**Abstract.** A knowledge gap exists concerning how chemical composition and sources respond to implemented policy control measures for aerosols, particularly in a semi-arid region. To address this, a single year's offline measurement was conducted in Hohhot, a semi-arid city in northern China, to reveal the driving factors of severe air pollution in semi-arid region and assess the impact of the COVID-19  
20 lockdown measures on chemical characteristics and sources of PM<sub>2.5</sub>. Organic matter, mineral dust, sulfate, and nitrate, accounted for 31.5%, 14.2%, 13.4%, and 12.3% of the total PM<sub>2.5</sub> mass, respectively. Coal combustion, vehicular emissions, crustal sources, and secondary inorganic aerosols were the main sources of PM<sub>2.5</sub> in Hohhot, at 38.3%, 35.0%, 13.5%, and 11.4%, respectively. Due to the coupling effect of emission reduction and improved atmospheric conditions, the concentration of secondary inorganic  
25 components, organic matter, elemental carbon, and chloride declined from the pre-lockdown period to the lockdown and post-lockdown period. Compared with the pre-lockdown period, the percentage of secondary inorganic components declined during the lockdown and post-lockdown period, while the mineral dust, organic matter, and elemental carbon increased. The rapid generation of secondary inorganic components caused by unfavorable meteorological conditions during lockdown led to serious  
30 pollution. This study elucidates the complex relationship between air quality and environmental policy.

**Keywords:** semi-arid city, source apportionment, chemical compositions, meteorological condition, COVID-19 lockdown

## 1 Introduction

35 With the rapid development of industrialization and urbanization, many developing countries, such  
as China and India, have suffered severe air pollution, especially from fine particulate matter ( $PM_{2.5}$ ,  
aerodynamic diameter  $\leq 2.5 \mu m$ ). To improve air quality, China has implemented various clean air  
policies (Zhang et al., 2019). As a result, the annual mean  $PM_{2.5}$  concentration in China decreased from  
50  $\mu g/m^3$  in 2015 (MEEC, 2015) to 33  $\mu g/m^3$  in 2020 (MEEC, 2020). However, the mean level of  $PM_{2.5}$  is  
40 still much higher than the new guideline of the World Health Organization ( $5 \mu g/m^3$ ) (WHO, 2021). It is a  
challenge to decrease the level of  $PM_{2.5}$  to such a low level in China, especially in northern China, which  
consumes the majority of coal for winter heating. Insufficient understanding of the complex relationship  
between air quality and environmental policy limits the effectiveness of our control measures to improve  
air quality.

To limit the spread of the COVID-19 pandemic, most cities around the world implemented strict  
45 lockdown measures, and the anthropogenic emission of air pollutants was reduced substantially, which in  
turn has caused considerable changes in the chemical composition and sources of  $PM_{2.5}$ . The lockdown  
provided a good opportunity to study the effect of emission reduction on air quality. In addition, this  
scenario can be used by policymakers to formulate effective policies to prevent atmospheric pollution.  
Stringent traffic restrictions during the COVID-19 lockdown led to important reductions in the  
50 concentrations of elemental carbon, metals, and nitrate in an urban site of the western Mediterranean  
(Clemente et al., 2022). The substantial reduction in nitrate in the Beijing-Tianjin-Hebei region during the  
lockdown period was attributed to the drastic reduction in vehicular movement and the suspension of  
public transport (Sulaymon et al., 2021). Primary pollutants were reported to have decreased dramatically  
due to the lockdown measures, while secondary pollutants were reported to have increased (Chang et al.,  
55 2020; Huang et al., 2021; Zheng et al., 2020). Secondary pollutants like  $PM_{2.5}$  and  $O_3$  depend more  
strongly on weather conditions and show a limited response to emission changes in single sectors  
(Matthias et al., 2021; Gao et al., 2021).

Extensive studies have been conducted to investigate the responses of atmospheric pollutants to  
emission reduction during the COVID-19 lockdown measures. However, most of the previous studies are  
60 based on online observation and/or satellite-derived data and have focused on the changes in atmospheric  
pollutants, influence of meteorological conditions, and emission reduction. Relatively few studies have  
focused on the chemical composition and sources of  $PM_{2.5}$  in semi-arid regions, especially using offline  
measurement. Source apportionment using an online dataset is impeded by the missing information on Si  
and Al (Gao et al., 2016), resulting in considerable uncertainty in the estimation of dust sources. Mineral  
65 dust was considered to be one of the main components of aerosols in semi-arid regions (Kumar and Sarin,  
2009; Wang et al., 2016). As a typical semi-arid city of northern China, Hohhot suffers frequent air  
pollution in spring and winter. The chemical characteristics, sources, and their response to implemented  
control measures in this region are still unclear.

In response to the substantial reduction in anthropogenic emission, the concentration of  $PM_{2.5}$  in  
70 most of the European cities (Matthias et al., 2021; Tobías et al., 2020), US cities (Pata, 2020), Indian

