**Abstract.** The Radio Occultations and Heavy Precipitation (ROHP) experiment aboard the Spanish PAZ satellite was deployed in 2018 with the objective of demonstrating the ability of Polarimetric Radio Occultation measurement (PRO) concept in detecting rain (liquid-phase precipitation). Analysis of these data has also demonstrated the ability of PRO to detect horizontally oriented frozen-phase precipitation. To verify these observations, a global climatological comparison is performed using the

5 Cloudsat (94-GHz) radar as a reference, for different heights and taking into account the radio occultation (limb-based) viewing geometry. A robust relationship (e.g. high correlation coefficient) is found between the polarimetric radio occultation observable differential phase shift ( $\Delta\Phi$ ) and the integrated ice water content (IWC) along the rays, globally, and for heights above the freezing level. PAZ observations capture the major precipitation features and the signatures of the Inter-Tropical Convergence Zone. The correlation coefficients maximize for tropical-oceans, for a range of heights between 5 and 12 km. The ratios  
10 between  $\Delta\Phi$  and along-ray integrated IWC mean climatologies are found to be within the range  $0.03 - 0.09 \text{ mm kg}^{-1} \text{ m}^2$ , although uncertainty due to the IWC retrieval algorithm must be noted. Further evaluation of the ratios with single particle forward scattering simulations indicate that the scattering by frozen hydrometeors with a combination of effective densities, axis ratios and tilt angle distribution yield results that agree well with the observations. Overall, the global climatological results obtained in this study show the presence of horizontally oriented particles across the whole globe, and for a wide range  
15 of height layers.

## 1 Introduction

The Radio Occultations and Heavy Precipitation (ROHP) experiment aboard the Spanish PAZ satellite (Cardellach et al., 2014) has demonstrated the ability of the polarimetric Radio Occultation (PRO) technique to complement well-established RO processing techniques (e.g. Kursinski et al., 1997) with the detection of heavy precipitation (Cardellach et al., 2019; 20 Padullés et al., 2022). The detection is based on the total differential phase shift ( $\Delta\Phi$ ) accumulated along the RO ray paths, traveling from the Global Positioning System (GPS) satellite emitter to the dual linearly polarized (H, V) receiver on the PAZ Low Earth Orbiter (LEO). Being a limb-sounding technique, the rays travel through deeper layers of the atmosphere as the occultation advances, penetrating into the layers where clouds and precipitation are expected. This differential polarimetric

phase measurement, in units of length, is set as the primary observable for PRO. It depends on the hydrometeors encountered  
25 along the rays as follows (Cardellach et al., 2014):

$$\Delta\Phi = \int_L K_{dp} dL \quad (1)$$

where  $K_{dp}$  is the differential phase shift and  $L$  is the traveled distance. The  $K_{dp}$  is defined as:

$$K_{dp} = \frac{\lambda^2}{2\pi} \int_D \Re\{S_{hh} - S_{vv}\} N(D) dD \quad (2)$$

where  $\lambda$  is the wavelength (i.e. in the case of L-band GPS signals,  $\lambda = 0.192$  m, corresponding to 1.575 GHz),  $S_{hh, vv}$  are  
30 the co-polar components of the scattering amplitude matrix, and  $N(D)$  is the particle size distribution as a function of the  
equivalent particle diameter,  $D$  - i.e. the diameter of a sphere having the same mass.

$K_{dp}$  contains the dependence of PRO observable on a series of microphysics parameters, such as the size, the shape and the  
amount of hydrometeors. The scattering amplitude matrix ( $\mathbf{S}$ ,  $2 \times 2$ ) provides information of the scattered field after propagating  
35 through an ensemble of hydrometeors. It depends on the shape and type of the hydrometeors (e.g. raindrops, pristine ice  
crystals, aggregate of ice particles, etc.). The dependence on the shape is often expressed in terms of the axis ratio, i.e. the ratio  
between the two main axis of the particle. For a perfectly spherical particle,  $S_{hh} - S_{vv} = 0$ .  $K_{dp}$  also depends on the size of  
the hydrometeors. This dependence on the size is proportional to its volume, and therefore it is affected by the third moment  
of the  $N(D)$ . The water content (WC) is also affected by the third moment of  $N(D)$  as (e.g. Bringi and Chandrasekar, 2001):

$$WC = \frac{\pi}{6} \rho_{w,i} \int_D D^3 N(D) dD \quad (3)$$

40 where  $\rho_{w,i}$  is the density, typically of water or ice. Therefore, it is expected that there exists a relationship between  $K_{dp}$   
and WC. In fact, the use of  $K_{dp}$  to retrieve WC has been attempted before, for rain (e.g. Jameson, 1985) and for ice (e.g.  
Vivekanandan et al., 1994; Ryzhkov et al., 1998; Bukovčić et al., 2018; Nguyen et al., 2019) using radar at different frequencies  
ranging from S to K bands. However, in the case of ice and snow, there are additional factors that must be taken into account,  
45 namely, the percentage of horizontally oriented particles with respect to those that are randomly oriented, the effective density,  
and the shape and composition (i.e., dielectric constant of the ice/air media). In the case that all particles were randomly  
oriented, the  $K_{dp}$  would cancel out regardless of the amount of WC.

Shape and orientation of ice particles have a direct relationship with the life-cycle of precipitation (e.g. Gong et al., 2020).  
Furthermore, knowledge of shape and orientation is crucial for space-based retrievals of, for example, total ice water paths  
(e.g. Kaur et al., 2022), and could help in the assimilation of passive microwave data in the all-sky assimilation schemes (e.g.  
50 Barlakas et al., 2021). In this regard, PRO observations have potential to help constraining the orientation of the hydrometeors  
globally, with high vertical resolution. Other limb-sounding techniques, such as the Microwave Limb Sounder (MLS), have

previously been used to sense ice particles (e.g. Wu et al., 2009) and constrain their orientation (e.g. Davis et al., 2005), but MLS vertical resolution is low.

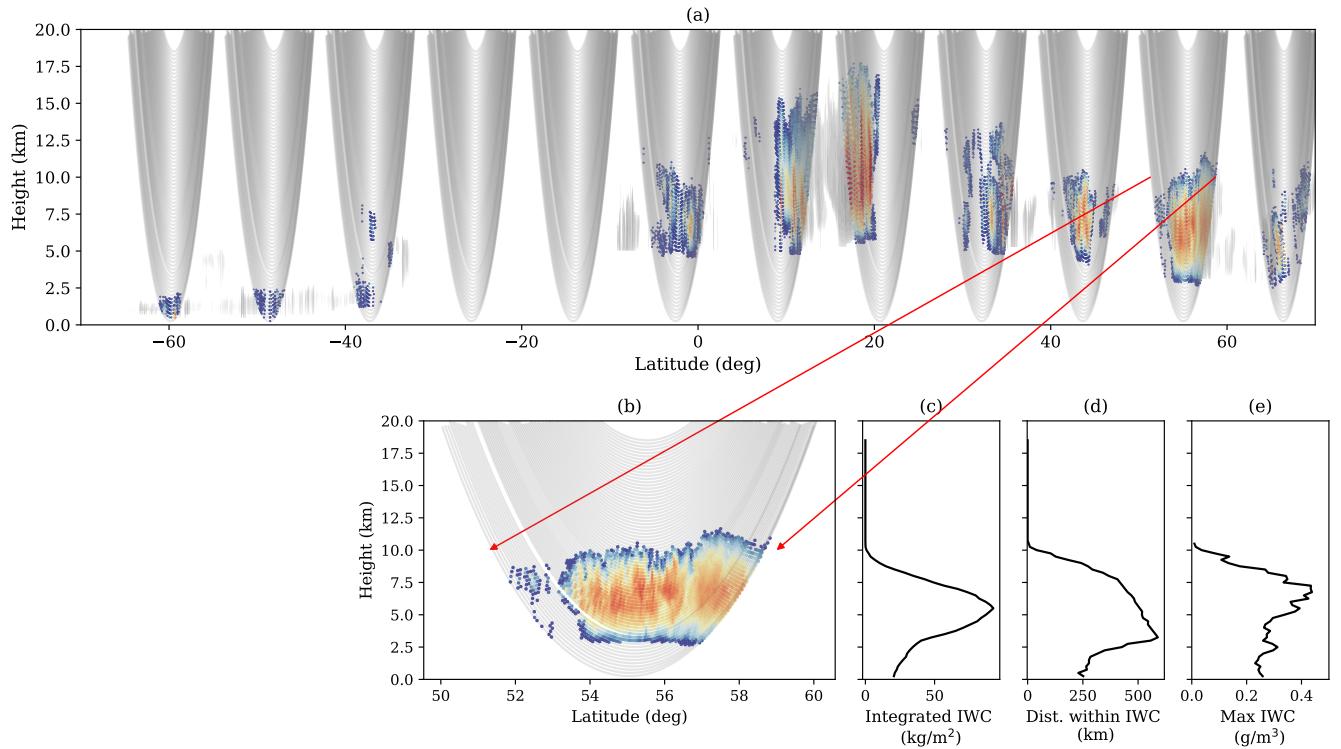

In Padullés et al. (2022), the authors showed that the presence of horizontally oriented frozen particles is required in order 55 to explain some of the PAZ PRO observations. In this new paper, we carry out an extensive analysis of the global relationships between ice water content (IWC) and  $\Delta\Phi$ . To do so, a synthetic radio occultation mission is simulated based on ice water properties provided by the Cloudsat data products between 2006-2016. That is, a set of actual radio occultation rays are artificially placed overlaying the Cloudsat curtain-like observations, continuously thorough the whole period. In this way the Cloudsat observations, like radar reflectivity, and its retrievals, like IWC, can be analyzed as if they were observed in RO 60 geometry. The statistics gathered from these observations would be equivalent to any other RO mission, if this was able to measure such quantities.

