Abstract. The nitrate depletion and HNO₃ release in internally mixed nitrate and dicarboxylic acids (DCAs) particles have been widely detected in field and laboratory studies. Nevertheless, considerable discrepancies are still present among these measurements, and the influence factors for this acid-displacement reaction have not yet been elucidated. In this work, the hygroscopic growth and chemical composition evolution of mixtures of NaNO₃ and DCAs, i.e., oxalic acid (OA), malonic

- 15 acid (MA), and glutaric acid (GA), were measured using attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) and vacuum FTIR techniques. The nitrate depletion from NaNO₃/OA mixtures was observed in both the measurements, owing to the relatively higher acidity of OA compared to MA and GA. At the same time, the NaNO₃ phase state was found to act as a key regulator of nitrate depletion. Amorphous NaNO₃ solids at relative humidity (RH) < 5% were inert to liquid OA. With increasing RH, the mixtures experienced three interesting stages of phase changes showing different
- 20 HNO₃ release rates, e.g., at around 15% RH, the slow HNO₃ release was detected by the vacuum IR spectra, potentially indicating the transformation of amorphous solids to semisolid NaNO₃; in the second stage (sudden RH increase from ~ 15% to 61%), the HNO₃ release rate was increased by about an order of magnitude; when NaNO₃ deliquescence occurred in the third stage, this displacement reaction proceeded due to more available NO₃⁻ ions formation. Compared to OA, MA and GA reacted with nitrate only in vacuum FTIR measurement, while in ATR-FTIR measurement, the mixtures tended to be
- 25 effloresced completely without nitrate depletion. Further, the influences of ambient pressure, chemical composition, and water activity on HNO₃ release rates were estimated via Maxwell steady-state diffusive mass transfer equation. The results showed that weaker acidity of MA and GA as well as relatively lower HNO₃ diffusion rate in ambient gas phase mainly contributed to the unobserved nitrate depletion in ATR-FTIR measurement. Our findings reveal that chemical component, phase state, and water activity of particles, as well as HNO₃ gas phase diffusion play crucial roles on HNO₃ release from

30 nitrate and DCAs mixtures. This work may provide a new perspective on nitrate depletion in the aging processes during transport of tropospheric aerosols.

1 Introduction

35

2012).

Aerosol particles in the atmosphere can play crucial roles in determining Earth's climate, air quality, and human health (Pöschl, 2006; Stevens and Feingold, 2009; Carslaw et al., 2013; Ramanathan et al., 2001; Brown et al., 2006), depending on their various physicochemical properties, e.g., chemical composition, phase state, volatility, reactivity, hygroscopicity, the ability to absorb and scatter solar light as well as act as cloud condensation nuclei (CCN) (Pöschl, 2006; Mcfiggans et al., 2006; Haywood and Boucher, 2000; Farmer et al., 2015; Shiraiwa et al., 2017; Freney et al., 2018; Kuwata and Martin,

Sea salt and mineral dust aerosols can provide highly reactive surfaces for nitrates production through heterogeneous 40 reactions of gaseous nitrogen oxides such as HNO₃, N₂O₅, NO₂, and NO₃ (Gibson et al., 2006; Song and Carmichael, 2001; Finlayson-Pitts and Hemminger, 2000). Furthermore, heterogeneous and aqueous oxidation of dicarboxylic acid precursors and gas-particle partitioning of dicarboxylic acids (DCAs) in the atmosphere will cause the internal mixing of DCAs with sea salt and mineral dust aerosols (Tervahattu et al., 2002; Sullivan and Prather, 2007; Laskin et al., 2012; Wang et al., 2010), greatly influencing the hygroscopic behaviour and surface tension of mixed particles (Facchini et al., 1999; Jing et al., 2018;

45 Peng et al., 2001; Ovadnevaite et al., 2017; Hodas et al., 2015).

It is well known that the displacement of strong acids, i.e., HCl or HNO₃, by weak organic acids, e.g., DCAs, is not thermodynamically favoured in bulk solutions (Laskin et al., 2012). Whereas, the nitrate and chloride depletion in mixed nitrate/chloride and organic acid particles has been widely detected in field and laboratory measurements, which could be expressed as (Laskin et al., 2012; Wang and Laskin, 2014; Ma et al., 2019b; Ghorai et al., 2014; Shao et al., 2018)