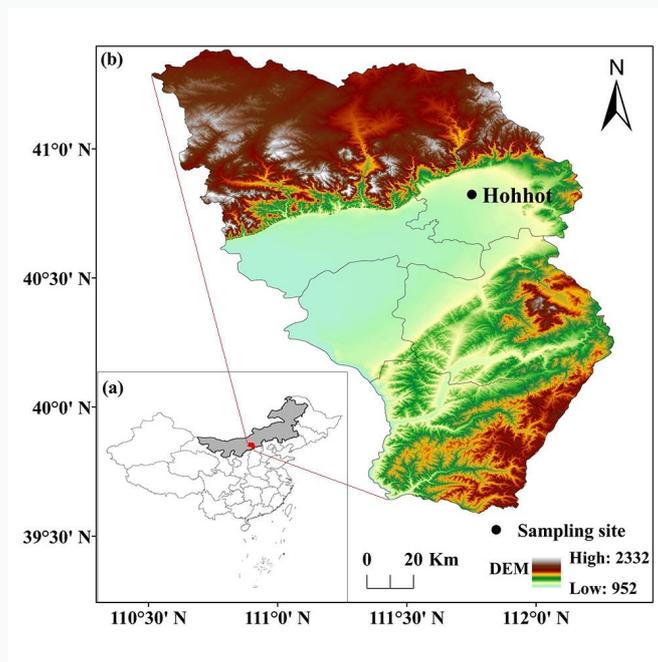

75 cities (Sharma et al., 2020), Chinese cities (Bao and Zhang, 2020), and the southeast Asia region (Kanniah et al., 2020) have decreased substantially, compared to pre-lockdown (pre-LD) periods and/or previous years. However, compared with the decreasing trends of most of the cities in the world, the concentrations of PM<sub>2.5</sub> in some cities of the North China Plain have increased unexpectedly. The anomalously enhanced nitrate in Tianjin during the lockdown (LD) period is a response to the abnormal increase in relative humidity (Ding et al., 2021). The abnormal increase in PM<sub>2.5</sub> in northern China during the LD period was probably caused by uninterrupted emissions from power plants and petrochemical facilities, as well as the influence of adverse weather conditions (Gao et al., 2021). The extreme reduction in anthropogenic emissions did not address the occurrences of severe haze events in northern China because of unfavorable meteorological events (Le et al., 2020; Shi et al., 2021), increased atmospheric oxidizing capacity (Wang et al., 2020), enhanced secondary formation (Chang et al., 2020; Huang et al., 2021), and regional transport (Shen et al., 2021; Lv et al., 2020; Zhang et al., 2021). There is no consensus on the reasons for the unexpected increase in PM<sub>2.5</sub> during the LD period. It is therefore essential to conduct a comprehensive study on the chemical composition and sources of PM<sub>2.5</sub> in this region, especially during the LD period.

80 The main objectives of this study were to (1) identify the long-term chemical characteristics and sources of PM<sub>2.5</sub> in a semi-arid city, (2) investigate the impact of COVID-19 lockdown measures on the chemical composition, (3) reveal the causes of the rapid increase in PM<sub>2.5</sub> during different heavy pollution episodes. The results of this study will provide a more comprehensive understanding of PM<sub>2.5</sub> pollution control in semi-arid regions.

## 2 Material and methods

### 2.1 Study area and sampling

95 Hohhot (40°51′ – 41°8′ N, 110°46′ – 112°10′ E) is located in the northern part of the North China Plain and the central part of Inner Mongolia Autonomous Region. It is a core city of the Hohhot-Baotou-Ordos urban agglomeration, with an area of 17,224 km<sup>2</sup> and a population of 3,446,100. Topographically, it is in the alluvial lake basin between the Yinshan Mountains and the Yellow River, with Daqing Mountains in the north and Manhan Mountain in the southeast. Hohhot has a typical semi-arid climate, with a mean annual precipitation of 335.2–534.6 mm, which occurs mainly in summer. Due to the minimal precipitation and dry continental terrain, frequent dust storms occur in spring. It has six months of coal-fired heating period (15<sup>th</sup> October–15<sup>th</sup> April the next year). The sampling site was located on the rooftop of the main building of the Ecological and Environmental Department of the Inner Mongolia autonomous region (Figure 1) and represents a typical semi-arid urban environment.

**Figure 1.** Location of (a) Hohhot in China, and (b) the sampling site in Hohhot

105 The 23-h (10:00 to 09:00 the next day)  $PM_{2.5}$  samples were collected in parallel on quartz filters  
(Pallflex Tissuquartz™, 90 mm, USA) and polypropylene filters (Beijing Safelab Technology Ltd., 90  
mm, China) by medium volume air samplers (Model 2050, Qingdao Laoshan Applied Technology  
Research Institute, China) with a flow rate of 100 L/min. The quartz filters were used for the analysis of  
water-soluble ions (WSIs) and carbonaceous aerosols (OC and EC), while polypropylene filters were  
110 used for inorganic elements. A total of 722  $PM_{2.5}$  samples (361 quartz and 361 polypropylene filters) were  
collected from 8<sup>th</sup> October, 2019 to 7<sup>th</sup> October, 2020. Before and after sampling, the quartz filters and  
polypropylene filters were conditioned for at least 24 h at a stable temperature ( $20 \pm 1$  °C) and relative  
humidity ( $50 \pm 5\%$ ) and then weighed by a microbalance (CP225D, Sartorius, Germany), with a  
sensitivity of  $\pm 0.01$  mg. After weighing, all of the filters were stored at  $-18$  °C until analyzed. The online  
115 hourly concentrations of gaseous pollutants ( $SO_2$ ,  $NO_2$ , CO, and  $O_3$ ) were collected at the same site. In  
addition, the hourly meteorological variables, including relative humidity (RH), wind speed (WS), wind  
direction (WD), ambient temperature (T), and atmospheric pressure (P) were observed synchronously  
using an automatic weather station (WS500-UMB, Lufft, Germany).

## 2.2 Chemical analysis

120 The water-soluble ions (WSIs, including  $SO_4^{2-}$ ,  $NO_3^-$ ,  $NH_4^+$ , Cl<sup>-</sup>, F<sup>-</sup>, K<sup>+</sup>, Ca<sup>2+</sup>, Na<sup>+</sup>, and Mg<sup>2+</sup>) were  
determined using ion chromatography (Metrohm 881Compact IC Pro, Switzerland). The organic carbon  
and elemental carbon (EC) were analyzed by a thermal/optical carbon analyzer (DRI Model 2001,

Atmoslytic Inc., USA) following the IMPROVE\_A protocol (Chow et al., 2007; Cao et al., 2005). The detailed descriptions of the procedures for WSIs and carbonaceous aerosols can be found in our previous studies (Zhou et al., 2018; Zhou et al., 2016). The inorganic elements, including Si, Al, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Cu, Zn, Co, and Pb were analyzed by energy dispersive X-ray fluorescence spectroscopy (Epsilon5, PANalytical B.V., Netherlands) according to the National Environmental Protection standard method of China (HJ 829-2017) and previous studies (Dao et al., 2022; Dao et al., 2021; Chiari et al., 2018). All the analytical procedures were strictly controlled to reduce artificial interference.

