-POA ratios
225 for each specific source and their references. For industrial process, industrial solvent-
226 use, and residential solvent-use sources, only I/SVOCs-G emissions were considered.
227 Their I/SVOCs-G-to-VOCs ratios and emission profiles were derived from the latest
228 version of SPECIATE 5.1 database (US EPA, 2021). For gasoline and diesel vehicles,
229 the I/SVOCs-G-to-VOCs and I/SVOCs-P-to-POA ratios and emission profiles were
230 referenced from a new mobile-source parameterization recommended by Lu et al.
231 (2020). Those of diesel machinery, marine vessel, and residential coal combustion were
232 determined by recent measurement results in China (Qi et al., 2019; Huang et al., 2018;
233 Cai et al., 2019). The I/SVOCs-G-to-VOCs ratios and profiles of cooking and biomass
234 burning emissions were derived from SPECIATE 5.1 database, while their particle-
235 phase ratios and profiles were referenced from two previous studies (May et al., 2013;
236 Louvaris et al., 2017). Table S1 and S2 show the I/SVOCs-G-to-VOCs and I/SVOCs-
237 P-to-POA ratios and their emission profiles of each specific source. The base emissions
238 of AVOCs and POA (See Table S3) were taken from a high-resolution emission
239 inventory for the year of 2017 developed in our previous study (An et al., 2021).

240 (3) Model input: Before being input into the model, the estimated I/SVOC-G and
241 I/SVOC-P emissions were summed and then redistributed according to their phase
242 equilibrium under the actual atmospheric state. The formula of phase equilibrium is
243 shown in Equation (1).

$$F_p = \frac{C_{OA}}{C_{OA} + C^*} \quad (1)$$

245 Where, F_p is the fraction of particle-phase I/SVOC emissions for each volatility
246 bin. C_{OA} represents the OA concentration in the atmosphere. We assumed it to be 10
247 $\mu\text{g}\cdot\text{m}^{-3}$ in this study. C^* is the effective saturation concentration of each volatility bin.
248 After redistribution, For gasoline and diesel vehicles, the I/SVOCs-G-to-VOCs and
249 I/SVOCs-P-to-POA ratios and their emission profiles were derived from a new mobile-

250 ~~source parameterization recommended by Lu et al. (2020). Those of diesel machinery,~~
251 ~~marine vessel, and residential coal combustion were determined by recent measurement~~
252 ~~results in China (Qi et al., 2019; Huang et al., 2018; Cai et al., 2019). The emission~~
253 ~~profiles of other sources were derived from the latest version of SPECIATE 5.1 database~~
254 ~~(US EPA, 2021). Table S1 and S2 respectively show the I/SVOCs G to VOCs and~~
255 ~~I/SVOCs P to POA ratios and their emission profiles for specific sources. The base~~
256 ~~emissions of anthropogenic VOCs (AVOCs) and POA (See Table S3) were taken from~~
257 ~~a high-resolution emission inventory for the year of 2017 developed in our previous~~
258 ~~study (An et al., 2021). The I/SVOCs emissions for each source category were~~
259 allocated into 4 km × 4 km grids and hourly temporal profiles using the same method
260 as the criteria pollutants.

261 2.2 Model configuration

262 We used Community Modeling and Analysis System (CMAQ version 5.3.2) to
263 simulate the concentrations of air pollutants. The domain of the simulation is presented
264 in Figure 1. The simulations were conducted for three nested grids with horizontal
265 resolution of 36 km (D1), 12 km (D2) and 4 km (D3), respectively. D1 covers most of
266 China and the surrounding countries including Japan and South Korea; D2 covers
267 eastern China and D3 covers the entire YRD region and its surrounding land and waters.

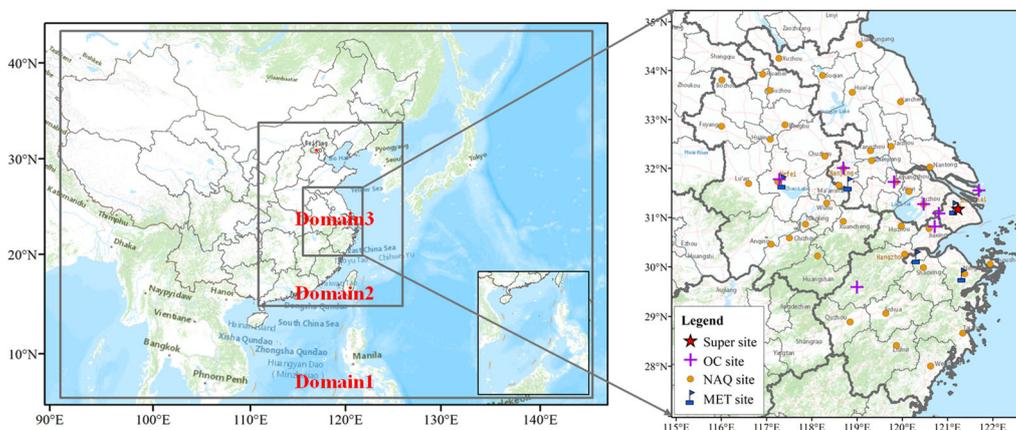

268 Meteorological fields were provided by the Weather Research and Forecasting
269 (WRF version 3.7) model with 27 vertical layers extending to the tropopause (100 hpa).
270 The initial and boundary conditions (ICs, BCs) in the WRF were based on the 1° × 1°
271 reanalysis data from the National Centers for Environmental Prediction Final Analysis
272 (NCEP-FNL). Physical options used in the WRF simulation are listed in Table S4.

273 The Sparse Matrix Operator Kernel Emissions (SMOKE,
274 <https://cmascener.org/smoke>) model was applied to process emissions for input to
275 CMAQ. CMAQ version 5.3.2 (<https://cmascener.org/cmaq/>) was used to simulate
276 atmospheric pollutants concentrations. ICs and BCs of D1 domain are based on a Model
277 For Ozone And Related Chemical Tracers (MOZART) global simulation

278 (<https://acom.ucar.edu/wrf-chem/mozart.shtml>). For the inner D2 and D3 domain, ICs
279 and BCs are extracted from the simulation results of the outer domains. Options selected
280 for the CMAQ simulations include the SAPRC07 gas phase chemistry, the AERO7
281 aerosol scheme, the Regional Acid Deposition Model (RADM) model aqueous phase
282 chemistry, ISORROPIA inorganic particulate thermodynamics.

283 The emission inventory developed in this study was used to produce the emission
284 system in the YRD region while emissions beyond YRD were supplied by
285 Multiresolution Emission Inventory for China (MEIC-2017, <http://meicmodel.org>),
286 Shipping Emission Inventory Model (SEIM) (Liu et al., 2016), and the Model Inter-
287 Comparison Study (MIX) emission inventory for 2010 (Li et al., 2017). The I/SVOC
288 emission inventory outside the YRD region was developed by multiplying the VOCs
289 and POA emissions with the average I/SVOCs-G-to-VOCs and I/SVOCs-P-to-POA
290 ratios of major source categories like industry, vehicle, marine vessel, and residential.

291 Biogenic volatile organic compounds (BVOCs) emissions were estimated based on
292 MEGAN (the Model of Emissions of Gases and Aerosols from Nature) version 2.10
293 driving by inputs of the leaf area index (LAI) from MODIS product, plant functional
294 types (PFT) base on remote sensing data, inline coupled emission factors and
295 meteorology simulated by the WRF model. Detail configurations of MEGAN can be
296 obtained from our previous study (Liu et al., 2018a).

297
298 **Figure 1.** Modeling domain and locations of observation sites. The blue marks are meteorological

299 monitoring sites. The yellow dots represent the national air quality monitoring sites. The purple
300 crosses are the observation sites with PM_{2.5} chemical composition measurements. The red star
301 represents the observation site of AMS measurement.

302 SOA formed from I/SVOCs was estimated using the parameterization within the
303 VBS framework in Lu et al. (2020). Specifically, the I/SVOC surrogates react with OH,
304 generating four oxygenated organic species with volatility spanning from $C^* = 10^{-1}$ to
305 $10^2 \mu\text{g}\cdot\text{m}^{-3}$, which may exist in both gas and condensed phase. The rate coefficient (i.e.,
306 k_{OH}) and product yields (i.e., α_i , $i=1, 2, 3, 4$) for each primary I/SVOC species were
307 derived based on previous laboratory results (Zhao et al., 2015; Zhao et al., 2016b).
308 Multi-generation oxidation was considered by implementing further oxidation of the
309 vapors from the initial oxidation, which redistributes the mass across the volatility bins
310 of $C^* = 10^{-2}$ to $10^2 \mu\text{g}\cdot\text{m}^{-3}$, and thus fragmentation and functionalization were included.
311 Additionally, SOA formation from SVOCs were treated similarly, and more details can
312 be found in Murphy et al. (2017). POA was treated as semivolatile to account for its
313 gas-particle partitioning and ageing process and segregated to several particle species,
314 which varied in their volatility that quantified with the metric $C^* = 10^{-1}$ to $10^3 \mu\text{g}\cdot\text{m}^{-3}$
315 (Donahue et al., 2006). I/SVOCs-P emissions from different sources were then
316 speciated and input as semivolatile accordingly. The remaining POA emissions
317 excluding I/SVOCs-P were treated as nonvolatile POC (primary organic carbon) and
318 PNCOM (primary non-carbon organic matter).