50 NaCl/NaNO₃(aq) + HA (org)(aq) ↔ NaA (org)(aq, s) + HCl/HNO₃(g)(↑) (R1) The driving force for this displacement reaction is mainly governed by the acidity difference and volatility difference between the organic acids and HCl/HNO₃ (Laskin et al., 2012; Wang and Laskin, 2014; Chen et al., 2021). The acidity difference tends to shift the reaction equilibrium to the left, demonstrating the more dominating driving force for the substitution of strong acids by weak organic acids is the volatility difference (Laskin et al., 2012; Chen et al., 2021). For

55 instance, dissociated HCl concentration is ~ 10¹⁰ times higher than dissociated citric acid within mixed NaCl/citric acid (1/1 molar ratio) droplets, while the equilibrium gas phase concentration of HCl far exceeds that of citric acid with a factor of ~ 10¹⁹, suggesting the HCl partition into the gas phase would manage the direction of acid-displacement reaction (Laskin et al., 2012). In general, the less acidity difference, i.e., higher acid dissociation constants (K_{al}) of organic acids, and larger volatility difference, i.e., higher Henry's law constants (K_H) of organic acids, are favourable for gaseous HCl/HNO₃
60 liberation.

As indicated by previous studies, reactions between nitrate or chloride and oxalic acid (OA), which had a log ionization constant ($pK_{a1} = -log_{10}K_{a1}$) of 1.23 (Haynes and Lide, 2011), always occurred in mixed aerosols, causing the formation of less hygroscopic metal oxalates (Ma et al., 2013, 2019a, b; Ma and He, 2012). Nevertheless, there were considerable discrepancies among earlier observations for internally mixed NaCl and malonic acid (MA) ($pK_{a1} = 2.83$). Laskin et al. (2012), Ghorai et al. (2014), Laskina et al. (2015), and Li et al. (2017) supported the occurrence of HCl substitution by MA, while Choi and Chan (2002), Pope et al. (2010), and Ma et al. (2013) did not observe this displacement reaction. Likewise, succinic acid (SA) ($pK_{a1} = 4.20$) was suggested not to react with internally and externally mixed NaCl by Ma et al. (2013), while Ghorai et al. (2014) found that glutaric acid (GA) ($pK_1 = 4.32$) was reactive to NaCl. In another publication, nitrates were proved to be reactive to MA and GA leading to nitrate depletion (Wang and Laskin, 2014). Indeed, the differences in particle sizes, substrate materials, acidity and volatility of DCAs may be responsible for these controversial results, but it is true that the interactions between organic acids and nitrate/chloride are still not clear.

To the best of our knowledge, the influence of particle-phase state on nitrate depletion has not been considered yet. As Wang et al. (2017) indicated, the OA droplets deposited on polytetrafluoroethylene (PTFE) substrate would crystallize to form OA dihydrate at \sim 71% relative humidity (RH) during dehydration, which further lost crystalline water to form

- 75 anhydrous OA at ~ 5% RH; meanwhile, no deliquescence was observed upon hydration. Pure NaNO₃ droplets might not be effloresced but convert into highly concentrated droplets at low RH upon drying (Liu et al., 2008), or effloresced at certain RH values, e.g., levitated NaNO₃ droplets effloresced at RH near 40% (Lamb et al., 1996), or deposited NaNO₃ particles on hydrophobic and ZnSe substrates effloresced at 34% RH and 62.5% RH, respectively (Zhang et al., 2014). Furthermore, atmospheric aerosols can exist in highly viscous (i.e., semisolid or glassy), solid, liquid, or solid-liquid mixing states
- 80 (Krieger et al., 2012; Mikhailov et al., 2009; Virtanen et al., 2010; Koop et al., 2011), depending on varying ambient RH, temperature, heterogeneous inclusions and so on (Ma et al., 2021b). Additionally, the particle-phase state has been proved to play a critical role in determining the reactivity of secondary organic material (SOM) upon ammonia exposure (Kuwata and Martin, 2012). These scenarios pose a key issue concerning how the particle-phase state would affect nitrate depletion in sea salt and mineral dust particles.
- 85 In this work, two measurement techniques, i.e., attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) and vacuum FTIR, were carried out to measure the hygroscopic behaviour and nitrate depletion of mixed NaNO₃ and DCAs particles. The effects of HNO₃ gas phase diffusion, as well as chemical component, phase state, and water activity of mixed particles on nitrate depletion were further explored. This work does enhance our understanding of interaction mechanisms of DCAs and nitrate.