### 2.3. Data analysis

The sulfur oxidation ratio (SOR), nitrogen oxidation ratio (NOR), organic matter (OM), mineral dust (MD), and secondary organic carbon (SOC) were calculated using the following equations (Xie et al., 2019; Liu et al., 2021):

$$\text{SOR} = [\text{SO}_4^{2-}] / ([\text{SO}_4^{2-}] + [\text{SO}_2]) \quad (1)$$

$$\text{NOR} = [\text{NO}_3^-] / ([\text{NO}_3^-] + [\text{NO}_2]) \quad (2)$$

$$\text{OM} = 1.6 \times [\text{OC}] \quad (3)$$

$$\text{MD} = 2.14 \times [\text{Si}] + 1.89 \times [\text{Al}] + 1.40 \times [\text{Ca}] + 1.43 \times [\text{Fe}] + 1.58 [\text{Mn}] + 1.21 \times [\text{K}] + 1.67 \times [\text{Ti}] \quad (4)$$

$$\text{SOC} = \text{OC} - \text{EC} \times (\text{OC}/\text{EC})_{\min} \quad (5)$$

### 2.4 Source apportionment

Positive matrix factorization (PMF, version 5.0) was used to estimate source contributions of  $\text{PM}_{2.5}$  in Hohhot according to the user guide of the United States Environmental Protection Agency (Norris et al., 2014) and previous study (Paatero and Tapper, 1994). A total of fifteen dominant species ( $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , OC, EC, Si, Cl, Ti, Fe, Zn, and Pb) were used as input files for the PMF modeling. The displacement (DISP) and bootstrap (BS) methods were conducted to estimate the uncertainty and rotation ambiguity of PMF solutions (Paatero et al., 2014). According to the changes of  $Q/Q_{\text{expected}}$  and estimation diagnostics analysis, six factors solutions were selected. All of the factors showed a BS mapping above 80 %. The decreased Q values were lower than 0.1 %, and no factor swap occurred. The results indicated that the BS uncertainties can be fully interpreted and the selected solutions were sufficiently robust (Tian et al., 2020; Wang et al., 2021). The summary of error estimation diagnostics from BS and DISP were shown in Tables S1–S5. The source profiles of  $\text{PM}_{2.5}$  were shown in Figures S3–S7.

## 3 Results and discussion

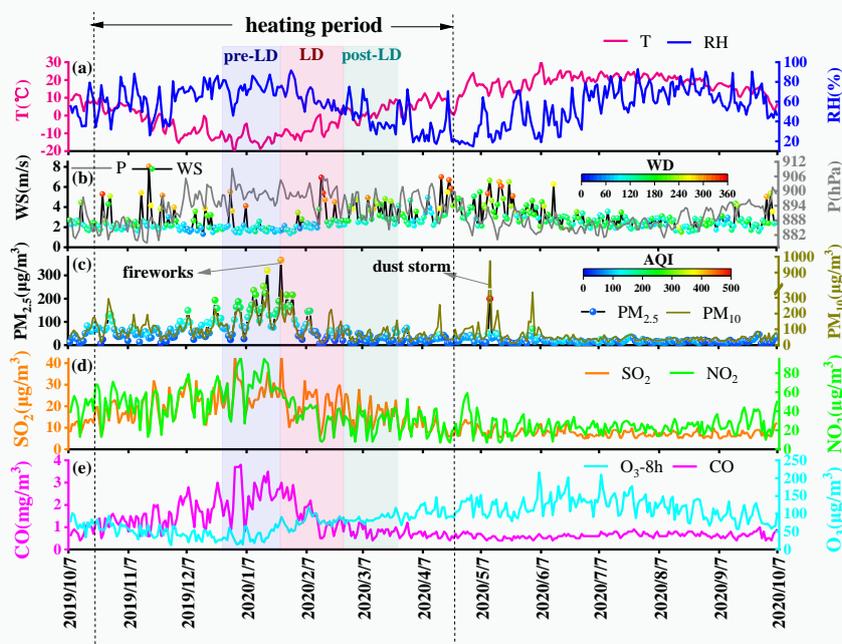

### 3.1 Temporal variation of $\text{PM}_{2.5}$ and chemical composition

The daily concentration of  $\text{PM}_{2.5}$  varied dynamically from 4.0 to 293.8  $\mu\text{g}/\text{m}^3$ , with an annual mean concentration ( $\pm$  standard deviation) of  $42.6 \pm 40.2 \mu\text{g}/\text{m}^3$ , which is higher than the annual mean concentration limits (35  $\mu\text{g}/\text{m}^3$ ) of the National Ambient Air Quality Standards (NAAQS, GB 3095-2012).

There were 51 daily  $\text{PM}_{2.5}$  concentrations higher than the 24-h average concentration limit ( $75 \mu\text{g}/\text{m}^3$ ) of NAAQS, accounting for 14.1% of the total number of sampling days. Furthermore, most of them occurred in the heating period, particularly with a predominant wind direction from the southeast. The high intensity of coal combustion for heating discharges a large number of gaseous pollutants ( $\text{SO}_2$ ,  $\text{NO}_2$ , and CO), coupled with unfavorable meteorological conditions (high RH and low WS, Figure 2a, 2b), lead to the rapid accumulation of air pollutants (Figure 2c, 2d).