This strategy arises from the fact that there are no coincident observations between the Cloudsat and PAZ, due to different orbit parameters. However, the artificially generated products enable us to compare, in a statistical or climatological way, the PAZ  $\Delta\Phi$  observations with retrievals from Cloudsat, such as the IWC.

65 In this paper we focus on the spatial correlations between the IWC as would have been sensed by RO geometries in Cloudsat measured backgrounds and the  $\Delta\Phi$  from PAZ. If these two quantities are related, the spatial patterns should agree and the correlation should be high. This paper is therefore structured as follows: in Section 2 the artificial products based on Cloudsat retrievals and actual RO geometries are described. In Section 3 the correlations and relationship between the actual PAZ observations and the generated products are investigated. Finally, in Section 4, forward scattering simulations are used to 70 validate and contextualize the relationships found in the previous section. The paper ends with a discussion on the findings.

## 2 Cloudsat retrievals projected to RO geometries

The Cloudsat satellite was launched in April 28, 2006, and was regularly providing observations until August, 2020. It orbits at an approximate height of 715 km in a polar orbit (inclination of 98.2 deg) with an equatorial crossing time of about 1:30 PM. It carries a Cloud Profiling Radar (CPR) operating at 94 GHz (W-band) aimed at observing and characterizing clouds (Stephens 75 et al., 2008). Its high frequency radar is particularly good at sensing the frozen part of clouds and precipitation, whereas it has problems in penetrating to the lower altitudes in the deepest convective regions of precipitating systems (e.g. Battaglia et al., 2007). The parameters observed and retrieved from Cloudsat, of interest for this study, consist of the radar reflectivity ( $Z_e$ ) in the 2B-GEOPROF product (Marchand et al., 2008), the IWC retrievals from the DARDAR product (Delanoë and Hogan, 2010) version 3 (Cazenave et al., 2019), and the IWC and particle size distribution parameters ( $N_t$  and  $\sigma$ ) in the 2B-CWC-RO 80 product (Austin et al., 2009). Auxiliary thermodynamic parameters such as temperature and humidity have been obtained from the European Centre for Medium-range Weather Forecasts (ECMWF) model, provided along the IWC retrievals. All these parameters are obtained with a vertical resolution of 240 m from the surface up to 25-30 km. Since the aim of this study is the comparison with the PRO observations from PAZ, these parameters are transformed to the "RO observing frame", as is defined below.

**Figure 1.** Example of half Cloudsat orbit observations (in this case, derived ice water content) with the RO rays overlapped. The Cloudsat orbit granule is 01075. In panel (a), only the Cloudsat ice water content being overlapped by RO rays are colored. IWC not being overlapped by RO rays are in gray-scale. Panel (b) shows a more detailed image of the Cloudsat derived ice water content interpolated into the RO rays, corresponding to one of the slices shown in panel (a) - indicated by the red arrows. In panels (c), (d), and (e) there is shown the corresponding integrated ice water content, distance traveled by the ray within the influence of IWC, and the maximum IWC encountered along the ray, respectively, as a function of each ray tangent height.

85 In brief, radio occultation observations consist of a Low Earth Orbiter (LEO) tracking a Global Navigation Satellite System (GNSS) emitted signal while it is occulting behind the Earth horizon (e.g. Kursinski et al., 1997; Hajj et al., 2002). This results in the electromagnetic waves from GNSS crossing the different layers of the atmosphere tangentially with respect to Earth's surface, what is commonly known as a limb sounding observation. One implication of this kind of measurement is that rays cross a long portion of the atmosphere, becoming longer as rays approach the surface. In fact, when rays penetrate below 20  
90 km (region where clouds are expected), their traveled distance can be as large as  $\sim 800$  km. In the particular case of PRO, this has been discussed in Turk et al. (2021). Therefore, direct comparisons between the nadir-looking radar obtained parameters with measurements from RO does not provide relevant information in terms of understanding PRO observations.

The approach followed in this study has been to re-map the Cloudsat observed and retrieved parameters into the RO geometry. This is accomplished by using a set of actual RO rays and moving and rotating them in order to place them overlaid to the

95 curtain-like Cloudsat observations. RO rays often suffer from a drift as the occultation advances (e.g. the collection of rays do not form a perfectly vertical plane) due to the relative movement of the GNSS satellite and the LEO. However, for this study, the RO rays are collapsed into the Cloudsat vertical plane. Each Cloudsat orbit is split into 1200 km segments (resulting in approximately 29 segments per orbit), and the RO rays are placed in the middle of each of these segments. The first segment of each orbit is randomly displaced to ensure an even sampling of the Earth. After that, Cloudsat observed and derived parameters  
100 are interpolated into the RO rays. See Fig. 1-(a and b) for an example of the procedure.

This approach permits the consideration of two relevant things. The first is that one can see the actual extent, and therefore the influence area, of the cloud structures as sensed by PRO. The second one is that the amount of IWC along RO rays can be quantified (e.g. see panel c in Fig. 1). Therefore, the integrated IWC along these RO rays can be compared with the PAZ  
105 PRO  $\Delta\Phi$  observations. Each RO ray is identified by the height of its lowest point along the ray (i.e. height of what is called the "tangent point"), so the integrated quantities are expressed as function of such height.

Such an exercise is repeated for all Cloudsat orbits between 2009 and 2013, resulting in 342,109 artificial RO observations. For each of these artificial ROs, the following parameters are stored:

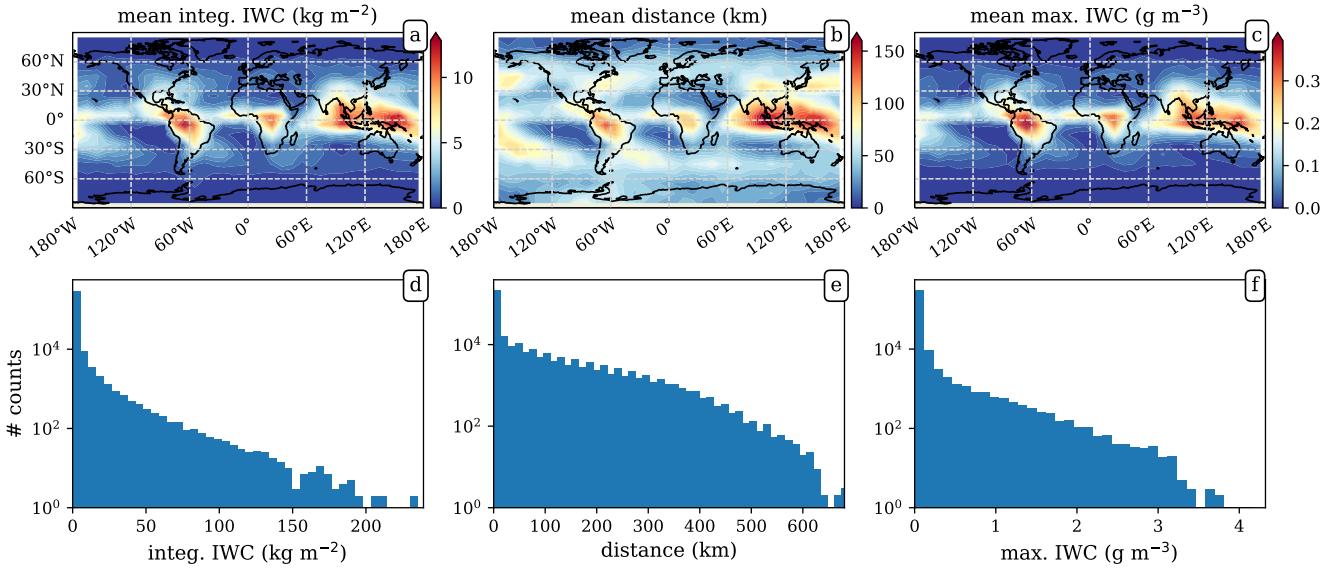

- Location and UTC time of each artificial RO observation. The location is determined by the latitude and longitude of the tangent point that has an altitude of 5 km. The UTC time is the one corresponding to the Cloudsat observation.
- The integrated IWC along each ray (as a function of tangent height), and the maximum IWC encountered along each ray (e.g. Fig. 1-(c and e)).
- The distance each ray traveled within the influence of non-zero water content (e.g. Fig. 1-(d)).
- Additionally, vertical profiles of some thermodynamic parameters at the location of each artificial RO, like the temperature, pressure and specific humidity, are obtained from the ECMWF auxiliary files.

115 The resulting data are called hereafter the Cloudsat-RO database. Since the focus will be only on the IWC, each Cloudsat-RO event is truncated at the freezing level to avoid major contributions from liquid phase precipitation. For this study, the effect of mixed-phase precipitation is not taken into account.