90 2 Experimental Section

95

2.1 Sample preparation

The 0.1 mol L⁻¹ solutions of NaNO₃/OA, NaNO₃/MA, and NaNO₃/GA with molar ratio of 1:1 (or 3:1) were prepared by dissolving nitrate and DCAs into ultrapure water (18.2 M Ω cm resistivity). The bulk solutions were nebulized ultrasonically to produce aerosol droplets deposited on two CaF₂ windows in vacuum FTIR measurement and the Ge substrate in ATR-FTIR measurement.

2.2 Vacuum FTIR measurement

The vacuum FTIR technique was composed of a vacuum FTIR spectrometer and a RH controlling system. The experimental apparatus and method have been described in detail by our previous studies (Leng et al., 2015; Zhang et al., 2017; Ma et al., 2019c). Briefly, the vacuum FTIR spectrometer (Bruker VERTEX 80v) consisted of a vacuum optics bench, a sample compartment and a vacuum pump. The RH controlling system was composed of a high purity water reservoir, a sample chamber, and another vacuum pump. Water vapor from the water reservoir was fed into the sample chamber, and was pumped out by the vacuum pump. Two solenoid valves were installed in the pipeline of water vapor to instantaneously switch water vapor inlet and outlet. Meanwhile, two needle valves were configured to respectively adjust the flow rates of water vapor inlet and outlet.

- The radius of deposited droplets on CaF_2 windows was in the range of ~ 1-3 µm (Zhang et al., 2017). After the nebulization, the CaF_2 windows were installed onto the sample chamber to seal it. The air in optics bench, sample compartment and sample chamber was pumped out to remove water vapor and CO₂. The baseline pressure in optics bench and sample compartment was pumped to ~ 0.21 kPa and the sample chamber arrived to ~ 0.01 kPa to remove water vapor and CO₂. A differential pressure transmitter (Rosemount 3051, accuracy > 0.5%) was used to measure water vapor pressure
- 110 in the sample chamber, which could be used to calibrate the ambient RH (Zhang et al., 2017). The water content of deposited particles could be estimated by the integrated absorbance of stretching vibration band of liquid water molecules at 3400 cm⁻¹ (Ma et al., 2019c). The resolution of collected IR spectra was 4 cm⁻¹. All measurements were made at 23-26 °C.

2.3 ATR-FTIR measurement

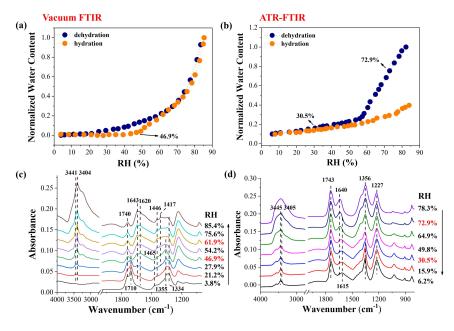

Detailed description of ATR-FTIR measurement has been reported elsewhere (Zhang et al., 2014; Ren et al., 2016). Briefly,
the IR spectra of deposited particles on a horizontal ATR (Spectra-Tech Inc. USA) accessory with the Ge substrate were measured by a Nicolet Magna-IR model 560 FTIR spectrometer equipped with a liquid-nitrogen cooled mercury-cadmium-telluride (MCT) detector. The ambient RH in the sample cell was controlled by adjusting the flow rate ratio of gas streams of dry and humidified nitrogen with a total flow rate of 800 mL·min⁻¹. The ambient RH and temperature were recorded by a hygrometer (Centertek Center 310, accuracy of ± 2.5%) in the outlet of sample cell. The diameter of deposited droplets was

- 120 1-5 μ m with a median diameter of ~ 3 μ m (Zhang et al., 2014). The IR spectra were collected between 4000 and 600 cm⁻¹
 - 4

with a resolution of 4 cm⁻¹. Similar to vacuum FTIR measurement, the water content in aerosol particles was determined by the integrated absorbance of the stretching vibration band of liquid water.