160

**Figure 2.** Daily variations in atmospheric pollutants and meteorological variables in Hohhot during the sampling period from 8<sup>th</sup> October, 2019 to 7<sup>th</sup> October, 2020. The blue, red, and green backgrounds represent the pre-lockdown, lockdown, and post-lockdown periods, respectively. T, RH, WS, WD, P, and AQI represent the ambient temperature, relative humidity, wind speed, wind direction, atmospheric pressure, and air quality index, respectively.

During haze episodes, a substantial increase in secondary inorganic components (sulfate, nitrate, and ammonium, SNA) was observed (Figure 3a–3c). The rapid increase of SNA was the main driving factor behind the increase in  $\text{PM}_{2.5}$ . High RH is conducive to the secondary formation of sulfates and nitrates, presenting higher SOR and NOR in these pollution periods (Figure 3a, 3b). In the heating period, in addition to the contribution of SNA to  $\text{PM}_{2.5}$ , the primary pollutants such as  $\text{Cl}^-$  and EC were higher than those in the non-heating period (Figure 3d, 3e). Hohhot is an inland city, basically unaffected by sea salt. Furthermore, a higher average  $\text{Cl}^-/\text{Na}^+$  ratio (3.43 for January) suggests the presence of non-marine anthropogenic sources of chloride. Chloride is mainly emitted from coal combustion facilities in Hohhot, especially during the heating period. It can be used as an auxiliary marker of coal combustion in Hohhot. Higher SOR was observed in winter and summer in Hohhot (Figure 3a). High SOR in winter is mainly

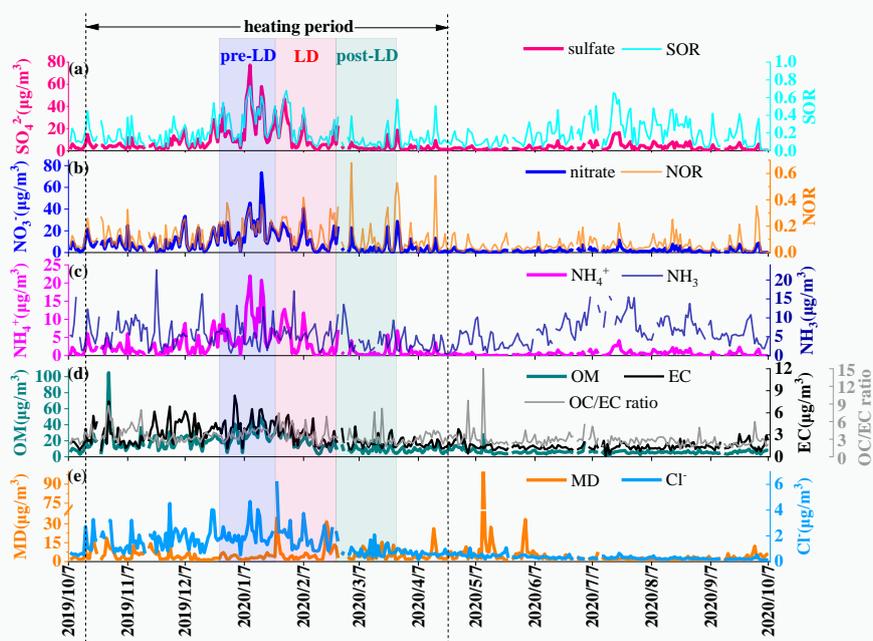

170

175

180

caused by heterogeneous processes under high RH conditions, while that in summer is caused by homogeneous gas-phase oxidation reactions under high temperatures and O<sub>3</sub> concentrations (Zhang et al., 2018; Li et al., 2017a). NOR was higher in winter, while lower in summer (Figure 3b). The higher NOR in winter can be ascribed to the rapid formation of nitrate under high RH. The lower NOR in summer may be related to the high temperature, which is favorable for nitrate volatilization (Daher et al., 2012).

185

**Figure 3.** Daily variations in chemical composition of PM<sub>2.5</sub>, SOR, NOR, NH<sub>3</sub>, and OC/EC ratio in Hohhot during the sampling period. The blue, red, and green background represent the pre-lockdown, lockdown, and post-lockdown periods, respectively. OM, MD, SOR, and NOR represent the organic matter, mineral dust, sulfur oxidation ratio, and nitrogen oxidation ratio, respectively.