## 2.1 Statistics

Given that Cloudsat is orbiting on a polar orbit similar to that of PAZ satellite, and that RO rays are obtained from real RO  
120 events, the statistics gathered from the artificial collocation exercise should resemble the reality observed by PAZ. Furthermore, the integrated parameters along the RO rays mimic the behavior of  $\Delta\Phi$  observations, also obtained by PAZ as function of the tangent height. Therefore, analysis of the statistics of the artificial Cloudsat-ROs provides us with valuable information in order to understand the PAZ observations.

Figure 2 shows statistics of the along-ray integrated IWC, distance (here defined as the distance traveled by each ray within  
125 the influence of positive IWC), and maximum IWC encountered along each ray, obtained from the Cloudsat-RO database using the DARDAR product, corresponding to the rays whose tangent height is 9 km. The first thing to observe is the large values

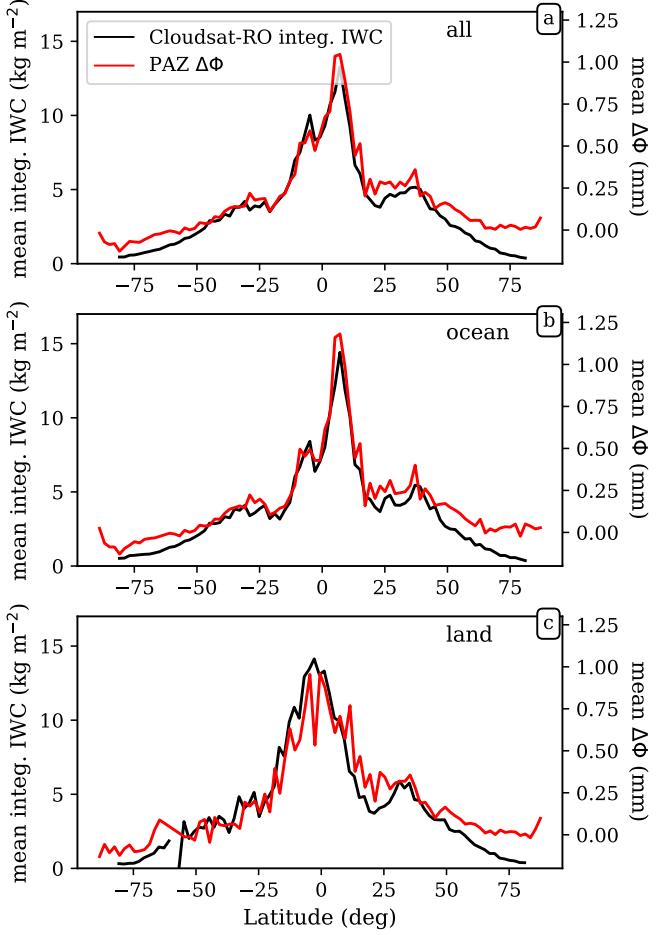

**Figure 2.** Statistics of the Cloudsat-RO database corresponding to the rays whose tangent height is 9 km. Panels (a), (b) and (c) show the mean value climatology for the along-ray integrated IWC, distance (i.e. distance traveled by each ray within the influence of positive IWC), and maximum IWC encountered along the ray, respectively. The used grid is  $10 \times 10$  deg. Panels (d), (e), and (f) correspond to the histograms for the total values for the same integrated IWC, distance, and maximum IWC as in the first row. IWC source is the DARDAR retrieval product.

for the along-ray integrated IWC (e.g. Fig 2-d, with values up to  $250 \text{ kg m}^{-2}$ ). This is due to the long distances that rays travel through IWC. In this geometry, the distance relates more to the size of the storms being observed, as opposed to the vertical water path which relates stronger to their intensity. However, the broad range of distances (see Fig 2-e), reveals the ambiguity 130 of PRO, i.e. it cannot distinguish between the effects of intensity of the storm (or amount of water content) and the distance within the influence of such water content (see Eq. 1).

The spatial/geographical patterns are also relevant. Higher concentrations of IWC at 9 km occur in the tropics (as expected), specially over land (south America and central Africa) and around the West Pacific warm pool. Regarding the distance, large values also appear over the mid- and high- latitude oceans. This results agree well with known patters and previous characterization 135 of storm features, such as in Liu and Zipser (2015), meaning that the RO geometry does not pose a problem in obtaining these global properties of heavy precipitation systems. Therefore, this database of IWC in RO geometry is well suited to both help understand the features observed in the PAZ  $\Delta\Phi$  and relate them to realistic precipitating systems.

For this study, the DARDAR V3 retrieval has been used as a reference for the cross-comparison with  $\Delta\Phi$ . The choice has been made taking into account the assumptions in the IWC retrieval of both DARDAR and 2B-CWC-RO. DARDAR V3 has 140 been recently improved with in-situ observations to help constrain the particle size distributions (Cazenave et al., 2019). A comparison between the integrated IWC from a Cloudsat-RO generated from DARDAR V3 and 2B-CWC-RO products is

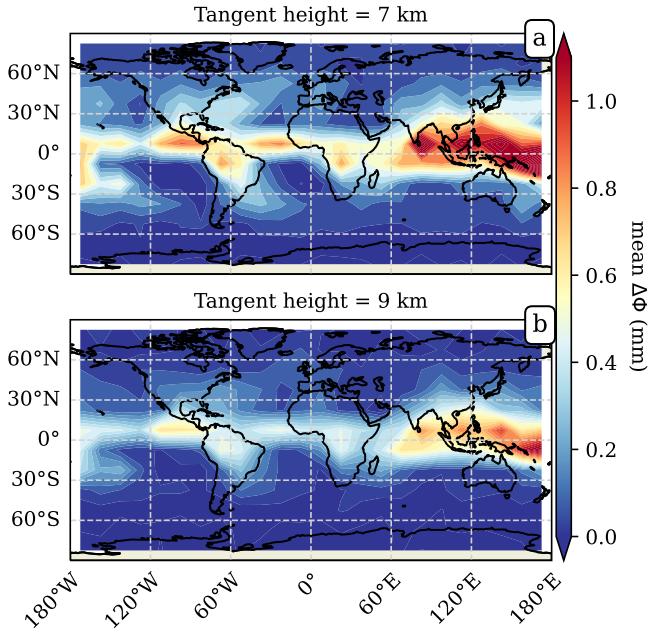

**Figure 3.** Mean values of integrated IWC (left axes) from the Cloudsat-RO dataset, and mean values of observed  $\Delta\Phi$  from PAZ (right axes), as a function of latitude, for all data (a), ocean (b) and land (c). Data correspond to tangent heights of 7 km. The mean values are computed for every 2 deg latitude bands.

shown in Figure A1. The results shown hereafter will refer to those obtained using the Cloudsat-RO generated from DARDAR V3.

### 3 Relationship between PAZ $\Delta\Phi$ and Cloudsat ice water content

145 As it has been discussed in the introduction, both  $K_{dp}$  and WC are affected by the third moment of the  $N(D)$ . Therefore, a relationship between the two is expected. Since the PRO observable ( $\Delta\Phi$ ) is an integral measurement, the integrated IWC along the same ray where  $\Delta\Phi$  has been measured would be the most suitable quantity to be compared with. However, the PAZ

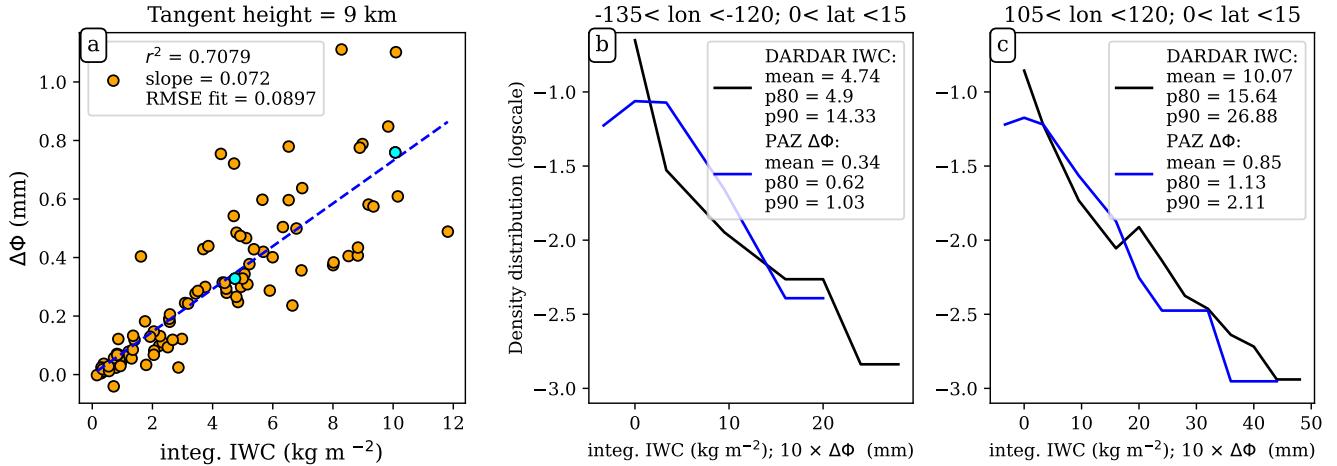

**Figure 4.** Global climatology maps for the mean PAZ  $\Delta\Phi$  observations corresponding to a tangent height of 7 km (panel a) and 9 km (panel b). The grid size where the means are computed is  $15 \times 15$  deg.

satellite is in an 6AM/6PM orbit optimized for its primary sensor, which results in few crossover measurements with the GPM and CloudSat radars. Therefore, the comparison is performed statistically with the Cloudsat-RO database.