3 Results and Discussions

3.1 Hygroscopic growth and chemical composition evolution of NaNO₃/OA mixtures

125

Figure 1. Hygroscopic growth curves of 1:1 mixed NaNO₃/OA particles measured by vacuum FTIR (a) and ATR-FTIR (b), as well as corresponding IR spectra during the humidification in vacuum FTIR measurement (c) and during the dehumidification in ATR-FTIR measurement (d).

The hygroscopic behaviour and IR features of individual components, i.e., NaNO3, OA, MA, and GA, are shown in the Supplement. Fig. 1 displays the hygroscopic growth and chemical composition evolution of 1:1 NaNO₃/OA mixtures during 130 a RH cycle. In vacuum FTIR measurement, the deposited droplets on CaF2 windows are first dried in vacuum, and then undergo a humidification-dehumidification cycle. As shown in Fig. 1c, there are two feature bands assigned to the stretching mode of COOH functional groups (ν (COOH)) at ~ 3.8% RH, i.e., the 1740 cm⁻¹ band assigned to liquid OA and 1710 cm⁻¹ band assigned to crystalline anhydrous OA (Wang et al., 2019), indicating the coexistence of liquid OA and anhydrous OA.

- The 1355 cm⁻¹ band is attributed to NO₃⁻ asymmetric stretching vibration ($v_3(NO_3^-)$) of amorphous NaNO₃ solids, as discussed in the Supplement. The weak absorption at 1620 cm⁻¹ indicates small amounts of crystalline oxalate formation (Hind et al., 1998; Wang et al., 2019), judged from the IR features of Na₂C₂O₄ solids shown in Fig. S4. In addition, the peak at 1465 cm⁻¹ is attributed to O-H bending mode of HC₂O₄⁻ ions (Villepin and Novak, 1971), indicative of the dissociated HC₂O₄⁻ formation. Likewise, Wang et al. (2017) observed the formation of NH₄HC₂O₄ in mixed (NH₄)₂SO₄/OA droplets
- 140 upon drying. As already indicated, the release of HNO_3 and associated organic acid salts formation have been detected in several previous studies, thus herein, Tthese scenarios observations can demonstrateconfirm the HNO_3 release and nitrate depletion and HNO_3 release from in NaNO₃/OA mixtures, which is expected to occur in the vacuuming process. As RH increases to 21.2%, the feature bands at 3441 and 3404 cm⁻¹ appear, indicating the transformation of anhydrous OA to OA dihydrate. After that, the stronger 1620 cm⁻¹ and 1417 cm⁻¹ bands, assigned to $C_2O_4^{2-}$ ion vibrating (Wang et al., 2019), and
- 145 weaker 1465 cm⁻¹ band indicate the conversion of aqueous NaHC₂O₄ to crystalline Na₂C₂O₄. Thus, the acid-displacement reaction for NaNO₃/OA mixtures can be expressed as

 $\begin{aligned} HC_{2}O_{4}^{-}(aq) + H^{+}(aq) + 2Na^{+}(aq) + 2NO_{3}^{-}(aq) \rightarrow HC_{2}O_{4}^{-}(aq) + 2Na^{+}(aq) + NO_{3}^{-}(aq) + HNO_{3}(g)(\uparrow) \rightarrow C_{2}O_{4}^{2-}(aq) + H^{+}(aq) + 2Na^{+}(aq) + NO_{3}^{-}(aq) \rightarrow Na_{2}C_{2}O_{4}(s) + HNO_{3}(g)(\uparrow) \end{aligned}$ (R2)