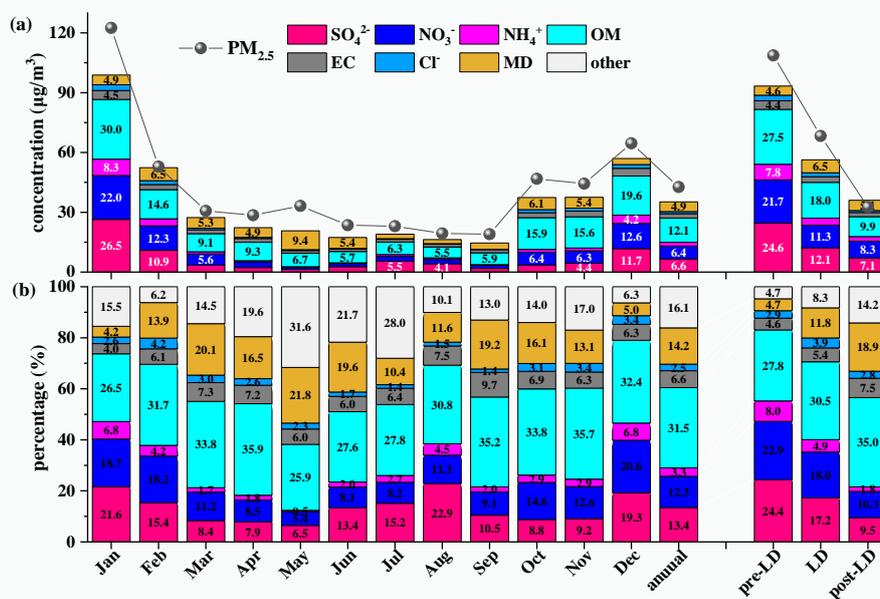

190

Hohhot initiated a Level-I public health emergency response control action on 25<sup>th</sup> January, 2020 and downgraded it to a Level-III response on 25<sup>th</sup> February, 2020. During this period, complete lockdown measures were taken to prevent the transmission of the COVID-19 coronavirus. The comparison of atmospheric pollutants (PM<sub>2.5</sub>, PM<sub>10</sub>, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, and CO) between the LD period (25<sup>th</sup> January to 24<sup>th</sup> February in 2020) and the same period in 2017–2019 are shown in Figure S1. The average concentrations of PM<sub>2.5</sub>, PM<sub>10</sub>, O<sub>3</sub>, and CO increased by 77.8%, 34.6%, 14.5%, and 5.9%, respectively, whereas the average concentrations of SO<sub>2</sub> and NO<sub>2</sub> decreased by 43.2% and 8.6%, respectively. An unexpected increase in PM<sub>2.5</sub> ( $p < 0.01$ ) was found during the LD period, whereas a considerable improvement was reported in most of the Asian (Ju et al., 2021; Ma and Kang, 2020; Sharma et al., 2020; Rodríguez-Urrego and Rodríguez-Urrego, 2020) and European cities (Collivignarelli et al., 2020; Gualtieri et al., 2020; Gkatzelis et al., 2021; Martorell-Marugán et al., 2021).

195

200 The monthly variation in chemical species of  $PM_{2.5}$  is shown in Figure 4. OM, MD, sulfate, and  
 nitrite were the major components of  $PM_{2.5}$ , accounting for 31.5%, 14.2%, 13.4%, and 12.3% of annual  
 average  $PM_{2.5}$ , respectively (Figure 4b). The proportion of MD was substantially higher than those of  
 other cities in South China (Huang et al., 2013), southwest China (Feng et al., 2021), southeast China (Li  
 et al., 2017b), and the Central Plains Urban Agglomeration (Liu et al., 2019), which is close to the cities  
 205 in northern China (Liu et al., 2021; Xie et al., 2019) and northwest China (Zhou et al., 2021). The result  
 indicates that the cities in arid or semi-arid regions (such as in northern China and northwest China) are  
 more susceptible to mineral dust sources. The monthly average concentrations of SNA and OM during  
 the heating period (15<sup>th</sup> October to 15<sup>th</sup> April next year), especially in January, were higher than those of  
 other non-heating months (Figure 4a), which were related to the coupled effect of a large amount of  
 210 atmospheric precursors ( $SO_2$ ,  $NO_2$ , and volatile organic compounds) and unfavorable meteorological  
 conditions (high RH and low WS, Figure S2). Due to the frequent dust storms, the average concentration  
 of MD in May (9.4  $\mu g/m^3$ ) was considerably higher than that of other months, accounting for 21.8% of  
 $PM_{2.5}$  mass. The relatively high proportion of sulfates in August may be caused by its higher SOR, which  
 is enhanced by photochemistry under high T, strong solar radiation, and high RH conditions.

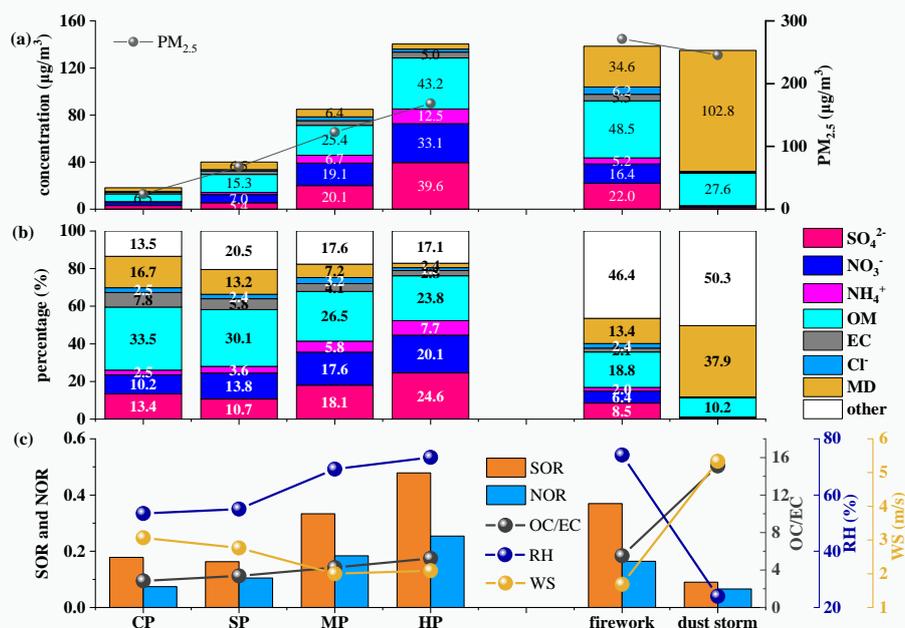

215 **Figure 4.** Monthly variation in (a) concentrations and (b) percentages of chemical components of  $PM_{2.5}$  in Hohhot during the sampling period. Pre-LD, LD, and post-LD represent the pre-lockdown, lockdown, and post-lockdown period, respectively. OM and MD represent organic matter and mineral dust, respectively.