150 For the  $\Delta\Phi$  observations, the whole PAZ mission is used. That is, 189,487  $\Delta\Phi$  profiles between May 10th 2018 and May 31th 2022. All these profiles have been selected so they have passed the initial quality controls and calibration (Padullés et al., 2020). PAZ  $\Delta\Phi$  data are available from <https://paz.ice.csic.es/>.

155 The noise of the individual  $\Delta\Phi$  observations is thoroughly assessed in Padullés et al. (2020). The noise is normally distributed around 0 mm (for the events with no clouds nor precipitation) with a standard deviation that ranges from 1.5-2 mm in the lowest tangent heights (e.g.  $\sim 2$ km, where the signal to noise ratio of the observations is low) to 0.5 mm above 10 km. The major source of uncertainty for the IWC are the retrieval assumptions, and it has been briefly discussed in Appendix A.

160 Figure 3 shows the comparison of the mean along-ray integrated IWC with the mean  $\Delta\Phi$ , as a function of latitude, corresponding to a tangent height of 7 km. It can be seen how the two quantities agree remarkably well when the whole datasets are considered (panel a). The agreement is specially good over ocean (panel b). In the tropics, the shape of both the along-ray integrated IWC and  $\Delta\Phi$  capture very well the global precipitation signature of the Inter-Tropical Convergence Zone (ITCZ) (e.g. Marshall et al., 2014; Schneider et al., 2014). Over land (panel c), the agreement is also good despite some small deviations between both quantities around the equator.

**Figure 5.** Panel (a) shows the scatter plot of the mean climatologies of Cloudsat-RO integrated IWC vs the PAZ  $\Delta\Phi$  obtained at the same grid cell, for the data corresponding to a tangent height of 9 km and over tropical ocean. Therefore, it is the comparison between the tropical ocean cells in Figure 4-b and Figure 2-a. Panels (b) and (c) show the distribution of Cloudsat-RO integrated IWC (black) and PAZ  $\Delta\Phi$  (blue) for two different grid cells at a tangent height of 9 km. The grid cells correspond to the two cyan points in panel (a) and its location is identified in the panel title with the corresponding longitude and latitude ranges.

On a map, the gridded mean (or climatology) of  $\Delta\Phi$  can be seen in Figure 4. Panel (a) corresponds to the mean  $\Delta\Phi$  at a tangent height of 7 km, and panel (b) at a tangent height of 9 km. The latter can be compared with Figure 2-a to investigate 165 whether the spatial patterns are equivalent or not. In order to quantify the spatial relationship between the two (e.g. PAZ  $\Delta\Phi$  and Cloudsat-RO IWC), the mean of both quantities are computed on the same grid. The chosen grid is 15×15 deg, so that spatial patterns of precipitation arise and there are enough PAZ observations to achieve significant statistics. The values for the mean of PAZ  $\Delta\Phi$  and integrated Cloudsat-RO IWC obtained at the same grid cells are compared against each other (e.g. Figure 5-a). For the case of data corresponding to a tangent height of 9 km, the relationship follows a linear trend. The Pearson's 170 correlation coefficient is 0.84 (e.g.  $r^2 = 0.7$ ) therefore exhibiting a robust relationship. The correlation coefficient for the spatial relationship between the mean PAZ  $\Delta\Phi$  and mean integrated Cloudsat-RO IWC is computed for heights between 2 and 17 km.

In addition to the mean, the 80th and 90th percentiles of both datasets are also computed at the same grid cells. That is, for each grid cell, the distribution for  $\Delta\Phi$  and for the Cloudsat-RO integrated IWC is represented, and the 80th and 90th percentiles of such distributions are computed. This results in a climatology for the 80th and 90th percentiles of  $\Delta\Phi$  and 175 Cloudsat-RO integrated IWC. The approach is shown for two grid cells in Figure 5-b,c. The comparison between the 80th and 90th percentiles climatologies of  $\Delta\Phi$  and Cloudsat-RO integrated IWC is performed in order to check if the relationships stands at the higher ends of the distributions. That is, to check whether there is a good agreement between  $\Delta\Phi$  and integrated Cloudsat-RO IWC for the whole distribution (and not only for the mean). The results are shown in Figure 6.

Along with the correlation coefficient, the ratio between the PAZ  $\Delta\Phi$  mean climatology and the Cloudsat-RO integrated IWC mean climatology (i.e. ratio =  $\Delta\Phi/\text{IWC}$ ) is also computed at the same heights as the correlation coefficients and is shown in Figure 7. It is computed from the linear fit between the mean PAZ  $\Delta\Phi$  and mean Cloudsat-RO integrated IWC at different cells (e.g. see Figure 5-a, where we assume that the intercept is zero).

### 3.1 Correlations

The correlation coefficients in Figure 6 quantify the agreement between the spatial or geographical patterns of the two datasets. High correlations can be understood as the two datasets observing the same kind of precipitation structures. One thing to note before digging deeper into the results is that the correlation coefficient is computed assuming a linear relationship between the two quantities.

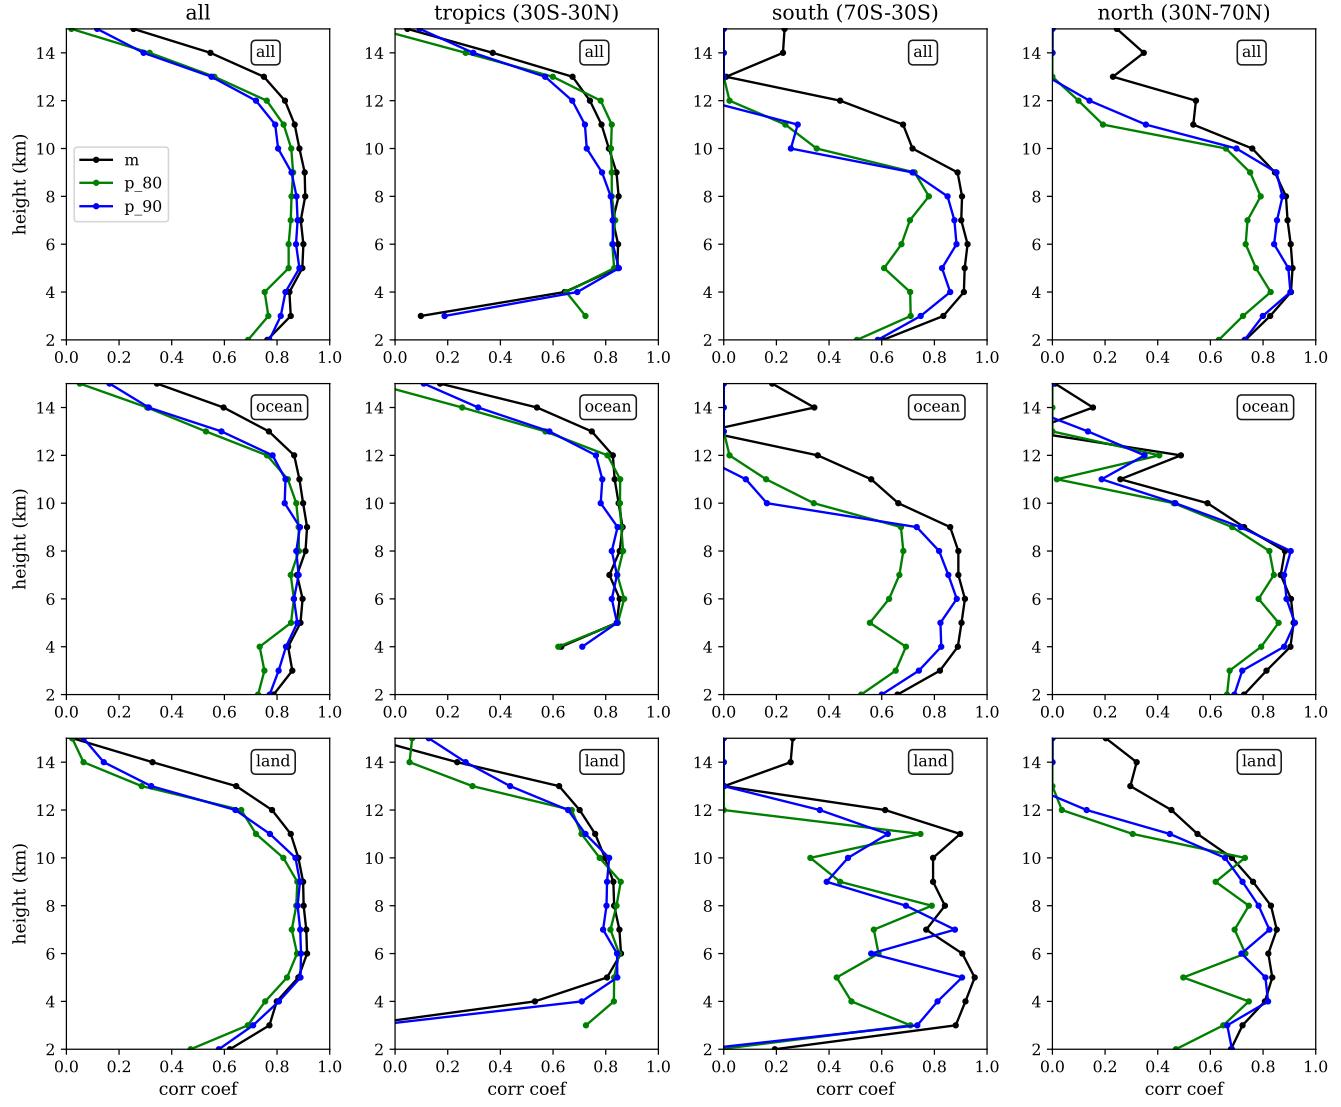

The results, in general (e.g. Figure 6 - first row), show a very high correlation coefficient (i.e.  $\text{cc}>0.8$ ) among most of the considered heights. The correlation is particularly high over the oceans, although over land the agreement is also good. This is true for the three statistics being considered, the mean climatology, and the climatologies for the 80th and 90th percentile of the distributions. However, the correlation coefficient corresponding to the mean tends to be slightly higher than the other two.