319 2.3 Model simulations

320 To investigate the model performance on OA simulations and the contributions of
321 different sources, we set 14 simulation cases using brute-force method (Zhang et al.,
322 2005). Table 1 shows the settings for these 14 cases. First was BASE simulation case,
323 in which the I/SVOC emissions was not included and the POA emissions were treated
324 as non-volatile. The second was the IMPROVE case, which augmented the high-
325 resolution I/SVOC emission inventory established in this study. In addition, the POA
326 emissions in the IMPROVE simulation were split into both non-volatile and
327 semivolatile parts. The non-volatile emissions were obtained by subtracting the

328 I/SVOCs-P from the total POA. The semivolatile emissions, that was I/SVOCs-P
 329 emissions, were treated with variable gas-particle partitioning and multigenerational
 330 aging in this simulation case. We then used the difference between IMPROVE and
 331 BASE cases to evaluate the OA contributions from I/SVOC emissions. CASE1 to
 332 CASE12 respectively excluded the VOC and I/SVOC emissions from different sources.
 333 We used the differences between IMPROVE and CASE1-12 to quantify the
 334 contribution of each source to OA concentration.

335 **Table 1.** Settings of simulation cases.

<u>Name</u>	<u>Sources with added I/SVOC emissions</u>
<u>BASE</u>	<u>none</u>
<u>IMPROVE</u>	<u>all</u>

CASE12	only without cooking VOC and I/SVOC emissions in the region

337 2.4 Model evaluation

338 To capture the characteristics of OA with different meteorological features in the
339 YRD region, we selected four periods to represent spring (Mar. 15th to Apr. 15th, 2019),
340 summer (Jul. 1st to 31st, 2019), autumn (Oct. 15th to Nov. 15th, 2018), and winter (Dec.
341 1st to 31st, 2018) to conduct the simulations. Evaluations on model performance were
342 made by comparing the simulation results with the observations obtained in the region,
343 including 5 meteorological observation sites, 10 PM_{2.5} chemical composition sites, and
344 41 national air quality monitoring sites, one in each city. The locations of the
345 meteorological and air pollutant observation sites are shown in Figure 1.

346 We also used the observation data of an AMS and a GC-MS/FID system at the
347 supersite in Shanghai to further verify the model performance on the simulation of POA,
348 SOA, and key VOC precursors. Details of AMS measurements and PMF analysis are
349 provided in our previous study (Huang et al., 2021). A total of 55 PAMS (Photochemical
350 Assessment Monitoring Stations) species were identified by the GC-MS/FID system
351 including 27 alkanes, 11 alkenes, acetylene and 16 aromatics. The supersite was located
352 on the top-floor of an eight-story building in Shanghai Academy of Environmental
353 Sciences (SAES, 31°10' N, 121°25'E), 30 m above the ground. The site was in a typical
354 residential and commercial area with significant influence from traffic emission.
355 Several petrochemical and chemical industrial factories sit around 50 km away from
356 the site to the south and southwest.

357 Model performance in simulation of meteorological parameters and major criteria
358 air pollutants are summarized in Table S5 and S6. The mean bias (MB), mean gross
359 error (MGE), root-mean-square error (RMSE), and index of agreement (IOA) of

360 temperature, humidity, wind speed, and wind direction in each season are within the
361 criteria recommended by Emery et al. (2001). Although the temperature in summer and
362 winter, and wind speed in autumn and winter were slightly overestimated, their MGE
363 and IOA values are within the uncertainties as recommended in Emery et al. (2001).

364 For the simulation of major criteria air pollutants, both mean fractional bias (MFB)
365 and mean fractional error (MFE) of all pollutants met the criteria recommended by
366 Boylan and Russell (2006). Since the addition of I/SVOC emissions would change the
367 PM_{2.5} simulation results, we thus presented the statistical results for both BASE and
368 IMPROVE cases in the Table S6. The modeled SO₂ was slightly overestimated, which
369 is likely due to the faster than expected reduction of SO₂ emissions, resulting in
370 overestimation of SO₂ emissions in the emission inventory. On the contrast, the
371 modeled NO₂ were underestimated in spring, autumn, and winter, likely due to the
372 overestimation of wind speed in these seasons. The modeled O₃ and PM_{2.5} were slightly
373 overestimated in the IMPROVE simulation case. Overall, the simulated meteorological
374 parameters and major criteria air pollutants are consistent with the observations.

375 **3. Results and discussion**

376 3.1 I/SVOC emission inventory

377 3.1.1 Source-specific I/SVOC emissions

378 Table 2 shows the I/SVOCs-G and I/SVOCs-P emission inventories
379 ~~emission inventories in gas and particle phase~~ for detailed source category for year
380 2017 in the YRD region. The total I/SVOC-G emission in the YRD region was
381 1148.42~~1128.26~~ Gg in 2017, lower than that in Wu et al. (2021) of 1360 Gg, but higher
382 than the estimate in Huang et al. (2021b) of 730 Gg. ~~The I/SVOC emissions in both Wu~~
383 ~~et al. (2021) and Huang et al. (2021b) were estimated by the POA scaling factor method.~~
384 ~~However, I/SVOCs-G emissions usually have stronger correlation with AVOCs, which~~
385 ~~is fully in gas phase, other than POA in particle phase (Lu et al., 2018). Especially for~~
386 ~~the industrial sectors, where gaseous organics dominate the primary organic emissions,~~

387 ~~there must be considerable uncertainties if POA scaling factor method is used for the~~
388 ~~estimation of I/SVOCs-G emissions.~~

389 We found industrial solvent-use was the largest contributor (489.383.64 Gg,
390 43.3842.11%) of total S/IVOCs-G emissions, followed by industrial process sources
391 (249.34.65 Gg, 2221.4030%), mobile source (320344.40-31 Gg, 2829.4098%),
392 residential source (58.5762.23 Gg, 5.1942%), and agriculture source (10.563.58 Gg,
393 0.941.18%). Specifically, chemical production, textile, and solvent-based coating were
394 major sectors of I/SVOCs-G emissions in the YRD region, accounting for 21.590.80%,
395 20.3719.51%, and 15.3307% of the total I/SVOCs-G emission, and their contributions
396 to AVOC emissions were 20.70%, 2.22%, and 23.42%, respectively (See Table S3). It
397 is interesting to note that the I/SVOCs-to-VOCs ratios are largely different for different
398 sources. For example, the textile industry only accounted for 2.22% of the total AVOC
399 emissions in the YRD region but contributed to 20.3719.51% of the I/SVOC-G
400 emissions due to its higher I/SVOCs-to-VOCs ratio (2.473). Another example is water-
401 based coatings, whose VOC emissions were approximately 10.2% of solvent-based
402 coatings, while their I/SVOC emissions were 29.1% of those from solvent-based
403 coatings. These findings indicate that reductions in VOC emissions not necessarily
404 corresponds to the simultaneous reductions in I/SVOCs emissions and subsequent SOA
405 formation, which should be considered in future control strategies. (Yuan et al., 2010).

406 For I/SVOCs-G emission of mobile origin, the major contributors were gasoline
407 vehicle, diesel vehicle, and non-road diesel machinery, accounting for 13.5264%,
408 10.5911.66%, and 3.962.11%, respectively. The total I/SVOCs-G emissions from
409 gasoline and diesel vehicles were 272.0390.57 Gg, much higher than the results
410 reported in Liu et al. (2017) (29.58 Gg) and Huang et al. (2021b) (16.0 Gg) using the
411 emission factor method, which likely underestimates the emission factors of I/SVOCs
412 due to the lack of localized emission factors. Our tunnel experiment results show that
413 the average IVOCs emission factors of gasoline and diesel vehicles were 15.3 mg·km⁻¹
414 ¹ and 219.8 mg·km⁻¹ (Tang et al., 2021), which were significantly higher than those

415 used in the above studies (Liu et al., 2017; Huang et al., 2021b). More comprehensive
 416 localized emission measurements are advocated to better constrain the I/SVOC
 417 emissions from mobile sources.

418 I/SVOCs-P emissions were 82.96~~118.39~~ Gg, ~~occupying 58.70% of the POA~~
 419 ~~emissions in the region. POA emissions and contributions from different sources can~~
 420 ~~be found in Table S3.~~ The largest contributor of I/SVOCs-P emissions came from
 421 ~~cooking emission~~~~biomass burning~~ and diesel vehicle, accounting for ~~53.24%~~~~58.08%~~
 422 and ~~11.88%~~~~20.53%~~ of the total, followed by gasoline vehicle (~~5.23%~~~~7.42%~~), ~~marine~~
 423 ~~vessel (2.66%), diesel machinery (2.54%), and~~ biomass burning (~~1.75%~~~~6.08%~~), ~~diesel~~
 424 ~~machinery (4.14%), and marine vessel (4.05%). Note that the I/SVOCs-P emissions~~
 425 ~~from coal combustion (e.g. power plants, boilers, etc.), other industrial processes, and~~
 426 ~~aircraft were not included in this study. On the one hand, the POA emissions (See Table~~
 427 ~~S3) from these sources were limited, accounting for less than 5%, which could be~~
 428 ~~expected that their I/SVOCs-P emissions were also relatively low. On the other hand,~~
 429 ~~the profiles of I/SVOCs-P components of these sources were still difficult to obtain.~~
 430 ~~More measurements of the I/SVOC emissions from these sources is very necessary in~~
 431 ~~the future.~~

432 **Table 2.** Source-specific emissions of I/SVOCs for the year 2017 in the YRD region.