220 The OM, sulfate, nitrate, and ammonium were the predominant components of  $PM_{2.5}$  during the pre-LD period (25<sup>th</sup> December, 2019 to 24<sup>th</sup> January, 2020), accounting for 27.8, 24.4, 22.9, and 8.0% of  $PM_{2.5}$  mass, respectively (Figure 4). During this period, the SNA contributed 55.3% of  $PM_{2.5}$ , slightly higher than those of the cities in northern China such as Xi'an (50.0%) (Tian et al., 2021) and Beijing (48.5%) (Ren et al., 2021), and lower than the cities in southern China such as Guangzhou (78.7%)  
225 (Wang et al., 2021), Nanjing (68.2%) (Ren et al., 2021), and Shanghai (75.4%) (Chen et al., 2020). OM contributed 27.8% of  $PM_{2.5}$ , lower than that of Xi'an (48.0%) (Tian et al., 2021), and higher than that of the other cities listed in Table S6. Most studies listed in Table S6 used online data, from which it is not possible to calculate the contribution of MD. However, our offline data showed that MD contributed  
230 11.8% and 14.2% of  $PM_{2.5}$  during the LD period and for the whole year, indicating that MD is one of the main contributors of  $PM_{2.5}$  that has been neglected in previous studies. The proportion of chemical species ranked as OM (30.5%) >  $NO_3^-$  (18.0%) >  $SO_4^{2-}$  (17.2%) > MD (11.8%) > EC (5.4%) >  $NH_4^+$  (4.9%) >  $Cl^-$  (3.9%) during the LD period (25<sup>th</sup> January, 2020 to 24<sup>th</sup> February, 2020), whereas the series OM (35.0%) > MD (18.9%) >  $NO_3^-$  (10.3%) >  $SO_4^{2-}$  (9.5%) > EC (7.5%) >  $Cl^-$  (2.8%) >  $NH_4^+$  (1.8%) occurred during the post-LD period (25<sup>th</sup> February, 2020 to 24<sup>th</sup> March, 2020). Due to the decline in the  
235 emission intensity under the strict control measures, the concentration of aerosol compositions (except for MD) decreased substantially (Figure 4a). Compared with the pre-LD period, the percentage of SNA decreased continuously during LD and post-LD, while the MD, OM, and EC increased. The atmospheric diffusion conditions improved during the post-LD period (Figure S2), and the concentration of OM, SNA, EC, and  $Cl^-$  decreased substantially. These results suggest that the substantial changes that occurred in  
240 source contributors after the COVID-19 outbreak resulted in dramatic changes to aerosol composition.

To elucidate the rapid increase in  $PM_{2.5}$ , the sampling days were divided into four categories according to the daily concentration of  $PM_{2.5}$ : clean (CP,  $PM_{2.5} < 35 \mu g/m^3$ ), slightly polluted (SP,  $35 \leq PM_{2.5} < 75 \mu g/m^3$ , moderately polluted (MP,  $75 \leq PM_{2.5} < 150 \mu g/m^3$ , and heavily polluted (HP,  $150 \mu g/m^3 \leq PM_{2.5}$ ). The values of 24<sup>th</sup> January, 2020 (Chinese New Year Eve) and 11<sup>th</sup> May, 2020 (a  
245 dust storm day) were excluded from the HP analysis. These two heavy pollution days were analyzed separately as two types, namely firework and dust storm. The meteorological conditions, gaseous precursors, and chemical composition of different pollution levels and types are shown in Figure 5. The concentrations of OM, sulfate, nitrate, and ammonium were in the order of CP < SP < MP < HP.

250 **Figure 5.** (a) Concentrations and (b) percentages of chemical components in PM<sub>2.5</sub>, (c) meteorological conditions, SOR, NOR, and OC/EC at different pollution levels and during different types of pollution events. CP, SP, MP, and HP represent clean period (PM<sub>2.5</sub> < 35 μg/m<sup>3</sup>), slightly polluted (35 ≤ PM<sub>2.5</sub> < 75 μg/m<sup>3</sup>), moderately polluted (75 ≤ PM<sub>2.5</sub> < 150 μg/m<sup>3</sup>, and heavily polluted (150 μg/m<sup>3</sup> ≤ PM<sub>2.5</sub>), respectively.

255 From CP to HP, the percentages of SNA increased (from 26.1% to 52.4%), whereas the percentages of OM and MD decreased (from 33.5% to 23.8%, and from 16.7 to 2.4, respectively). This response is related to the adverse meteorological conditions characterized by high RH and low WS, leading to the enhanced formation of SNA (higher SOR and NOR). The values of SOR increased from 0.18 during CP to 0.48 during HP. The values of NOR increased from 0.07 during CP to 0.25 during HP. The results suggest enhanced SNA formation during heavy pollution episodes. The coupled effects of high RH and