When the data are split in different regions (e.g. tropics vs extra-tropics), more detailed features can be explored. The first relevant one is the fact that the correlation coefficient in the tropics (Figure 6 - second column) is higher for a wider range of heights than for the extra-tropical cases (Figure 6 - third and fourth columns). Also, it can be seen how for heights below  $\sim 4$  km, the correlation in the tropics drops due to the fact that the profiles have been truncated below the freezing level, and therefore there are almost no data below  $\sim 4$  km. The second relevant feature is that the correlation for the climatologies of the 80th and 90th percentiles are lower outside the tropics. Finally, one must note that the panel corresponding to land in the southern hemisphere (70S-30S) is contributed by a relatively small amount of data points, hence exhibiting a large dispersion of the correlation coefficients among different heights.

### 3.2 Ratios

The ratio between the mean climatologies of PAZ  $\Delta\Phi$  and Cloudsat-RO integrated IWC provides an empirical relationship between the two quantities and it is shown in Figure 7 (black line). Furthermore, the uncertainty of such ratio (e.g. defined here as the root mean squared error around the linear fit) is obtained at each height when performing the linear regression between the mean climatologies (e.g. as shown in Figure 5-a).

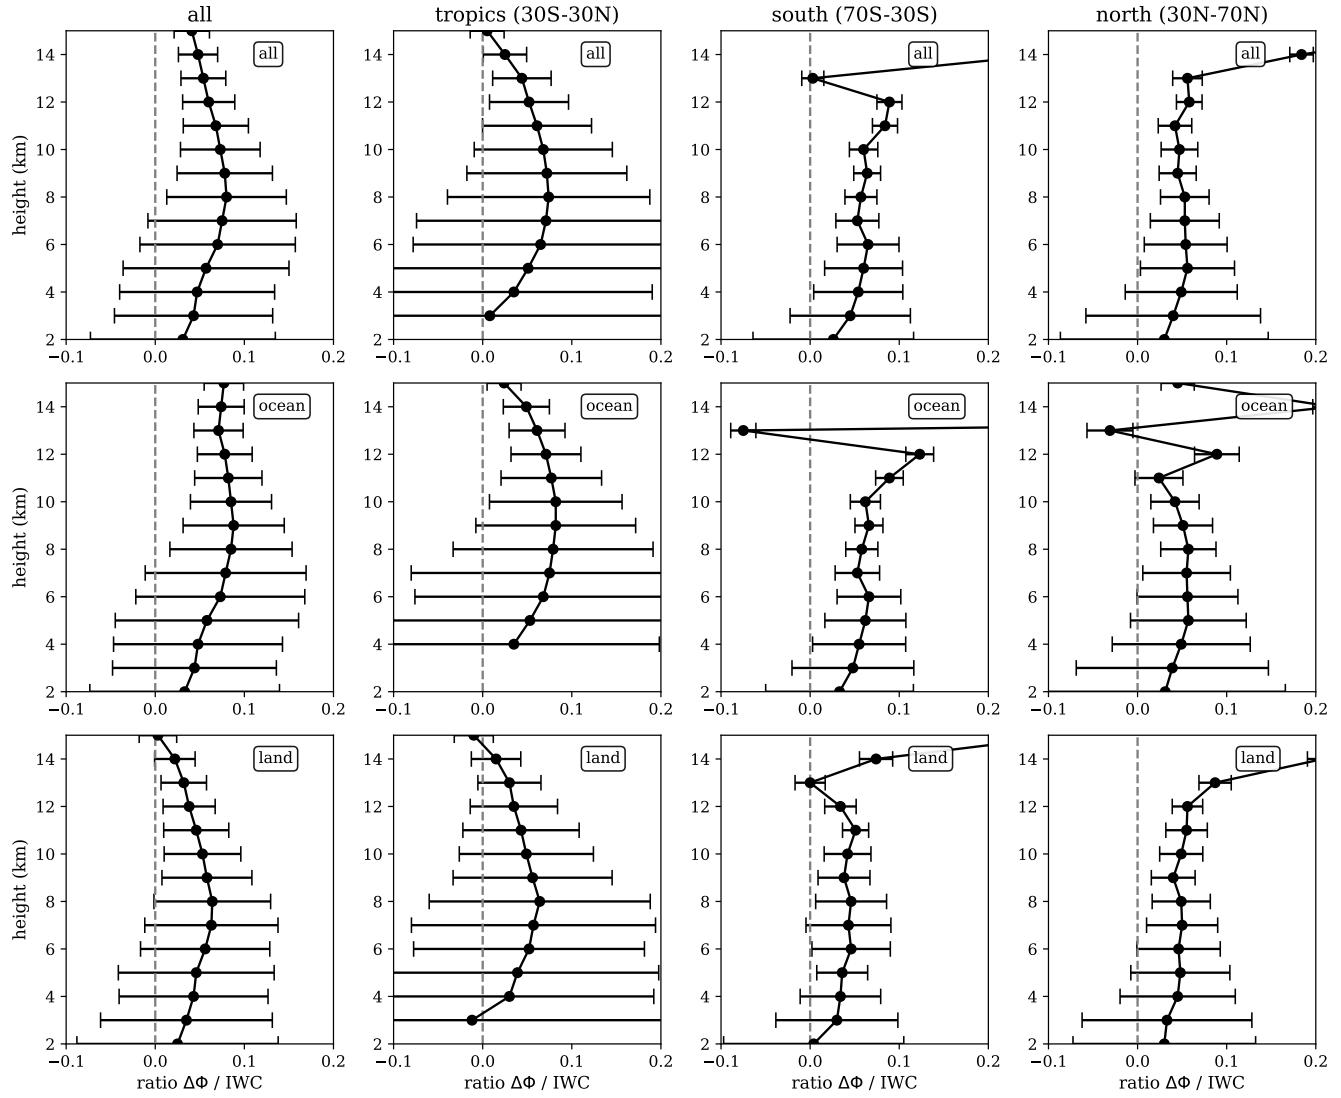

The ratio is considered meaningful in the heights and regions where the correlation coefficient is high (e.g.  $\text{cc} > 0.8$ ). The values obtained for the ratio of the mean climatologies in such regions and heights ranges from  $0.03\text{-}0.09 \text{ mm kg}^{-1} \text{ m}^2$ . It can be seen how it has a trend with height. In general, the ratio tends to maximize at around 8/10km in the tropics, and at a lower heights in the extra-tropics.

**Figure 6.** Correlation coefficients between PAZ  $\Delta\Phi$  and Cloudsat-RO IWC, as a function of height (y-axis), for different areas across the globe (all globe, tropics, southern extra-tropics, and northern extra-tropics), and different surfaces (all, ocean, land). The black lines correspond to the mean climatologies, the green lines to the 80th percentile and the blue lines to the 90th percentile climatology.

#### 4 Forward scattering simulations of ice and snow

210 The correlation coefficients obtained in Sect. 3.1 indicate a robust relationship between  $\Delta\Phi$  and integrated IWC, especially over tropical ocean. However, the meaning of the ratio between  $\Delta\Phi$  and integrated IWC depend on more factors. The aim of

**Figure 7.** Ratio between PAZ  $\Delta\Phi$  mean climatology and Cloudsat-RO integ. IWC mean climatology, as a function of height (y-axis), for different areas across the globe (all globe, tropics, southern extra-tropics, and northern extra-tropics), and different surfaces (all, ocean, land). The x-axis errorbars show the root mean squared error around the fit from which we obtain the ratio (e.g. see Figure 5).

this section is to determine whether the ratios in Sect. 3.2 are physically meaningful or not. That is, to determine if the ratios are compatible with the characteristics of hydrometeors that are known to be present in clouds.

For this, the idea is to compute the  $K_{dp}$  - IWC relationship for a series of different hydrometeors and ice particle habits. 215 This relationship can then be compared with the ratios in Figure 7. To perform such comparison, first, the scattering amplitude matrix  $\mathbf{S}$  is computed for a set of different single hydrometeors and ice particle habits. Then, a set of particle size distributions

from one week of Cloudsat observations are used to generate the corresponding  $K_{dp}$  and IWC using Eqs. 2 and 3. Note that for this study, only single-particle scattering is considered.