434 3.1.2 Volatility distributions of I/SVOCs

435 Figure 2 shows the volatility distribution of I/SVOC emissions from different
436 sources as well as their gas-particle distributions. The I/SVOC emissions generally

437 ~~showed an increasing trend with the increase of volatility. With the I/SVOC emission~~
438 ~~profiles of each source category (Table S1 and S2), we successfully compiled the~~
439 ~~volatility distribution of I/SVOC emissions from different sources as well as their gas-~~
440 ~~particle distribution (Figure 2). The I/SVOC emissions generally showed an increasing~~
441 ~~trend with the increase of volatility.~~ As shown in Figure 2(a), IVOC emissions (logC*
442 bins at 3–6) accounted for ~~8986%~~89.86% of the total I/SVOCs emissions, overwhelmingly
443 dominated by industrial process and mobile sources. SVOCs (logC* bins at 0–2) and
444 low-volatile organic compounds (LVOCs, logC* bins at -1) contributed to 10% and 1%
445 of the total I/SVOCs emissions. In terms of the contributing sectors, mobile sources,
446 industrial process, and solvent-use dominated the total I/SVOC emissions. While the
447 IVOCs were equally contributed by above-listed three sources, industrial process and
448 mobile sources dominated the SVOCs and LVOCs emissions.

449 We further investigated the contributions of different volatility bins to each source
450 category. The mobile source was dominated by IVOC emission (88%). ~~Note that IVOCs~~
451 ~~in vehicle exhaust are dominated by aromatics, which have faster OH reaction rates and~~
452 ~~higher SOA yields compared to aliphatics in the same volatility bin (Zhao et al., 2016b;~~
453 ~~Drozd et al., 2019). Lu et al. (2020) therefore defined two additional lumped IVOC~~
454 ~~species with logC* bins at 5 and 6 to account for the aromatic IVOCs in vehicle exhaust~~
455 ~~according to the measurements in previous studies (Zhao et al., 2015; Zhao et al.,~~
456 ~~2016b). Here in this study, we also split the aromatic IVOC emissions from mobile~~
457 ~~sources and found that aromatic IVOCs accounted for 23% of the total I/SVOC~~
458 ~~emissions from the mobile source. Note that we also split the aromatic IVOCs emission~~
459 ~~from mobile source using the method in Lu et al. (2020) and found that aromatic IVOCs~~
460 ~~accounted for 23% of the total I/SVOC emissions from the mobile source.~~ The
461 industrial process and solvent-use sources were also dominated by IVOC emissions,
462 accounting for 81% and 97%, respectively. The volatility distribution of residential
463 sources was relatively uniform, with IVOCs, SVOCs and LVOCs accounting for ~~4640%~~
464 ~~2730%~~27.30%, and ~~2730%~~27.30%. Agricultural (i.e., biomass burning) sources were more

465 concentrated in IVOCs, accounting for 71.76%, while SVOCs ~~and LVOCs~~ accounted
 466 for 20% and 94%, respectively. ~~Except agricultural sources, I/SVOC emissions from~~
 467 ~~all sources are dominated by gas-phase species. The agricultural sources were~~
 468 ~~dominated by particle-phase species, taking up 78% of the total I/SVOC emissions with~~
 469 ~~the VBS bins concentrated in the $\log C^*$ range of 0–4.~~ It should be noted that other than
 470 mobile sources, the emission profiles of the other sources were mainly derived from
 471 SPECIATE 5.1 database (US EPA, 2021) in this study, which may be inconsistent with
 472 real-world emissions in China. To further reduce the uncertainty in this newly establish
 473 I/SVOC estimation inventory, measurements of I/SVOC emissions from different local
 474 sources are therefore important and urgently needed in the future.

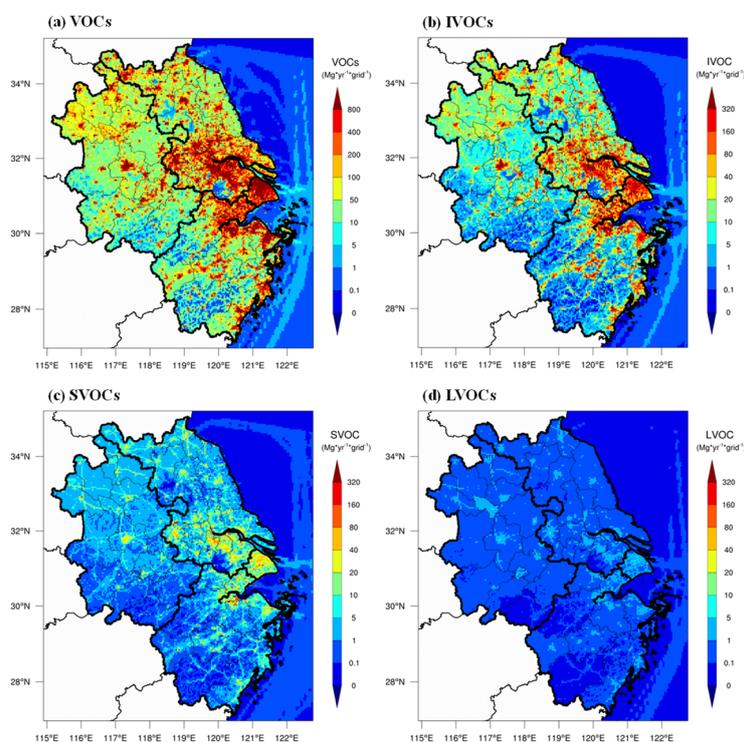

476
 477 **Figure 2.** Volatility distributions of I/SVOCs emitted from different sources in the YRD region.

478 3.1.3 Spatial distributions of I/SVOC emissions in YRD region

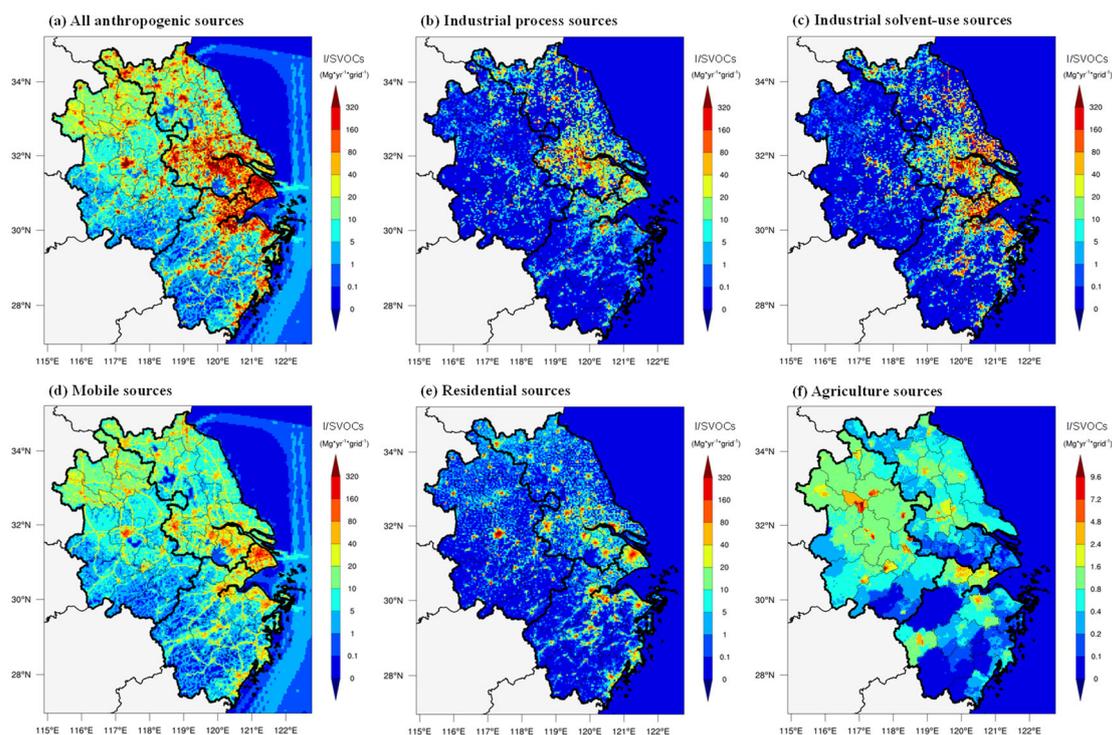

479 Figure 3 compares the spatial distributions of AVOC, IVOC, SVOC, and LVOC
480 emissions in the YRD region. The IVOC, SVOC, and LVOC emissions were largely
481 concentrated in city clusters in eastern YRD, and hotspots can also be observed in the
482 northern agglomerations. The distributions of I/S/LVOC emissions were generally
483 consistent with that of the AVOC emissions in the region. Compared to the spatial
484 distributions of I/S/LVOC emissions in Chang et al. (2022), our emissions had similar
485 spatial distributions but at a higher resolution. Emission hotspots in urban areas can be
486 captured more clearly in this study, which will help improve the simulation in urban
487 areas.