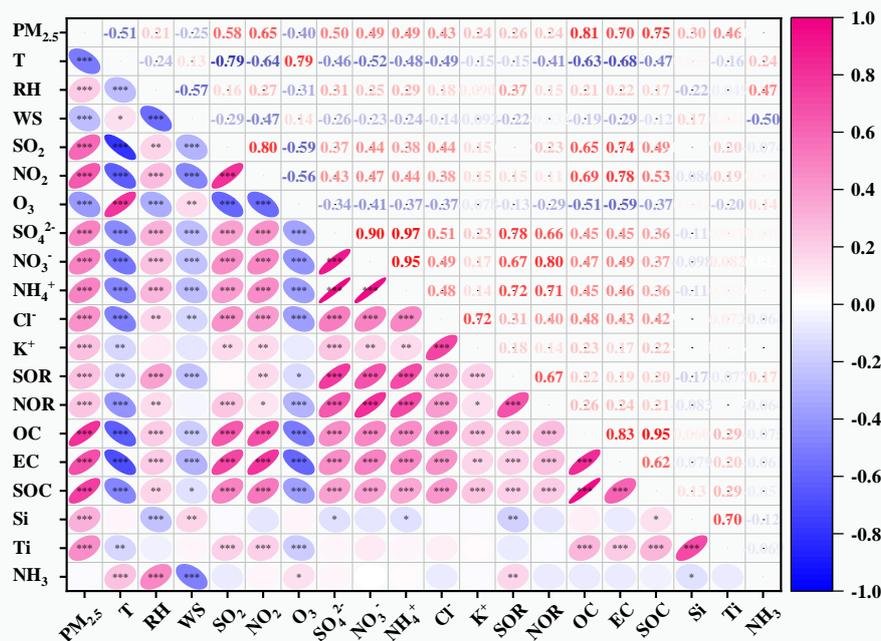

260 low WS promoted the rapid increase of fine particulate matter on haze days in Hohhot. The high WS is beneficial for the elimination of atmospheric pollutants, resulting in low concentrations of SO<sub>2</sub> and NO<sub>2</sub> on dust storm days. Furthermore, the low RH is detrimental to the secondary formation of SNA (lower SOR and NOR), resulting in a lower SNA content in dust storm days. MD and OM contribute 102.8 and 27.6 μg/m<sup>3</sup> to PM<sub>2.5</sub> during dust storm days, accounting for 37.9% and 10.2% of PM<sub>2.5</sub>, respectively. The proportion of MD was highest in dust storm days, mainly because of the relatively high WS and low RH that were conducive to the re-suspension of crustal dust. During Lunar New Year, fireworks discharge a large number of gaseous pollutants, coupled with low WS and high RH, the concentrations of SNA, OM, and EC increased rapidly, resulting in serious pollution.

265

270 **3.2 Factors influencing PM<sub>2.5</sub>**

The correlation between the chemical composition of PM<sub>2.5</sub>, metrological variables, and air pollutants are shown in Figure 6. PM<sub>2.5</sub> was negatively correlated with O<sub>3</sub>, T, and WS at  $p < 0.001$ , indicating that high WS was beneficial for the elimination of fine particulate matter, while O<sub>3</sub> and T were mainly related to seasonal variation in sources and meteorological conditions. PM<sub>2.5</sub> was positively correlated with most of the aerosol components and gaseous pollutants, indicating that the source of PM<sub>2.5</sub> was very complex and influenced by a variety of factors. The SNA in PM<sub>2.5</sub> was positively correlated with RH ( $p < 0.001$ ), indicating that high RH was beneficial to the heterogeneous formation of SNA.

280 **Figure 6.** Correlation between chemical components of PM<sub>2.5</sub>, metrological variables, SOR, NOR, and air pollutants in Hohhot during the sampling period (\*  $p < 0.05$ , \*\*  $p < 0.01$ , \*\*\*  $p < 0.001$ ).

The results suggest that RH played a vital role in the formation of haze by accelerating the conversion of SO<sub>2</sub> to SO<sub>4</sub><sup>2-</sup> and NO<sub>2</sub> to NO<sub>3</sub><sup>-</sup>, deteriorating the air quality. NOR was negatively correlated with T at  $p < 0.001$ , which may be related to the volatility of NH<sub>4</sub>NO<sub>3</sub>, which decomposes easier at higher T (He et al., 2012). SOR and NOR was positively correlated with RH at  $p < 0.001$  and  $p < 0.05$ , respectively, suggesting that both SOR and NOR were influenced by RH. SNA was negatively correlated with WS ( $p < 0.001$ ), indicating that high WS was conducive to the rapid elimination of SNA. SNA and its gaseous precursors (SO<sub>2</sub> and NO<sub>2</sub>) were positively correlated ( $p < 0.001$ ) but not related to NH<sub>3</sub>, indicating that the formation of SNA was mainly controlled by SO<sub>2</sub> and NO<sub>2</sub> rather than NH<sub>3</sub>. The carbonaceous aerosols (OC, EC, and SOC) were positively correlated with Cl<sup>-</sup>, SNA, SO<sub>2</sub>, and NO<sub>2</sub> ( $p <$

290 0.001), which are mainly affected by their common source in coal, used in heating. Silicon was positively correlated with WS ( $p < 0.01$ ), indicating that high WS is beneficial to the re-suspension of soil or dust, resulting in an increase in Si in  $PM_{2.5}$ . Silicon was negatively correlated with RH ( $p < 0.001$ ), which was related to high WS and low RH in dust storm days.