#### 4.1 Hydrometeors and ice particle habits

220 The forward scattering simulations used for this study have been done using Rayleigh approximation. This formulation assumes that the particles can be approximated as oblate spheroids, with a certain axis ratio and effective density. The list of hydrometeors and ice particle habits that have been used are pristine ice crystals, aggregates of pristine ice, and wet snow. The adequacy of using Rayleigh approximations is justified by the long wavelength of GNSS signals, i.e.  $\sim 190.3$  mm, much larger than the typical size of frozen hydrometeors. For Rayleigh approximations, the formulations in Ryzhkov et al. (2011) 225 and in Bringi and Chandrasekar (2001) have been followed. That is, the forward scattering amplitude co-polar components are computed using:

$$S_{hh,vv} = \frac{\pi^2 D^3}{6\lambda^2} \frac{1}{L_{hh,vv} + \frac{1}{\epsilon - 1}} \quad (4)$$

where  $\epsilon$  is the dielectric constant, and  $L_{hh,vv}$  are the shape parameters:

$$L_{hh} = \frac{1 + f^2}{f^2} \left( 1 - \frac{\arctan(f)}{f} \right), \quad f = \sqrt{\frac{1}{ar^2} - 1} \quad (5)$$

230

$$L_{vv} = \frac{1 + L_{hh}}{2} \quad (6)$$

where  $ar$  is the axis ratio of the particle. For the dielectric constant, the Maxwell-Garnett formula is used in order to account for the effective density of the particles as mixtures of ice, air, and water (Maxwell Garnett, 1904). Below there are the specific details for each of the hydrometeors and habits used in this study.

235 **4.1.1 Pristine ice crystals**

The simplest type of particles used in this study are pristine ice dendrites and thick plates. For the Rayleigh computation, the density of solid ice is used, and the values in Ryzhkov et al. (2011, Table 1) are used for the axis ratio. A fully horizontal orientation of the particles is assumed.

#### 4.1.2 Aggregates

240 For more complex shapes, we use aggregates of pristine ice particles. For the Rayleigh approximation, an spheroid of air filled with portions of ice is used, following Ryzhkov et al. (2011) and taking different values for the effective density and axis ratio. The computation is performed for effective densities ranging from 0.1 to 0.9  $\text{g cm}^{-3}$ , and axis ratios ranging from 0.2 to 0.9. Note that using an effective density of 0.9 means that the spheroid is filled with ice, approaching a pristine ice particle. The 245 results using the Rayleigh method for fixed densities and fixed axis ratios for the whole range of equivalent diameters are called dry aggregates.

### 4.1.3 Wet snow

Finally, wet snow aims to represent frozen particles at the initial stages of melting. For this, the same spheroids as in the previous subsection are used, but for this case a mass fraction of liquid water of a 10% of the total mass is used, in addition to pure ice and air, to compute  $\epsilon$ . The presence of water in the particle enhances  $\epsilon$  which in turn increases the  $K_{dp}$  with respect to the dry aggregates with same parameters (of equivalent density and  $ar$ ).  
250

## 4.2 Orientation angle distribution

The results for pristine ice, aggregates and wet snow are computed using single particle scattering and forcing the different particles to be horizontally oriented. This is unlikely to be the case in real clouds and storms, where the orientation of these particles is more complex. To account for different orientation angles, we assume a Gaussian distribution of tilt (or canting) 255 angles centered at  $0^\circ$  (hence mean angle  $\beta = 0^\circ$ ) with a certain standard deviation  $\sigma$ . This implies that varying  $\sigma$  we can range from total horizontal orientation ( $\sigma = 0^\circ$ ) to completely random orientation (large  $\sigma$ ). To keep the computations simple, we can use the horizontal orientation values and multiply them by a factor that accounts for such canting (Oguchi, 1983):

$$K_{dp}^\sigma = \frac{1 + e^{-2\sigma^2} \cos(2\beta)}{2} e^{-2\sigma^2} K_{dp}^{\sigma=0} \quad (7)$$

## 4.3 Simulations results

260 Using one week of Cloudsat retrieved  $N(D)$  at different heights above the freezing level, the IWC and  $K_{dp}$  are computed using the same particle type. This results in a set of  $K_{dp}$  vs IWC relationships for different hydrometeors or ice particle habits, and different properties such as effective density ( $\rho$ ) and axis ratios. In addition, for each combination of particle type,  $\rho$  and  $ar$ , the corresponding result at different distributions of tilt angles are performed. Figure 8 it is shown the variability of the 265  $K_{dp}$  vs IWC relationship, for dry aggregates (and wet snow), when one of the properties is varied (e.g. distribution of tilt angles -panel a-, effective density -panel b-, axis ratio -panel c-, and effective density for wet snow -panel d-).

The ratios between the  $K_{dp}$  and IWC for a subset of particles and different properties are shown in Table 1. The ratios with a value within the range [0.03 - 0.09] are highlighted in bold. These are the values agreeing with the reported ratios between  $\Delta\Phi$  and integrated IWC in Sect. 3.

270 In these results, it can be seen how for more pristine and thin particles, certain canting angle is required (e.g. fully horizontal orientation is overestimating the observed  $K_{dp}$ ), whereas for more complex particles, these are required to stay more horizontally oriented to better match the actual data. It can also be observed that very low density particles with high axis ratios (i.e. approaching empty spheres) alone cannot explain the observations.

275 To further validate observations and results obtained in Section 3 and allow for a more equivalent comparison between the results, a simple exercise is performed. It consists of computing the integrated IWC and  $\Delta\Phi$  using the simulations just described, and proceeding with the same procedure followed in Section 3 in order to obtain the same relationships. That is, to compute the mean climatological values at the same grid bins and heights, but in this case, for the simulated  $\Delta\Phi$  values. The obtained values for  $\Delta\Phi$  at all grid bins and heights are shown as a function of the corresponding integrated IWC at the same

**Table 1.** Ratio between  $K_{dp}$  and IWC for the different hydrometeors shown in Fig. 8, when a certain standard deviation is assumed in the orientation distribution (Gaussian distribution centered at  $0^\circ$  and  $\sigma$ )  $\sigma = 0^\circ$  represents the scenario where all particles are horizontally oriented, while for large  $\sigma$  all particles would be randomly oriented (see Eq. 7). In bold, the ratios within the range [0.03 - 0.09], in agreement with the observed ratios in Fig. 6.

grid bins and heights in Figure 9 -top row-. This is done for dry aggregates with a different combination of  $\rho$  and  $ar$ , and for different tilt angles distribution. The same approach is used to compare the simulated  $\Delta\Phi$  with the observed one, as shown in

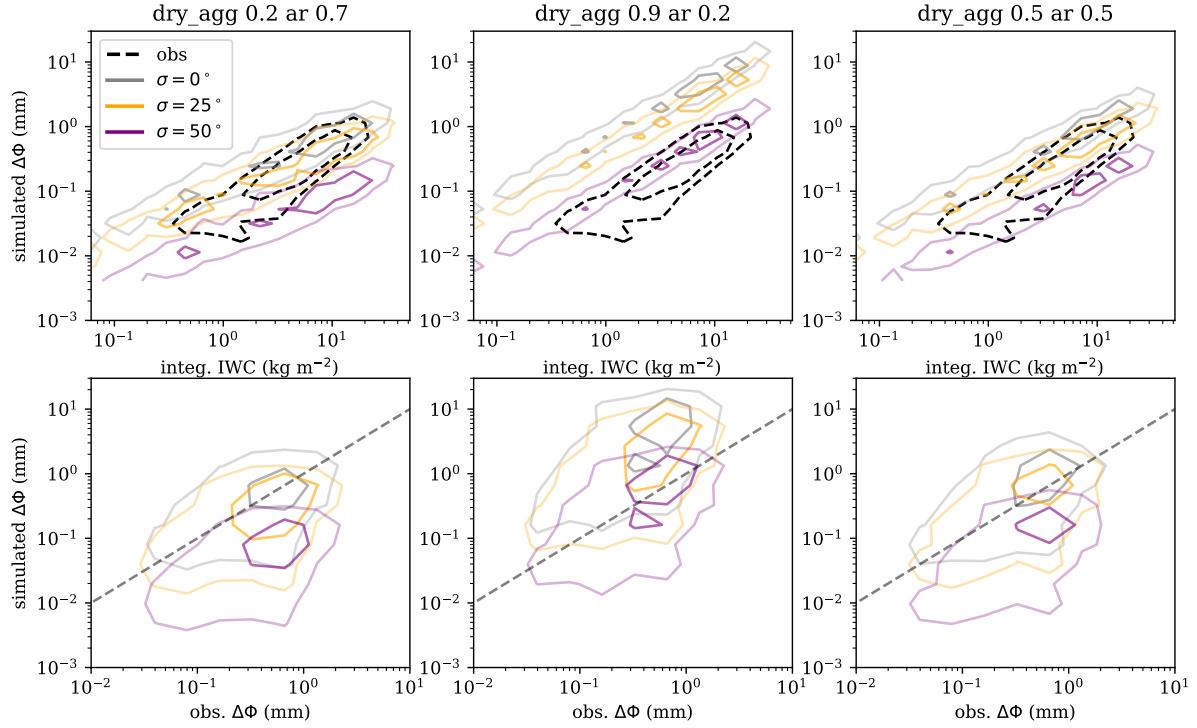

280 Figure 9 -bottom row-.

For simplicity, these results are obtained assuming the same hydrometeor type at all heights for all situations, which is unrealistic. Similarly, the same effective density has been assumed for each hydrometeor at different sizes, while a more realistic approach would be to assume that the density decreases with particle size. However, these simulations can be used to explain the bulk of the observations, and further assess the effect of considering more or less tilted particles in the simulations

285 in reproducing the observations. Comparing the simulated results with the observations (represented in the top row of Figure 9 as black dashed contour) it can be seen how the bulk observations can be reproduced using dry aggregated particles with a diversity of effective densities and axis ratios depending on the tilt angle distribution. For example, dry aggregates with  $\rho = 0.9$   $g\text{cm}^{-3}$  and  $ar = 0.2$  must have a standard deviation of the tilted angle distribution larger than  $50^\circ$  in order to explain the observed relationships.