488 Figure 3-4 shows the spatial distributions of source-specific I/SVOC emissions in
489 the YRD region. ~~There were considerable differences in the spatial distributions of~~
490 ~~I/SVOC emissions from different sources. The I/SVOC emissions from industrial~~
491 ~~sources (including industrial process and industrial solvent-use) were mainly~~
492 ~~concentrated in the eastern urban agglomeration, which was related to the developed~~
493 ~~industrial activities in the region. The I/SVOC emissions were largely concentrated in~~
494 ~~city clusters in eastern YRD, and hotspots can also be observed in the northern urban~~
495 ~~agglomerations. The spatial distribution of total I/SVOC emissions was resulted from~~
496 ~~combined emissions from mobile, industrial process and solvent use sources. The~~
497 I/SVOC emissions from mobile and residential sources clustered into multiple hotspots
498 in urban areas, while emissions from agricultural sources were mainly distributed in
499 northern YRD, where frequent agricultural activities exist. ~~The distribution of I/SVOC~~
500 ~~emissions was generally consistent with that of the VOC emissions in the eastern and~~
501 ~~central area of the region. But higher I/SVOC emissions than VOC emissions were~~
502 ~~observed in northern YRD (See Figure S1). This can be explained by the difference in~~
503 ~~I/SVOCs-G to VOCs ratios among different sources. For example, industrial and~~
504 ~~mobile sectors are major sources of I/SVOC emissions, yet AVOC emissions were~~
505 ~~mainly dominated by industrial sectors.~~

506 We also compare the spatial distributions of I/SVOC emissions with those of POA
507 and BVOCs. We found that POA emissions were more concentrated in urban centers
508 associated with mobile and residential sources (See Figure S1). BVOC emissions in the
509 YRD region were mainly distributed in the southern area, where AVOC and IVOC
510 emissions were relatively low. The difference in the spatial distributions of I/SVOC,
511 AVOC, BVOC, and POA emissions implies that the sources of organic components in
512 different areas of the region are quite different, which will be discussed in the following
513 sections.

514
515 **Figure 3.** Spatial distributions of anthropogenic VOC, IVOC, SVOC, and LVOC emissions in the
516 YRD region for the year 2017.

517

518 **Figure 34.** Spatial distributions of I/SVOC emissions from different source categories in the YRD
 519 region for the year 2017.

520 3.2 Comparison between model simulation and observation

521 3.2.1 Simulation results of VOCs and IVOCs

522 Since model performance on the simulation of VOCs are critical for SOA
 523 estimation, we first compare the modeled concentrations of VOCs with those of the
 524 measured at the SAES supersite for several aromatic VOCs, including benzene, toluene,
 525 and m-/p-/o-xylenes. As shown in Figure S2, the model simulation was able to capture
 526 the hourly variations of these species measured, with Pearson correlation coefficients
 527 (r) of 0.54–0.65, 0.45–0.60, 0.54–0.69 for toluene, xylene, and benzene respectively.
 528 Although the simulation results of toluene were 28% lower and xylene and benzene
 529 were 41% and 22% higher than those of the measured, the model results are within the
 530 uncertainties. Overall, the simulation results of the VOC species showed good
 531 agreements with the observations, which could be further used for the model simulation
 532 of SOA formation.

533 Long-term continuous observations of I/SVOC concentrations were sparse, so the
 534 simulation results of IVOCs were compared with those obtained from offline

535 measurements reported in our previous studies (Li et al., 2019; Ren et al., 2020). The
536 reported IVOC concentrations (sum of gas- and particle-phase concentrations) in
537 summer and winter Shanghai in 2018 respectively varied between 1.5–17.2 and
538 2.2–43.1 $\mu\text{g}\cdot\text{m}^{-3}$ with average concentrations of 6.8 ± 3.7 and $18.2 \pm 11.0 \mu\text{g}\cdot\text{m}^{-3}$. In this
539 study, our modeled average concentrations of IVOCs in spring, summer, autumn, and
540 winter at the SAES supersite in Shanghai were 12.8 ± 5.6 , 9.0 ± 3.2 , 12.2 ± 5.2 , and
541 $12.4 \pm 7.6 \mu\text{g}\cdot\text{m}^{-3}$, respectively. Although there was still a deviation of 20%–30%
542 between the simulation and observation, not to mention the diurnal patterns and spatial
543 distributions also remained unknown, the simulation results are at least comparable to
544 those of the measured concentrations, suggesting the modeled I/SVOCs is appropriate
545 to be used in the estimation of SOA production from different sources. Continuous long-
546 term measurements of I/SVOC at multiple locations are strongly recommended in the
547 future to improve the model performance and reduce the uncertainties in SOA
548 estimation.

549 3.2.1 Simulation results of OA concentrations

550 Figure 4-5 presents the OA concentrations originated from different sources,
551 including POA and SOA formed from AVOCs, BVOCs, and I/SVOCs, in four seasons
552 in YRD from both BASE and IMPROVE simulations. Here we used the average of the
553 modeled concentrations at 41 national air quality monitoring sites (See the yellow dots
554 in Figure 1) to represent the regional average. The regional average concentration of
555 OA (~~9.628.75~~ $\mu\text{g}\cdot\text{m}^{-3}$) in the IMPROVE simulation was ~~3822~~% higher than that from
556 BASE simulation (~~6.987.17~~ $\mu\text{g}\cdot\text{m}^{-3}$) due to the involvement of I/SVOCs in the
557 IMPROVE simulation.

558 The seasonal average concentration of POA was ~~5.0-5~~ $\mu\text{g}\cdot\text{m}^{-3}$ in the BASE case,
559 with the lowest in summer (~~3.3-8~~ $\mu\text{g}\cdot\text{m}^{-3}$) and the highest in winter (~~56.9~~ $\mu\text{g}\cdot\text{m}^{-3}$). High
560 POA concentrations in winter was mainly induced by the stagnant meteorological
561 conditions such as low wind speed and boundary layer height, and vice versa in summer.
562 For the spatial distributions as presented in Figure 56, POA concentrations in northern

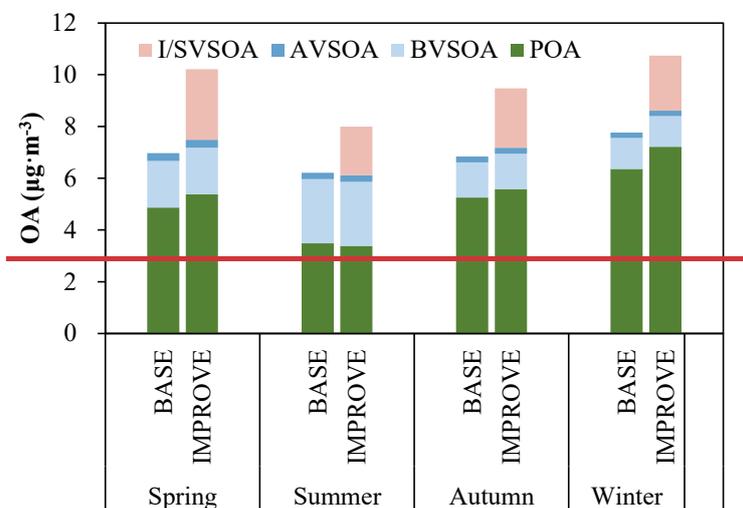

563 YRD were high and mainly concentrated in urban areas, which was consistent with the
564 distributions of POA emissions (Figure S1). The POA concentrations in the IMPROVE
565 simulation decreased by 12%–20% compared with the BASE case.~~The POA~~
566 ~~concentrations in the IMPROVE simulation were 3%–13% apart from those in the~~
567 ~~BASE simulation.~~ In the IMPROVE simulation, the POA was treated as semi-volatile,
568 where gas–particle partitioning and multigeneration oxidation were considered
569 (Murphy et al., 2017). Entering into the atmosphere, more semi-volatile compounds
570 evaporated into gas-phase and then generated SOA through multigeneration oxidation,
571 which reduced the POA concentrations relatively.~~The differences between these two~~
572 ~~cases were then determined by the competitive effects of functionalization and~~
573 ~~fragmentation. In summer, more aged products were transferred to higher volatility bins~~
574 ~~to produce SOA and thus reduced POA concentrations.~~

575 ~~BASE and IMPROVE simulations show similar results in the average~~
576 ~~concentrations of SOA formed from AVOCs (AVSOA).~~ The seasonal average
577 concentration of AVSOA was only ~~0.25–22~~ $\mu\text{g}\cdot\text{m}^{-3}$. The average AVSOA concentration
578 in the IMPROVE case increased by 17% compared with the BASE case due to higher
579 OA loading. Nonetheless, AVSOA still, exhibiting exhibited very limited contribution
580 to the regional OA concentration, whereas average concentration of BVOC derived
581 SOA (BVSOA, $1.7 \mu\text{g m}^{-3}$ in the IMPROVE simulation case) was much higher than
582 expected. Also, evident seasonal variations were observed for BVSOA, with the highest
583 in summer (~~2.48–2.27~~ $\mu\text{g}\cdot\text{m}^{-3}$), followed by spring (~~1.80–65~~ $\mu\text{g}\cdot\text{m}^{-3}$), autumn (~~1.36–62~~
584 $\mu\text{g}\cdot\text{m}^{-3}$), and winter (~~1.49–11~~ $\mu\text{g}\cdot\text{m}^{-3}$). Hotspots of BVSOA concentrations were
585 concentrated in the western and southern YRD. The observed seasonal variations and
586 spatial distributions of BVOC derived SOA were consistent with those of the BVOC
587 emissions in YRD (Liu et al., 2018a).