### 3.3 Source apportionment of $PM_{2.5}$

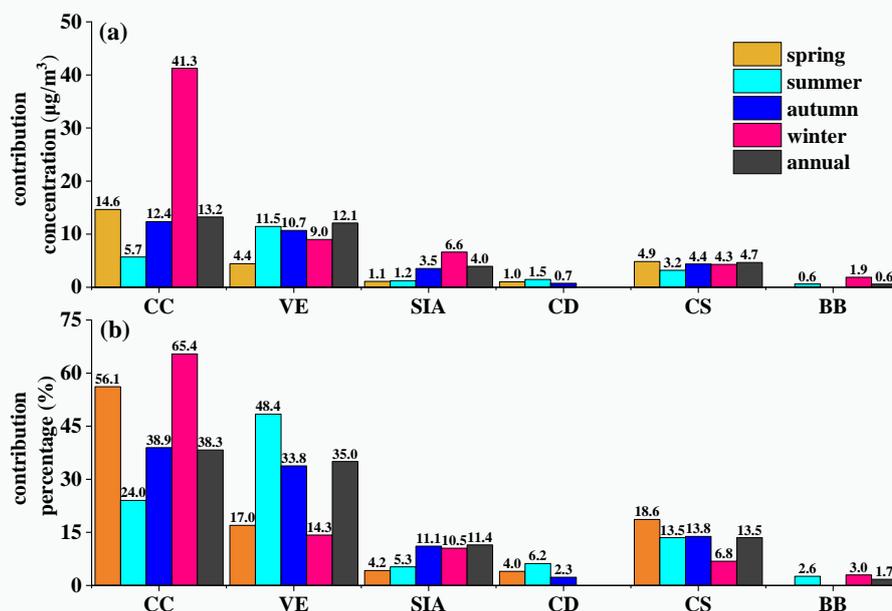

295 The sources of  $PM_{2.5}$  were apportioned using the PMF model (EPA PMF 5.0). The results of the source apportionment during different sampling periods are shown in Figure 7 and summarized in Table S7. The  $PM_{2.5}$  concentrations in spring, summer, autumn, winter, and annual were 32.4, 24.3, 37.0, 80.8, 42.6  $\mu\text{g}/\text{m}^3$ , respectively. Coal combustion (CC), vehicular exhaust (VE), crustal sources (CS), and secondary inorganic aerosols (SIA) were the main contributors to  $PM_{2.5}$  over the year, contributing 38.3%, 300 35.0%, 13.5%, and 11.4% to  $PM_{2.5}$ , respectively. The contribution of primary sources such as CC, VE, and dust source (refer to the sum of construction dust and crustal sources in this study) in Hohhot was higher than the megacities such as Beijing (Zkov á et al., 2016), Tianjin (Tian et al., 2021), and Shanghai (Feng et al., 2022), whereas the SIA and BB contributions were lower than these cities (Table S7). Therefore, the control of primary sources is an effective way to reduce the concentration of  $PM_{2.5}$  in 305 Hohhot.

The CC contribution to  $PM_{2.5}$  in spring, summer, autumn, and winter were 14.6, 5.7, 12.4, and 41.3  $\mu\text{g}/\text{m}^3$ , with a contribution percentage of 56.1%, 24.0%, 38.9%, and 65.4%, respectively. Coal combustion was the main contributor to  $PM_{2.5}$  in Hohhot, especially during the heating period. Summer is the only season for completely no coal-fired heating, relative low contribution of CC was observed in 310 summer. The VE contribution concentrations in spring, summer, autumn, and winter were 4.4, 11.5, 10.7, and 9.0  $\mu\text{g}/\text{m}^3$ , contributing 17.0%, 48.4%, 33.8%, and 14.3% to  $PM_{2.5}$ , respectively. The peak seasonal contribution percentage of VE was observed in summer. This is mainly attributable to a substantial decline in the contribution of other sources, increasing the proportion of VE. The contribution concentration of SIA followed the order of winter (6.6  $\mu\text{g}/\text{m}^3$ ) > autumn (3.5  $\mu\text{g}/\text{m}^3$ ) > summer (1.2 315  $\mu\text{g}/\text{m}^3$ ) > spring (1.1  $\mu\text{g}/\text{m}^3$ ), with a contribution percentage of 10.5%, 11.1%, 5.3%, and 4.2%, respectively. The higher contribution of SIA can be attributed to the large amount of gaseous precursors emitted by CC in winter, whereas the higher SIA contribution in autumn was related to the high oxidation rate. A relatively low contribution was observed in spring. The lower contribution of SIA in spring may be related to the high WS and low RH, which is unfavorable for SNA formation and accumulation.

320 The contributions concentration of CS followed the order of spring (4.9  $\mu\text{g}/\text{m}^3$ ) > autumn (4.4  $\mu\text{g}/\text{m}^3$ ) > winter (4.3  $\mu\text{g}/\text{m}^3$ ) > summer (3.2  $\mu\text{g}/\text{m}^3$ ), with a contribution percentage of 10.5%, 11.1%, 5.3%, and 4.2%, respectively. A relatively high contribution of CS to  $PM_{2.5}$  was observed in spring, which is associated with the increased long-range transportation of crustal sources due to dry and windy weather in Hohhot. The higher contribution of dust sources to  $PM_{2.5}$  have been reported in some other 325 semi-arid regions, such as Guanzhong basin (Li et al., 2022) and Lanzhou (Liang et al., 2019), indicating that the semi-arid regions are more susceptible to dust source. The source apportionment result indicated

that primary sources such as CC, VE, and dust sources in Hohhot were predominant, which is different from cities with high secondary pollution.

330 **Figure 7.** (a) Concentration and (b) percentage of source contribution to  $PM_{2.5}$  in Hohhot in spring,  
summer, autumn, winter, and over the year. CC, VE, SIA, CD, CS, and BB present coal combustion,  
vehicular emission, secondary inorganic aerosol, construction dust, crustal sources, and biomass burning,  
respectively.

#### 4 Conclusion

335 A single year's offline measurement was conducted in Hohhot to reveal the chemical characteristics  
and sources of  $PM_{2.5}$  in a semi-arid region. Organic matter, mineral dust, sulfate, and nitrite were the  
predominant components of  $PM_{2.5}$  in Hohhot, and the coal combustion, vehicular emission, crustal  
sources, and secondary inorganic aerosols were the main contributors to  $PM_{2.5}$ . The high proportion of  
340 mineral dust composition and higher contribution of crustal sources to  $PM_{2.5}$  indicated that cities in semi-  
arid regions are more susceptible to dust sources. The heavy pollution in winter can be attributed to the  
rapid increase of SNA under high RH and low WS conditions, while the heavy pollution in spring was  
associated with long-range transmission of crustal sources due to the dry and windy weather. Compared  
with the pre-lockdown period, the percentage of secondary inorganic components declined during the  
lockdown and post-lockdown period, while the mineral dust, organic matter, and elemental carbon  
345 increased.

A relatively high contribution of primary sources, such as coal combustion and dust sources, was  
observed in Hohhot. Therefore, the control of primary sources could be an effective way to reduce the

concentration of PM<sub>2.5</sub> in Hohhot. The unfavorable metrological conditions played an integral role during winter and promoted SNA formation and accumulation, causing frequent heavy pollution events. The  
350 reduction in anthropogenic activities and the important role of meteorology in the formation of air  
pollutants should be considered in aerosol quality and policy measures. This study can provide a new  
insight for the formulation of effective policies to improve aerosol pollution in semi-arid regions.