**Figure 8.** Results of simulated  $K_{dp}$  as a function of IWC for dry aggregates (a-b-c), and wet snow (d), varying the standard deviation of the tilt angle distribution (a), the effective density (b), axis ratio (c), and the effective density of wet snow (d).

**Figure 9.** Results of the distributions of simulated  $\Delta\Phi$  vs integrated IWC (top row) and vs the observed  $\Delta\Phi$  (bottom row) compared at the same grid bins (same approach and same grid bins as in Figure 4) and accounting for all heights. Panel (a) and (d) show the results obtained using a single type of particle at all locations and heights - the dry aggregates with effective density of  $0.2 \text{ g cm}^{-3}$  and an axis ratio of 0.7. Panels (b) and (e) correspond to results using dry aggregates with effective density of  $0.9 \text{ g cm}^{-3}$  and an axis ratio of 0.2, and (c) and (f) using dry aggregates with effective density of  $0.5 \text{ g cm}^{-3}$  and an axis ratio of 0.5. The different colors of the contours correspond to different standard deviation in the distribution of tilt angles as described in the legend. The dashed contours (in the top row) correspond to the observed relationships as obtained in Sect. 3. The dashed line (in the bottom row) indicates the perfect 1:1 agreement. The same color inner and outer contours represent the contour containing 30% and 70% of the data, respectively.

290 **5 Summary and discussion**

**5.1 Observations**

The relationship between the PRO observable  $\Delta\Phi$  and ice water content has been investigated in a global and statistical (or climatological) way. For this purpose, retrievals from the Cloudsat mission have been used. These have been re-mapped into the RO observation geometry so that comparisons take into account the important features of the observation geometry of PRO.

295 An important one is the long distances that rays traveling from the GNSS satellites to the receivers in Low Earth Orbit spend in the lower layers of the troposphere. Such re-mapping allows an evaluation of the geometry itself. It can be assessed whether a limb-sounding measurement like PRO is able to capture important features of precipitation or not.

The results in Figure 2 show the agreement between the climatology of the along-ray integrated ice water content (and related products such as the distance rays traveled within areas of non-zero ice water content, or the maximum ice water 300 content encountered per ray) with known and previously studied heavy precipitation features (e.g. Liu and Zipser, 2015). This is further confirmed with the results in Figure 3 (showing the mean climatology as function of latitude for water content, solid black line), which agrees very well with the signature of the ITCZ. Therefore, the good climatological agreement enables the use of the Cloudsat-based artificially collocated RO database of along-ray integrated ice water content for understanding the PRO observations of precipitating cloud structures. For this study, only ice water content retrievals are used, and the RO 305 profiles are truncated at the freezing level. The use of ice only retrievals is justified because Cloudsat observations in the liquid region of deep cloud structures (such as those specifically targeted by the ROHP experiment) may be degraded due to the high frequency and penetration issues.

The PRO observable  $\Delta\Phi$  is the integrated  $K_{dp}$  along each RO ray. Both  $K_{dp}$  and water content are affected by the third moment of the  $N(D)$ , and therefore a relationship between them is to be expected. Such relationship is investigated by evaluating 310 the correlation coefficient between the geographical patterns of the high and low concentrations of  $\Delta\Phi$  and along-ray integrated IWC, split in different regions and heights. Overall, correlation coefficients (e.g. Figure 6) are high for the heights where frozen particles are expected (which changes by region, e.g. tropics vs. outside tropics). The correlation coefficients maximize for Tropical oceans.

When the correlation coefficient is evaluated for the higher ends of the distribution (i.e. the climatologies for the 80th and 315 90th percentiles), similar behavior is observed in the tropics, whereas differences between the mean climatology and the higher percentiles are observed in the mid-latitudes, especially over the southern oceans. This means that the features exhibited in the tail of the distribution of the retrieved IWC in this region are not well captured by PAZ  $\Delta\Phi$ . One hypothesized explanation could relate to the retrievals within mixed-phase clouds in the Southern Oceans (which are present in the lower heights in these areas), that have posed a longstanding issue for observations (e.g. Mace et al., 2021). Hence, further work must be carried 320 out to assess whether the discrepancies between PAZ  $\Delta\Phi$  and Cloudsat-retrieved ice water content in these areas are due to microphysical reasons (e.g. smaller ice particles, lack of preferred orientation, etc.), observational errors, or still unaccounted factors.

The ratio between the mean climatology of  $\Delta\Phi$  and Cloudsat-RO integrated IWC aims at quantifying the empirical relationship 325 between both. Results in Figure 7 show the empirical relationship along with its uncertainty, at each height and for different regions. The found ratio lays between 0.03 and 0.09  $\text{mm kg}^{-1} \text{m}^2$ . The uncertainties show the variation of the ratio around its mean and it shows how, even for mean climatological values, there is a large dispersion that may be explained in part by the non-unique relationships between  $\Delta\Phi$  and integrated IWC.

This has been in fact observed in Gong and Wu (2017), where a decrease in the passive microwave polarimetric brightness 330 temperature difference at 166GHz and 89Ghz is seen at very cold brightness temperatures, associated with very deep convective areas. An extreme example of such scenario applied here could be a region of large IWC with totally random oriented particles, where the ratio between  $\Delta\Phi$  and IWC would tend to 0 despite having high IWC. This effect would be masked in the mean

climatology, but could appear in individual observations. A more detailed study should be conducted to assess these situations, desirably with coincident observations between PRO and radars.

Another interesting feature of the ratio between  $\Delta\Phi$  and IWC shown in Figure 7 is that it is in general not constant with height. This could be associated to the presence of different particles at different heights, consistent with particle shape dependence on temperature and supersaturation (e.g. Bailey and Hallett, 2009). Furthermore, differences in the ratio trend with height can be observed between over-ocean and over-land, especially in the tropics, where a decrease in the correlation coefficient is observed at lower heights than for over-ocean. Two main hypothesis could explain the differences: (1) differences in the microphysics over-ocean and over-land, impacting the shape and orientation of the frozen particles; (2) differences owing to different local time observations between PAZ (6am/pm) and Cloudsat (1:30am/pm). The latter would have stronger effect over land, but to discern between the two hypotheses more observations at different orbital planes are needed.

The robust relationships between PRO  $\Delta\Phi$  and integrated IWC has an implicit and important implication: it demonstrates the systematic presence of horizontally oriented frozen particles thorough the different vertical cloud layers (above freezing level), globally. This conclusion expands upon results in Defer et al. (2014); Gong and Wu (2017); Zeng et al. (2019), where the presence of horizontally oriented particles was observed globally using the Microwave Analysis and Detection of Rain and Atmospheric Structures (MADRAS) instrument on board the Megha-Tropiques satellite and the Global Precipitation Mission Microwave Imager (GPM-GMI) polarization differences (PD) at 157, 89 and 166 GHz. Thanks to the off-nadir looking instrument, the PD can be related to differential extinction by asymmetric particles. Also, similarly as here with  $\Delta\Phi$ , using PD from passive microwave radiometers provide a single column measurement, but in the quasi-vertical direction. Here, however, we can include the vertical information lacking to off-nadir looking microwave measurements.

## 5.2 Simulations

Seeking to assess the feasibility of the results in Section 3, single particle forward scattering simulations have been used to assess whether the relationships obtained between  $\Delta\Phi$  and ice water content are reliable, according to the typical types of hydrometeors found in clouds. The assumptions made for the simulations are quite simple, e.g. mostly focused on dry aggregates with a range of  $\rho$ ,  $ar$  and tilt angle distributions.

Using a subset of  $N(D)$  and the simulated  $S$ , the relationship between IWC and  $K_{dp}$  is shown in Figure 8, where a wide diversity of combinations of tilt angle distributions, effective densities and axis ratios are computed. Many different combinations yield similar results in the relationship  $K_{dp}$  vs IWC, revealing the large amount of degrees of freedom in ice particle forward scattering simulations.

The results of the ratio between  $K_{dp}$  and IWC for a subset of particles with some combinations of  $\rho$ ,  $ar$  and tilt angle distributions are summarized in Table 1. It is also compared with the results in Section 3.2. The comparison allow us to corroborate that the observed ratios in the regions with high correlation coefficients can be explained with the simulations using simple approximations, and could potentially help constraining the plausible distributions of ice crystals that can reproduce the ratios. For example, particles with large axis ratios (e.g. approaching spheres) cannot reproduce the bulk of observed ratios

365 between  $\Delta\Phi$  and IWC. Similarly, thin, solid ice particles would need to be oriented with a large dispersion in the tilt angle for the ratios to be consistent with observations.