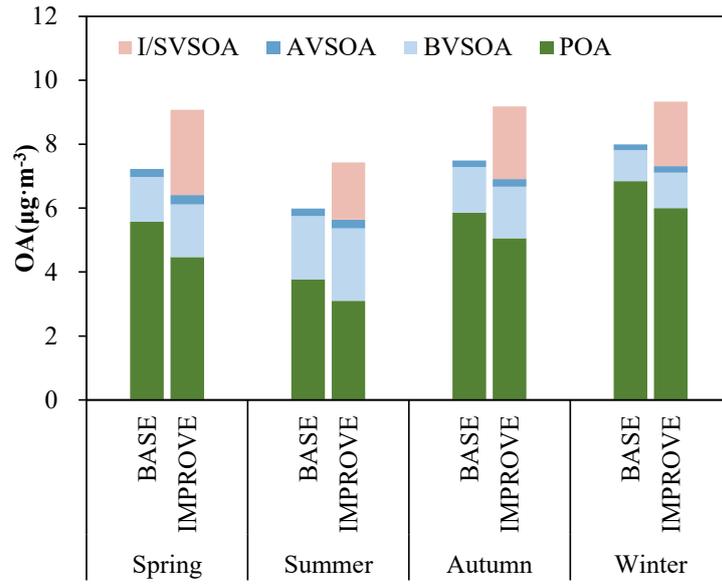

588 The average concentration of I/SVOC derived SOA (I/SVSOA) in IMPROVE
589 simulation was ~~2.26–18~~ $\mu\text{g}\cdot\text{m}^{-3}$, with the highest in spring (~~2.73–66~~ $\mu\text{g}\cdot\text{m}^{-3}$) and the
590 lowest in summer (~~1.87–79~~ $\mu\text{g}\cdot\text{m}^{-3}$), which is a combined effect of emission, oxidation

591 and meteorological conditions. For example, Qin et al. (2022) suggested that in spring
 592 the enhanced solar radiation and OH oxidation potentially promote the secondary
 593 conversion from I/SVOCs to SOA. The low concentration in summer was likely due to
 594 the better meteorological conditions than the other seasons. By incorporating I/SVOC
 595 emissions into the IMPROVE simulation, the modeled average SOA concentration in
 596 the region increased from 1.96-66 (BASE) to 4.22-10 $\mu\text{g}\cdot\text{m}^{-3}$; and high concentrations
 597 of I/SVSOA were observed in central and northern YRD. Overall, the addition of high-
 598 resolution I/SVOC emissions significantly increase the SOA concentration by 44-6148%,
 599 which will be further constrained by the observation in next section.

600 To validate the model performance on regional OA simulation, we compared it
 601 with the measured concentrations of organic carbon (OC) in $\text{PM}_{2.5}$ at multiple sites in
 602 the YRD region (Figure S3). Although both BASE and IMPROVE simulations showed
 603 good correlations with the observation as shown in Figures S3c, S3f, S3i, and S3l, 6e, 6f,
 604 6i, and 6l, OC concentrations in IMPROVE simulations in different seasons were all
 605 higher than those in the BASE simulations. In the BASE simulation, the modeled OC
 606 concentrations of each season only explained 49-51% to 59-71% of the observations.
 607 With the addition of I/SVOC emissions into IMPROVE simulation, the modeled OC
 608 concentrations much better agreed with the observations, with modeled OC increased
 609 to 75-70% to 93-91% of the observations. Details for the statistical evaluation of model
 610 performance on OC in BASE and IMPROVE simulations are shown in Table S6-S7.

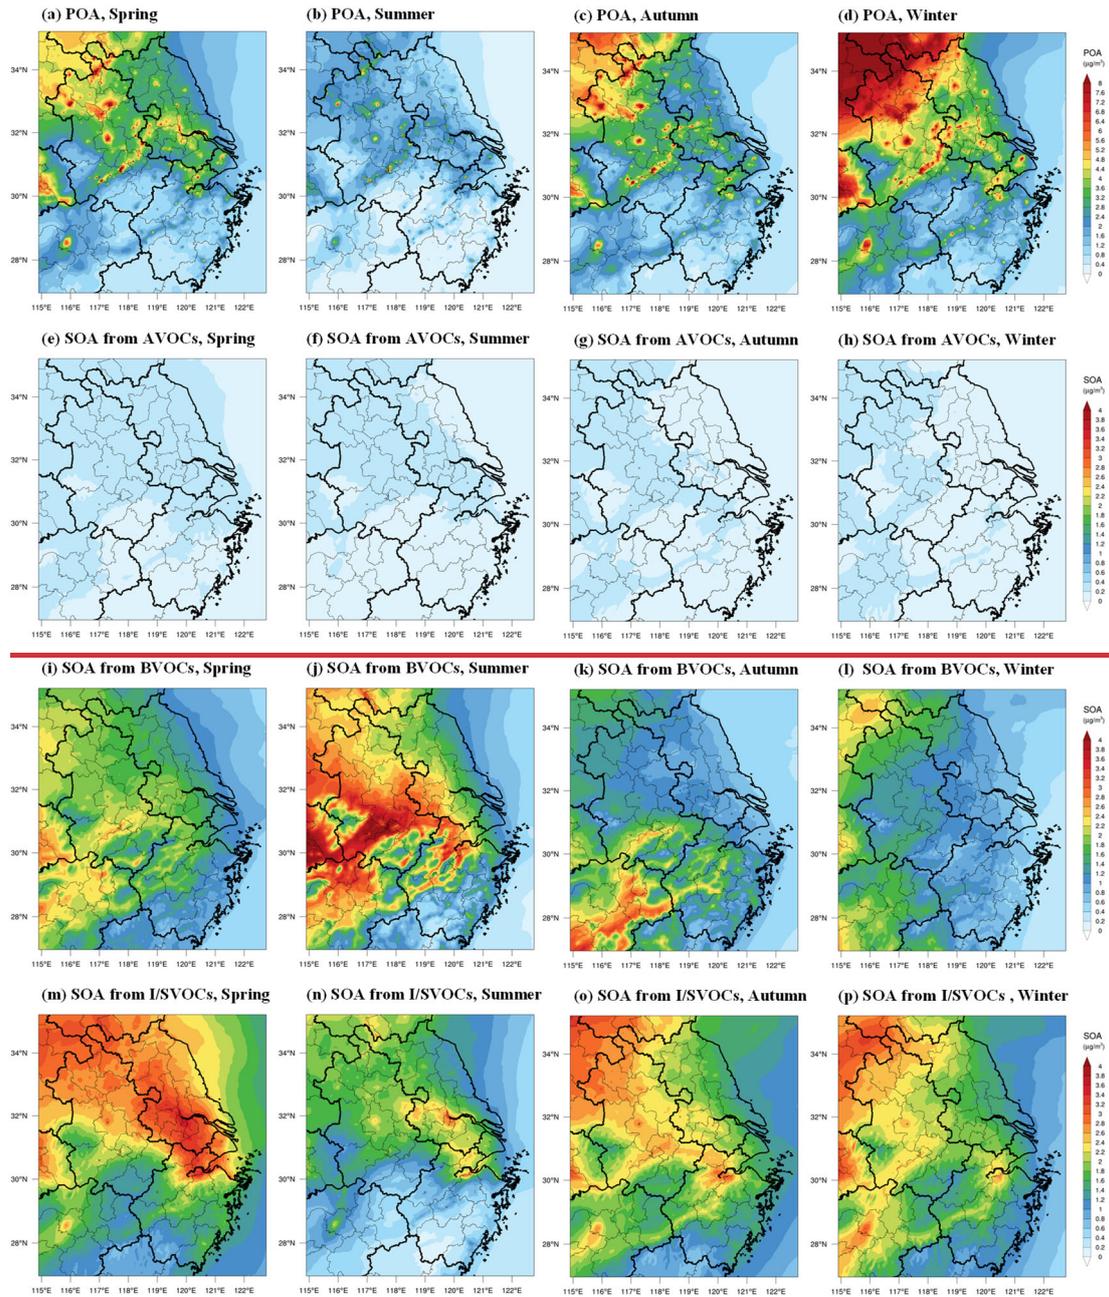

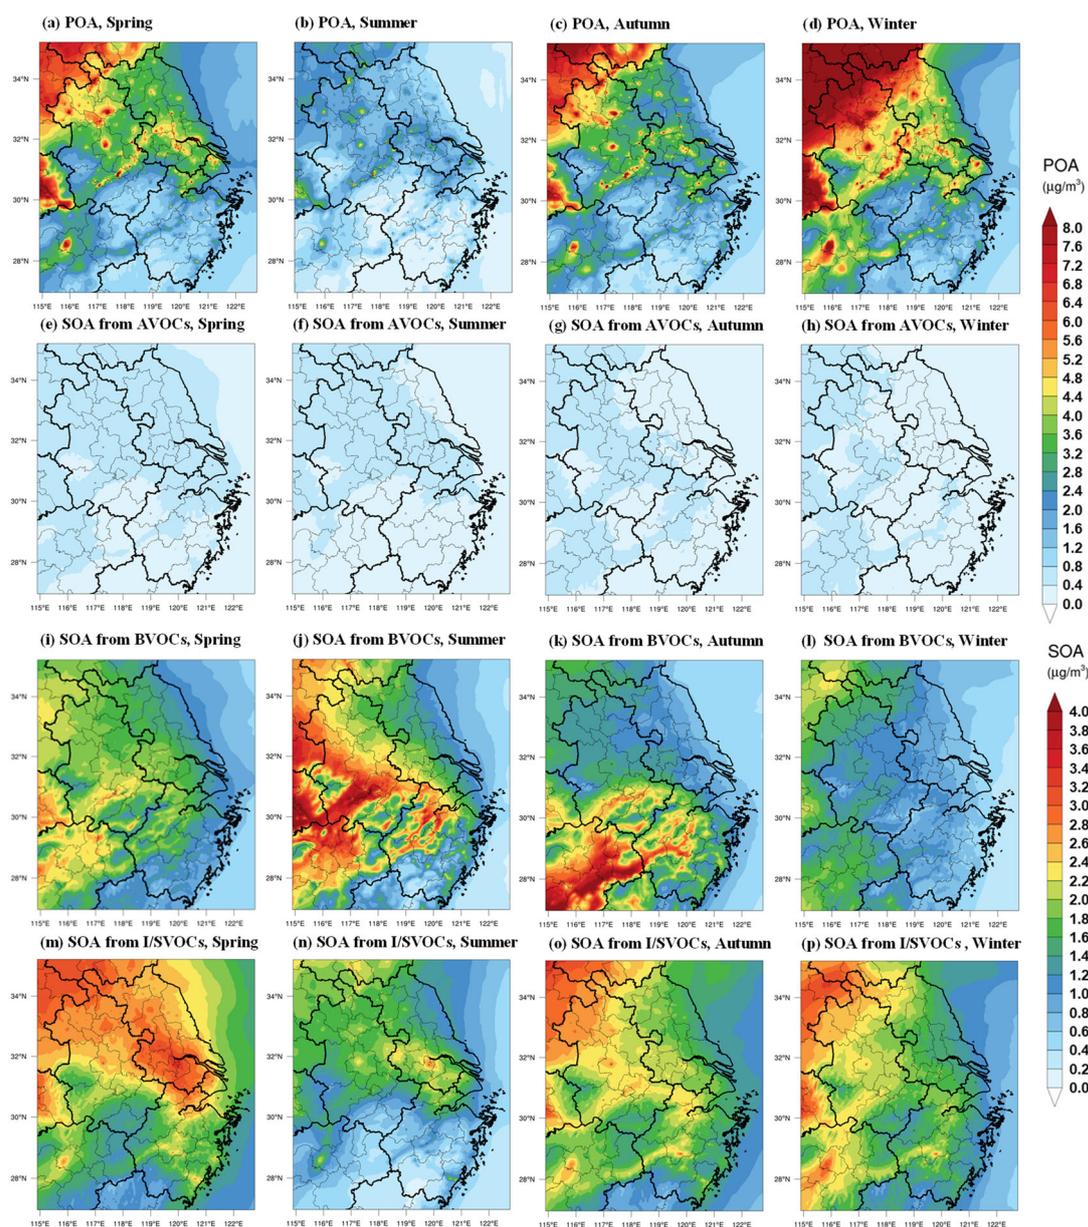

611

613 **Figure 45.** Comparisons of the regional average concentrations of POA and SOA formed from
 614 AVOCs, BVOCs, and I/SVOCs in different seasons from the BASE and IMPROVE simulations.

616

617 **Figure 56.** Spatial distributions of modeled POA and SOA formed from AVOCs, BVOCs, and
 618 I/SVOCs in different seasons in the IMPROVE simulation.

619 3.2.2 Temporal variations of OA components: simulation vs. AMS observation

620 To further validate the model performance on the simulations of POA and SOA,
 621 we compared the simulation results with those measured by an AMS at the SAES
 622 supersite. Both simulation and observation results were obtained for PM₁ aerosol
 623 particles (aerodynamic diameter < 1 µm). Figure 6-7 shows that the simulation results
 624 of POA, SOA and OA were similar to the observation results not only in average
 625 concentration levels but also in temporal variations. For POA, the BASE and

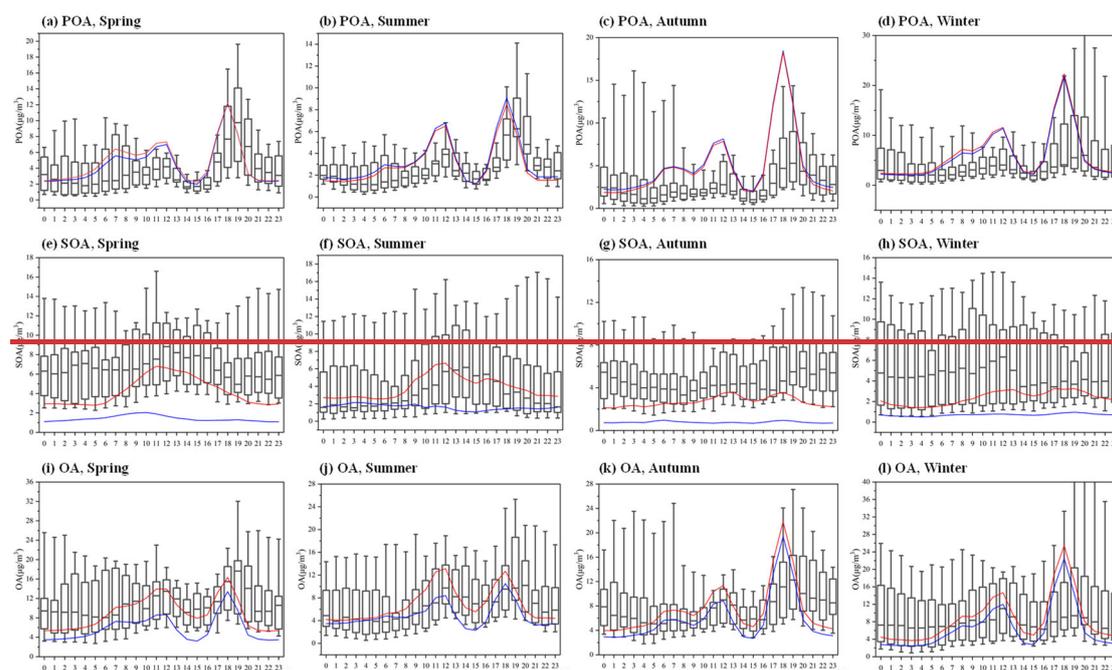

626 IMPROVE simulations agree with each other (Figure S4) and both can reproduce the
627 observed concentrations and diurnal variations of POA though a small deviation of
628 ~~34%~~-~~2618%~~ between the simulated and observed concentrations in different seasons
629 still existed. Similar to the observation results, the simulated POA concentrations
630 peaked at noon and early evening, which were mainly contributed by cooking emissions
631 as reported in our previous study (Huang et al., 2021).

632 For SOA, the average concentrations in spring, summer, autumn, and winter in
633 BASE simulation were 1.~~42~~, 1.6, 0.8, and 0.7 $\mu\text{g}\cdot\text{m}^{-3}$, respectively, which were only
634 ~~1314%~~-~~3130%~~ of those observed by the AMS (see Figure S4). The SOA simulation
635 was greatly improved in IMPROVE simulation with the modeled SOA concentrations
636 of ~~4.23.8~~, ~~3.87~~, 2.7, and ~~2.43~~ $\mu\text{g}\cdot\text{m}^{-3}$ in spring, summer, autumn, and winter respectively.
637 The SOA concentrations in IMPROVE simulation were ~~12.4~~-~~23.46~~ times higher than
638 those in BASE simulation, which is ~~4340%~~ to ~~7572%~~ of the observation, indicating the
639 large contributions of I/SVOCs emissions to SOA production.

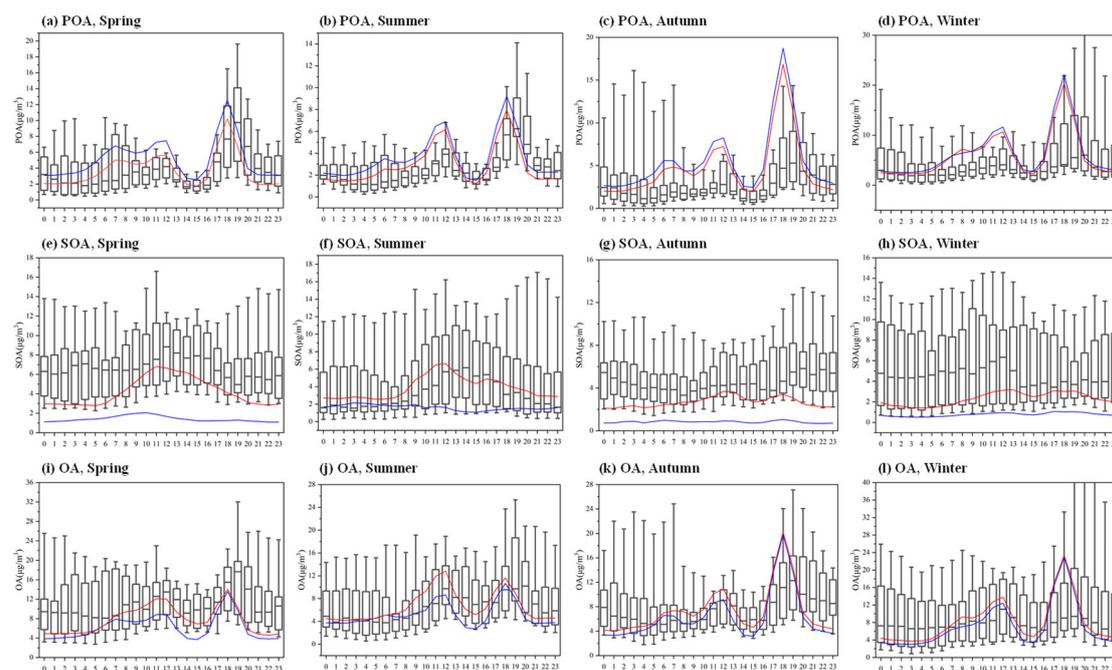

640 The IMPROVE simulation also demonstrated improvements in reproducing the
641 temporal variations of SOA, especially during the daytime (Figure ~~6e-7e~~ - ~~6h7h~~).
642 Compared with the BASE simulation, evident increases in SOA concentrations during
643 daytime can be observed in IMPROVE simulation, which agrees better with the
644 observation, likely driven by photochemistry. Although the SOA simulations were
645 improved in all four seasons, best simulation results were found in summer, when both
646 the concentrations and diurnal variations of SOA were well reproduced.