370 Statistically comparing the simulated and observed  $\Delta\Phi$  and IWC relationship repeating the approach followed in Section 3 but using the simulated  $K_{dp}$  (Figure 9), a fairly good agreement is also reached with simple assumptions about the particles and changing the tilt angle distributions. However, the dispersion in Figure 9- bottom row, when comparing simulated with observed gridded mean  $\Delta\Phi$  is probably indicating that using the same particle assumptions for all regions and heights is not realistic. A better simulation exercise would be required, e.g. with Numerical Weather Prediction model outputs with detailed information about the hydrometeor species, to further constrain the valid particle shapes and tilt angle distributions that better match the observations (similarly to what is done in Brath et al. (2020)). However, and despite the simplicity, the results obtained here seem compatible with those by Brath et al. (2020). They showed how previously observed relationships between 375 passive microwave brightness temperatures and its polarization differences could be explained accounting for tilted large snow thin plates, or less tilted more complex snow aggregates.

380 An important note to add is that the results presented here are valid for the chosen IWC retrieval algorithm (in this case, the DARDAR V3), and are therefore dependent on that choice. In particular, the DARDAR V3 algorithm assumes non-spherical ice particle shapes (Delanoë and Hogan, 2010; Cazenave et al., 2019) as opposed to the 2B-CWC-RO algorithm, which uses spherical solid ice particles (Austin et al., 2009). However, none of them takes explicitly into account the orientation of such particles. As can be seen in Appendix A, differences between IWC retrieved in the 2B-CWC-RO product and DARDAR can be large at some heights. This results (not shown) in differences in the computed correlation coefficients at lower heights (i.e. near the freezing level), where the results using DARDAR exhibit larger values for a wider range of heights for most regions. Some differences also appear in the values of the ratios, as can be deduced from Figure A1-panels b and c. As a consequence, 385 the combination of  $\rho$ ,  $ar$  and tilt angle distributions that explain the observed ratios would change, but for most of the cases considered in this study (i.e. above the freezing level) would remain within equivalent ranges.

## 6 Conclusions

390 This study assessed the global relationship between polarimetric radio occultation observable  $\Delta\Phi$  and ice water content retrieved by Cloudsat. First of all, the integrated IWC retrievals from Cloudsat have been re-mapped into the RO-like geometry. This has been used to demonstrate that RO-type limb-sounding observations can be used to sense and detect known precipitation features globally.

395 The global climatology of Cloudsat-retrieved integrated IWC has been compared to the  $\Delta\Phi$  climatology from PAZ. It has been shown how the spatial/geographical correlation between the two datasets is high ( $cc>0.8$ ) for a wide range of heights, including both ocean and land areas. This means that the IWC concentration patterns are well captured by PRO observations, globally and at different heights. The correlation coefficient maximizes and it is particularly good over tropical oceans for a range of heights ranging from 5 to 12 km.

The ratios between the mean  $\Delta\Phi$  and the mean integrated IWC climatologies are found to be within the range 0.03-0.09 mm kg<sup>-1</sup> m<sup>2</sup>. Their analysis yields interesting results as well. First of all, the existence of such relationship between both quantities implies the systematic presence of horizontally oriented hydrometeors contributing to IWC, globally and at all heights. 400 Second, the dispersion and differences at different heights indicate that indeed different particles have different  $K_{dp}$ /IWC ratio.

Furthermore, forward scattering simulations of simple snow aggregates accounting for a range of effective densities, axis ratios, and tilt angles distributions can explain the bulk of the ratios (i.e. the mean climatological values). The simulation framework described here, although being very simple, can easily scale in complexity for arbitrary complex inputs of ice particle habits from, e.g. Numerical Weather Prediction models, or to account for more realistic assumptions about the effective 405 density.

Despite the high correlation between the mean values of  $\Delta\Phi$  and integrated IWC, further work must be pursued to explore individual simultaneous observations of  $\Delta\Phi$  and IWC, and assess when and under which scenarios the relationship holds (i.e. horizontally oriented particles contribute to the IWC) or does not apply (i.e. mostly non oriented ice contributing to IWC). This is enabled by the fact that  $\Delta\Phi$  observations inherently provide unique information of the orientation of hydrometeors.

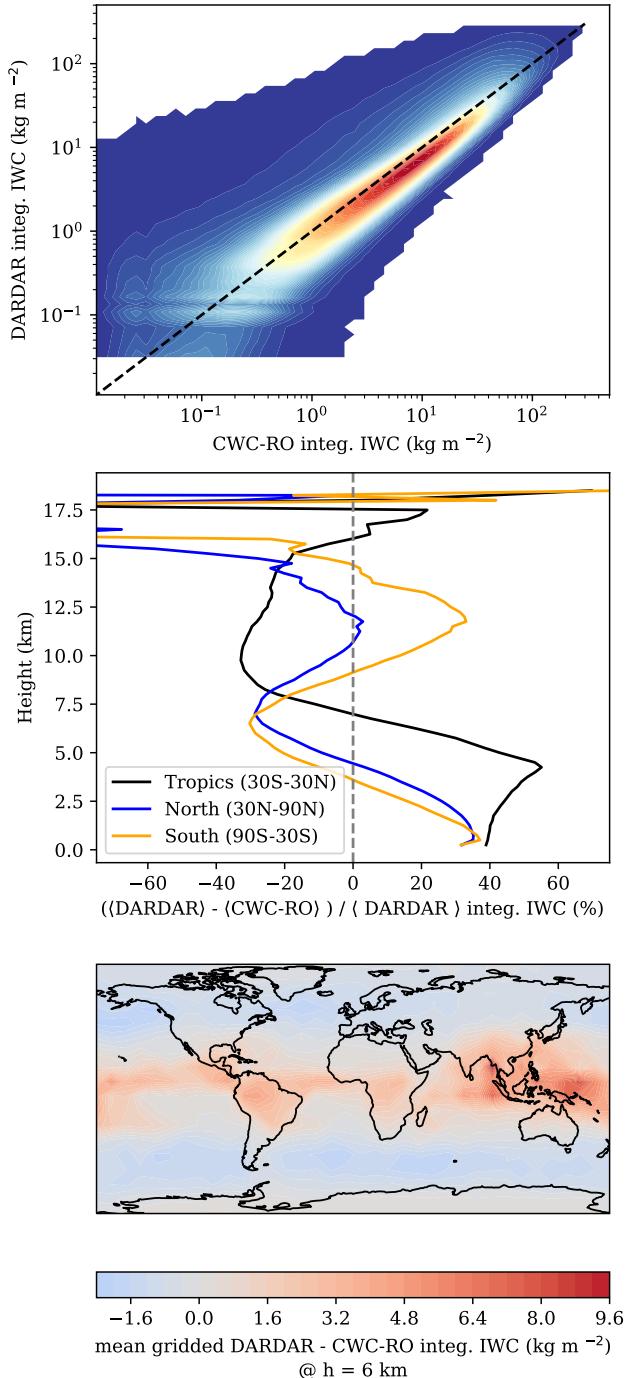

#### 410 **Appendix A: Comparison between DARDAR and 2B-CWC-RO integrated IWC profiles**

A comparison of the integrated IWC from the Cloudsat retrieval using the 2B-CWC-RO and DARDAR V3 products has been performed and is shown in Figure A1. The differences in general are shown in panel (a). A more detailed view of the comparison between DARDAR V3 and 2B-CWC-RO integrated IWC at different heights is shown in panel (b), representing the fractional difference between the two datasets. The differences are positive (i.e. DARDAR V3 > 2B-CWC-RO) and larger 415 at lower layers, and shift to negative (i.e. DARDAR V3 < 2B-CWC-RO) at upper layers. A map showing how the differences are distributed on the grid cells used thorough the paper is shown in panel (c) for a tangent height of 6km.

The differences arise from different assumptions regarding the treatment of the Cloudsat observations near the freezing level, the assumptions about the particle size distributions, and DARDAR includes Calipso observations to complement Cloudsat observations (Delanoë and Hogan, 2008; Austin et al., 2009; Delanoë and Hogan, 2010; Cazenave et al., 2019).

420 The differences in the integrated IWC would change the results from Section 3. The correlation coefficient exhibit lower values for heights near the freezing level when 2B-CWC-RO is used, and regions over land also exhibit lower correlation coefficient with 2B-CWC-RO. The ratios between the  $\Delta\Phi$  and the integrated IWC change accordingly to the differences between the two IWC products, since  $\Delta\Phi$  would be the same (e.g. see Figure A1-b).

*Data availability.* The datasets used for this work are the following: The PAZ polarimetric Radio Occultation data can be obtained from 425 <https://paz.ice.csic.es> (last accessed: October 12, 2022). The DARDAR dataset can be obtained from <https://www.icare.univ-lille.fr/> (last accesses: October 12, 2022). The Cloudsat 2B-CWC-RO dataset can be obtained from <https://www.cloudsat.cira.colostate.edu/> (last accessed: October 12, 2022)

**Figure A1.** Comparison between the integrated IWC from the Cloudsat retrieval using the 2B-CWC-RO and DARDAR V3. Panel (a) shows the relationship between integrated IWC from the 2B-CWC-RO (x-axis) and DARDAR V3 (y-axis) for all observations regardless of height. Panel (b) shows the fractional difference between the mean DARDAR V3 and 2B-CWC-RO integrated IWC as a function of height, for three different latitudinal bands (see legend). Panel (c) shows the gridded mean DARDAR - 2B-CWC-RO integrated IWC corresponding to a tangent height of 6 km