647 While our current results presented great improvements in SOA simulation, gaps
648 were still left between the simulation and observation especially during the nighttime.
649 The main reasons for the discrepancy between the simulated and measured SOA are:
650 (1) I/SVOC emissions from outside of the YRD region might be underestimated due to
651 the lack of detailed base emission inventory, resulting in the corresponding
652 underestimations of the transported SOA, which were prominent especially in autumn,
653 winter and spring in Shanghai; (2) current model simulation only consider the oxidation

654 processes driven by OH oxidation. However, an increasing body of experimental and
 655 observational evidence suggest that heterogeneous and multiphase reactions also played
 656 important roles in SOA formation especially during pollution episodes (Guo et al., 2020;
 657 Kim et al., 2021). Recent studies also found that nocturnal NO_3 oxidation was also an
 658 important route for SOA formation (Yu et al., 2019; Decker et al., 2021). Yet mechanism
 659 and parameterizations of these processes remain unclear, making the involvement of
 660 these processes in the model difficult.

661

662

663 **Figure 67.** Diurnal patterns of modeled POA, SOA, and OA concentrations in different seasons and
664 their comparisons with the observations at the SAES supersite. The boxplots represent the diurnal
665 patterns of the AMS observations. The blue and red lines respectively represent the diurnal patterns
666 of the simulation results in BASE and IMPROVE cases.

667 3.3 OA source contributions

668 3.3.1 POA and SOA sources in the region

669 Based on the high-resolution I/SVOC emission inventory established in this study,
670 we successfully simulated the POA and SOA concentrations from each source. Table 3
671 summarizes the regional average concentrations of POA and SOA originated from
672 different sources and their relative contributions. Residential POA dominated the
673 regional OA, with average concentrations ranged from ~~1.90–56~~ to ~~3.51–2.35~~ $\mu\text{g}\cdot\text{m}^{-3}$ in
674 different seasons, accounting for ~~23.79–19.47%~~–~~32.66–25.31%~~ of the total OA, among
675 which cooking emission is the dominant source (*ca.* ~~94–98%~~) of residential POA. Other
676 POA sources include industrial, biomass burning, and mobile sources, accounting for
677 ~~8.02%–8.63%, 4.45%–8.28%, and 5.03%–5.78%~~~~7.25%–8.67%, 4.94%–10.23%, and~~
678 ~~3.42%–4.35%~~ of the total OA, respectively. The cumulative fraction of POA in total
679 OA from industrial and mobile sources was ~~13.44%–14.41%~~~~10.67%–12.86%~~, close to
680 that of HOA (15%) observed by the AMS measurement in Shanghai (Figure S5).

681 Industrial sources were the main source of SOA in the YRD region, with average
682 SOA concentrations of ~~0.84–1.21~~~~0.91–1.38~~ $\mu\text{g}\cdot\text{m}^{-3}$ in four seasons, accounting for
683 ~~8.98%–15.64%~~~~8.71%–13.65%~~ of the total OA, among which, industrial process and
684 solvent-use sources had almost equal contributions. Mobile sources were the second
685 largest source of SOA in this region, with an average concentration of
686 ~~0.31–0.50~~~~0.37–0.57~~ $\mu\text{g}\cdot\text{m}^{-3}$, accounting for ~~3.36%–6.69%~~~~3.42%–6.09%~~ of the total
687 OA. Among them, the source contribution of gasoline vehicles to SOA was
688 ~~1.77%–3.07%~~~~1.80%–2.84%~~, and that of diesel vehicles was
689 ~~1.18%–2.55%~~~~1.20%–2.44%~~. BVSOA showed significant seasonal differences with
690 concentrations of ~~0.88, 1.26, 0.70, and 0.11~~~~0.76, 1.61, 0.59, and 0.12~~ $\mu\text{g}\cdot\text{m}^{-3}$,
691 respectively in spring, summer, autumn, and winter, accounting for ~~9.64%, 16.94%,~~

692 ~~7.60%, and 1.15%~~~~7.40%, 20.20%, 6.21%, and 1.14%~~ of the total OA.

693 Overall, cooking emission was the major source of POA in YRD, accounting for
694 ~~19.14%–24.99%~~~~27.69%–32.45%~~ of the total OA, which is consistent with our
695 observations in Shanghai (Huang et al., 2021; Zhu et al., 2021). Both simulations and
696 observations demonstrated higher contributions of cooking emission in urban China
697 than those reported overseas (17%–18%) (Chen et al., 2021), which is attributed to the
698 difference between Asian-style and Western-style cooking. The results emphasize that
699 cooking emission has become a non-negligible source of non-fossil carbon in urban
700 areas in eastern China. Contributions from industrial sources were running the second
701 among all sources, accounting for ~~17.02%–24.12%~~~~16.51%–21.64%~~ of OA and ~~24.7%–~~
702 ~~26.8%~~~~23.33%–28.57%~~ of SOA, which is attributed to the high I/SVOC emissions from
703 industrial sources and is consistent with previous studies (Miao et al., 2021). Other
704 sources mainly include mobile sources (~~8.76% to 11.72%~~~~7.77% to 9.68%~~ of OA) and
705 biomass burning (~~5.19%–8.87%~~~~5.63%–11.15%~~ of OA). Specifically, diesel and
706 gasoline vehicles were the major contributors among mobile sources, with higher
707 contribution from the former (~~3.95%–4.66%~~~~3.98%–4.68%~~) than the latter
708 (~~3.05%–4.02%~~~~2.79%–3.73%~~), followed by diesel machinery
709 (~~1.32%–2.11%~~~~0.86%–1.06%~~) and marine vessels (~~0.43%–0.93%~~~~0.15%–0.30%~~). The
710 contribution of biomass burning was highest in winter (~~8.87%~~~~11.15%~~) compared to
711 contributions of ~~5.19%–7.28%~~~~5.63%–7.29%~~ in other seasons and it was even higher
712 than contribution of mobile sources (~~8.76%~~~~7.77%~~) in winter. The remaining
713 ~~14.54%–35.64%~~~~15.44%–27.03%~~ of OA was from super region scale, which
714 represented OA originated from emissions outside the YRD region. Our results were
715 generally similar with those of Chang et al. (2022) for the YRD region. We both found
716 the domestic combustion mainly engaged in cooking emissions had a major
717 contribution to OA. Next was volatile chemical products (VCPs), especially the use of
718 solvents, paints, and adhesives in industrial sector, also made a high contribution. Note
719 that industrial process also took up a high fraction in our OA simulation, while it was

lower in Chang et al. (2022)'s study. The difference in I/SVOC emission estimates was the main reason for this divergence. Mobile sources in both studies had similar contributions, which accounted for about 10% to total OA. Comparatively, our source classification was more specific, which will help identify more specific OA sources to design more refined regional control countermeasures.

728 3.3.2 Spatial distributions of SOA originated from different sources

729 Figure 7-8 shows the spatial distributions of modeled SOA originated from
730 different sources in each season in YRD region. Note that we only considered the SOA
731 formed from the intraregional VOC and I/SVOC emissions, excluding those transported

732 from the super region. A large spatial variability was observed for the sources of SOA
733 driven by emissions. For example, industrial and mobile SOA concentrated in the
734 eastern and central YRD, where I/SVOC emissions were high (Figure 34). Residential
735 and agricultural SOA presented a more uniform spatial distribution than industrial and
736 mobile SOA, with enhanced formation in central and western YRD (Figures 78i-78l).

737 Although absolute source-dependent SOA concentrations differ in different
738 seasons, low spatial variabilities were observed for different seasons. Industrial, mobile,
739 and residential sources were the predominant contributors to SOA formation in eastern
740 and central YRD, especially for the area along the Hangzhou Bay and Yangtze River
741 driven by the enhanced I/SVOC emissions. The spatial distributions of BVSOA have
742 been discussed above and will not be detailed here.

744

745 **Figure 78.** Spatial distributions of modeled SOA concentrations from different sources in each
 746 season in YRD region.

747 3.3.3 Predominant OA sources in sub-regions of YRD

748 To characterize the source contributions in different parts of the region, we
 749 categorized the simulation region into six sub-regions: northern YRD, western YRD,

750 central YRD, eastern YRD and southern YRD. And six representative cities in these
751 six regions were further selected for detailed comparison in source contributions,
752 including Xuzhou (XZ), Hefei (HF), Nanjing (NJ), Hangzhou (HZ), Shanghai (SH) and
753 Jinhua (JH). Figure 8 shows their locations and OA source contributions during summer
754 and winter.

755 In Northern YRD, represented by XZ, enhanced contribution from super-regional
756 scale to the local OA was observed for both winter (~~64.6%~~~~53.2%~~) and summer
757 (~~27.7%~~~~28.9%~~) and the contributions from industrial processes (~~14.0%~~~~23.4%~~ in winter
758 and ~~21.0%~~~~18%~~ in summer) were also higher than other sub-regions. Other major
759 sources include biogenic (~~12.0%~~~~12.6%~~) and cooking emissions (~~14.1%~~~~14.7%~~) in
760 summer and cooking (~~14.1%~~~~9.3%~~) and other residential emissions (~~8.3%~~~~10.4%~~) in
761 winter. Taken together, super-regional transportation and industrial processes are
762 predominant contributors of OA in northern YRD, accounting for ~~78.6%~~ and ~~48.7%~~~~76.6%~~
763 ~~and 46.9%~~ in summer and winter respectively, followed by cooking emissions.

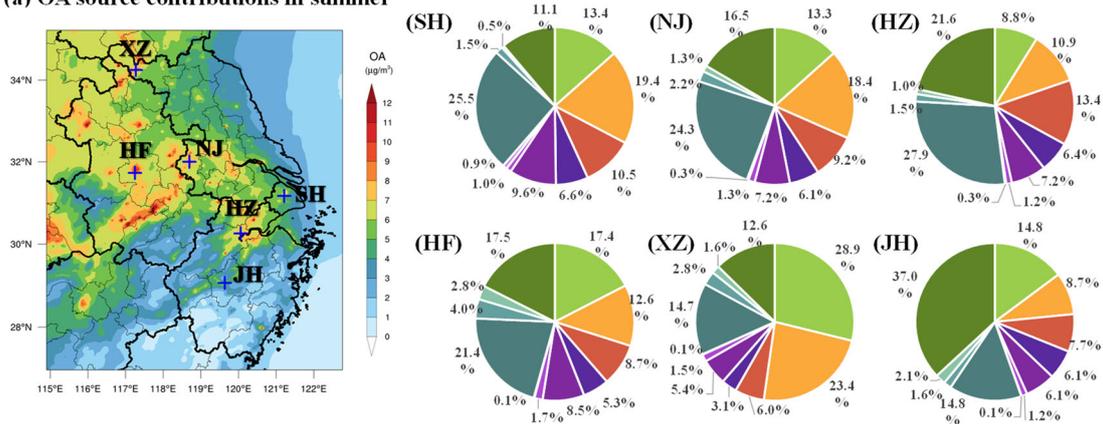

764 In western YRD, represented by HF, cooking emission was the largest contributor
765 to OA with contributions of ~~17.8%~~ and ~~26.3%~~~~21.4%~~ and ~~32.5%~~ in both summer and
766 winter respectively, followed by super-regional contributions of ~~15.7%~~ ~~17.4%~~ (summer)
767 and ~~29.2%~~~~25.8%~~ (winter). Other major sources also include mobile source of
768 ~~15.5%~~~~14%~~, biogenic source in summer (~~17.8%~~~~17.5%~~) and industrial processes in both
769 summer (~~12.3%~~~~12.6%~~) and winter (~~8.9%~~~~10.5%~~). In central YRD, represented by NJ
770 and HZ, the relative source contributions were very similar to those in western YRD,
771 with predominant contributions from cooking (~~22.8%~~~~32.6%~~~~24.3%~~~~38%~~), followed by
772 super-regional transportation (~~7.4%~~~~31.8%~~~~8.8%~~~~27.8%~~), industrial processes (~~11.3%~~~~-~~
773 ~~18.4%~~~~10.9%~~~~18.4%~~) and mobile source (~~13.1%~~~~-16.3%~~~~10%~~~~13%~~).

774 In eastern YRD, represented by SH, the largest OA source was cooking emission,
775 account for ~~24.3%~~~~25.5%~~ and ~~36.6%~~~~43.6%~~ of OA in summer and winter respectively,
776 followed by mobile sources of ~~19%~~~~16%~~, super-regional transportation of ~~11.5%~~~~13.4%~~
777 (summer) and ~~22.2%~~~~25.8%~~ (winter) and industrial processes of ~~17.3%~~~~19.4%~~ (summer)

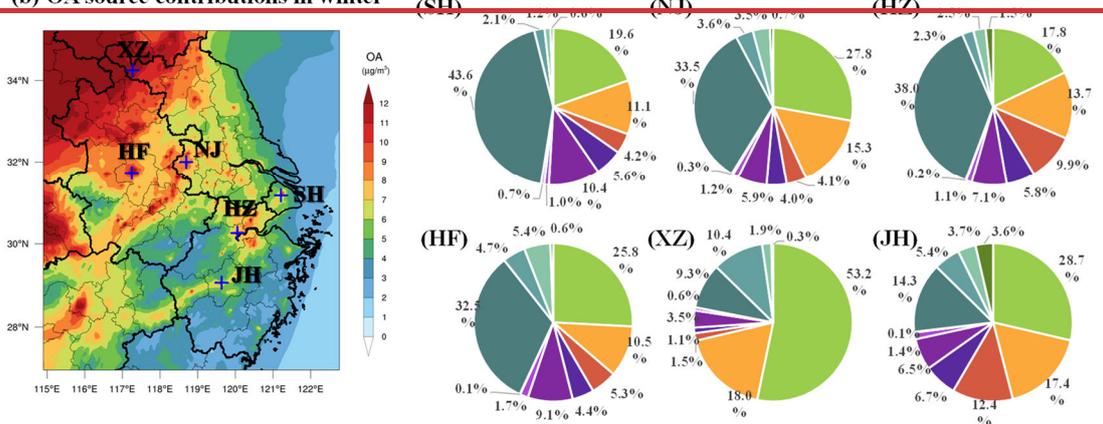

778 and ~~11.4%~~~~10.5%~~ (winter). In southern YRD, represented by JH, while biogenic
779 contribution was prevailing in summer (~~38.2%~~~~37%~~), super-regional transportation was
780 significant in winter (~~31.8%~~~~28.7%~~). Similar to other sub-regions, other major sources
781 also included the contributions of cooking emission of ~~12.2%~~~~14.8%~~ (summer) and
782 ~~11.4%~~~~14.3%~~ (winter), industrial processes of ~~12.9%~~~~8.7%~~ (summer) and ~~117.9%~~~~7.4%~~
783 (winter) and mobile sources of 13%. Yet southern YRD presented more evident increase
784 in the contribution from industrial solvent-use compared with other sub-regions.

785 To summarize, cooking, super-regional transportation, industrial process and mobile
786 sources were the predominant sources of OA in all sub-regions regardless of the season,
787 albeit enhanced contributions from biogenic sources to the OA formation in summer
788 was observed, especially in southern YRD. High contributions of cooking sources were
789 in accordance with the distributions of populations and high contributions of mobile
790 sources were somewhat expected, especially in the city centers. Source contributions of
791 OA varies in the intraregional scale implies that more targeted control measures need
792 to be designed according to the emission features of each city. Specifically, for densely
793 populated area, it is necessary to strengthen the future control strategy of cooking
794 emissions; special attention needs to be paid to the I/SVOC emissions from industrial
795 sources in eastern, central, and northern YRD region; mobile sources show its
796 significance in urban area of the region, dominated by the equal contributions from
797 gasoline and diesel vehicles, indicating further reductions on the I/SVOCs from vehicle
798 emissions are therefore critical for pollution control on city scale.

801 **Figure 89.** Source contributions of modeled OA concentrations from different sources during
 802 summer and winter in different cities of the region.

803 **4. Conclusions**

804 In this study, we established a high-resolution I/SVOC emission inventory with
 805 detailed source profiles and applied it into CMAQ v5.3 to simulate POA and SOA
 806 formation in YRD region of China. With the addition of I/SVOC emissions, simulation
 807 results show significant improvements on both temporal variations and spatial
 808 distributions of OA. Compared with the BASE simulation, where I/SVOC emissions
 809 were not included, the simulated SOA increased by 1.2-5 times in IMPROVE simulation,
 810 highlighting the significant contributions of I/SVOC emissions to SOA production. The
 811 remaining 10%-30% underestimation of OA indicates that future work is still
 812 needed in bridging the gap between simulation and observations, such as, measuring
 813 local emission factors and source profiles of I/SVOC from various local sources,

814 updating SOA formation mechanisms in model framework.

815 With the addition of source specific I/SVOC emissions, we successfully quantified
816 the contribution of each source to POA and SOA concentrations in YRD. For POA,
817 cooking emission is the predominant source, which concentrates in urban area of YRD
818 in accordance with the population distribution. For SOA, for the first time, we
819 demonstrate that I/SVOCs from industrial sources are dominant contributor, followed
820 by those from mobile sources. In summer, the contributions of biogenic emission to
821 total SOA are also non-negligible, especially for the cities in southern YRD. Spatial and
822 seasonal variations in the source contributions suggest that control strategies for OA
823 pollution should vary by cities and seasons. On regional scale, cooking emissions has
824 been emerging as an important POA source, not to mention their impacts on SOA
825 formation are not yet certain. Our results suggest the control measures on the cooking
826 emissions should be strengthened in the future for the further reduction of POA. We
827 also found that SOA in the region is primarily contributed by industrial I/SVOC
828 emissions, which urges in-depth studies of emission factors and source profiles of
829 I/SVOC emissions from industrial sources as well as the corresponding control
830 measures. On intraregional scale, for urban area, continuous reduction in I/SVOC
831 emissions from mobile sources, especially gasoline and diesel vehicles, are effective
832 measures in the mitigation of urban air pollution, which is also technically feasible as
833 has been demonstrated in Qi et al. (2021). Continuous improvement in emission
834 standards is one way to promote the reduction of motor vehicle related SOA.

835 *Data availability*

836 The gridded emissions of I/SVOCs from various sources for the YRD region
837 developed by this study at a horizontal resolution of 4 km × 4 km can be downloaded
838 from the following website (<https://doi.org/10.6084/m9.figshare.19536082.v1>).
839 Additional related data are available upon request by contacting the corresponding
840 author (Cheng Huang; huangc@saes.sh.cn).

841 *Supplement*

842 The supplement related to this article is available online.

843 *Author contributions*

844 CH, JA, DH, and MQ designed the research. CH and JA developed the I/SVOC
845 emission inventory. JA, MQ, and RY performed the model. DH, LQ, MZ, YL, SZ, and
846 QW collected the observation data. CH, JA, DH, and HW analyzed the results. CH, JA,
847 and DH wrote the paper.

848 *Competing interests*

849 The authors declare that they have no conflict of interest.

850 *Acknowledgement*