- In previous studies, the reaction between NaCl or NaNO₃ and OA was found to produce disodium oxalate (Ma et al., 2013, 2019b). To our knowledge, the formation of intermediate product of sodium hydrogen oxalate is first observed here.
 - As shown in Fig. 1a and 1c, we can infer that the NaNO₃ deliquescence proceeds at 46.9%-61.9% RH in NaNO₃/OA mixtures, significantly lower than the DRH of pure NaNO₃ particles (seen Fig. S2). Indeed, the aerosol DRH can be significantly reduced by the mixing of organic acids and inorganic salts, according to experimental measurements and thermodynamic model predictions (Bouzidi et al., 2020; Hodas et al., 2015; Marcolli et al., 2004). Furthermore, the OA
- dihydrate and crystalline Na₂C₂O₄ cannot be fully deliquesced due to their very high DRHs (Ma et al., 2013; Wang et al., 2019). Note that a solid-liquid equilibrium may be established, i.e., small amounts of OA dihydrate and Na₂C₂O₄ dissolve into the aqueous phase (Hodas et al., 2016). The IR spectra during the dehumidification are shown in Fig. S5a. As seen, the 1357 cm⁻¹ band becomes sharper at ~ 13.6% RH, indicating the remaining NaNO₃ efflorescence. Moreover, the residue of reactants indicates the incomplete reaction between OA and NaNO₃, consistent with the observations by Ma et al. (2019b) for Ca(NO₃)₂/OA, NaNO₃/OA and Zn(NO₃)₂/OA mixed systems.

Figure 1b and 1d display the hygroscopic growth and IR spectra of 1:1 NaNO₃/OA mixtures measured by ATR-FTIR.

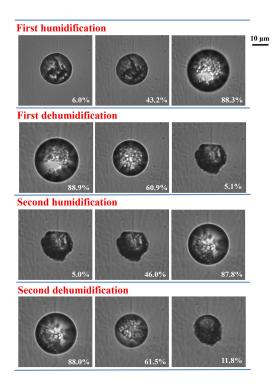

Mixed particles undergo a dehumidification-humidification cycle. Upon dehydration, the water content of particles gradually decreases with decreasing RH. When the RH attains \sim 72.9%, the shoulder bands at 3445 and 3405 cm⁻¹ assigned to OA dihydrate appear, as shown in Fig. 1d. Meanwhile, a new peak located at 1615 cm⁻¹ is observed, suggesting the formation of

disodium oxalate. As RH decreases to 30.5%, the 1356 cm⁻¹ band assigned to $v_3(NO_3^{-1})$ becomes sharper, indicating the NaNO₃ efflorescence. Upon hydration, the water content above ~ 60% RH (orange solid circles in Fig. 1b) is far below that upon dehydration (blue solid circles), owing to the persistence of crystalline OA and Na₂C₂O₄ (Ma et al., 2013; Wang et al., 2017; Peng and Chan, 2001; Wu et al., 2011). Only NaNO₃ solids are deliquesced, identified by the broader NO₃⁻ feature **带格式的:**下标

band at 1356 cm⁻¹ (seen Fig. S5b). For a better illustration of phase state changes of mixed particles, the optical images of

- 170 1:1 NaNO₃/OA mixture during two RH cycles are determined by an optical microscope operated with a video camera, which has been described in detail elsewhere (Ma et al., 2021a). For comparison with our vacuum FTIR measurement, the sample droplet first undergoes the rapid drying process and then two humidification-dehumidification cycles. As shown in Fig. 2, at 6.0% RH in the first humidification process, the particle shape is roughly round and smooth, indicative of the amorphous structure of NaNO₃ component (Hoffman et al., 2004; Laskin et al., 2006; Tang and Fung, 1997). As RH increases to ~
- 43.2%, the particle morphology becomes darker, potentially indicating the uptake of trace amounts of water. After NaNO₃ deliquescence, nonhygroscopic OA dihydrate and Na₂C₂O₄ still remain in crystalline states. The mixed particle exists in solid-liquid mixing state involving liquid OA and NaNO₃, crystalline Na₂C₂O₄ and OA dihydrate. When the RH decreases to 5.1%, the particle surface becomes irregular, differing from the initial particle morphology, which may be attributed to the higher fraction of crystalline Na₂C₂O₄ as a reaction product. During the second RH cycle, the particle absorbs and releases
 180 water routinely, indicative of the presence of residual nitrate.
 - Besides, as shown in Fig. 1c, the absorbance of 1620 cm⁻¹ band assigned to oxalate shows a slight increase at RH as

low as 21.2%, implying the nitrate depletion proceeds at relatively low RH. Therefore, the effect of nitrate phase state on nitrate depletion needs to be further explored.

185 Figure 2. Optical images of 1:1 mixed NaNO₃/OA particle during two RH cycles. The corresponding ambient RH is marked at the bottom right of the images.

3.2 Effect of nitrate phase state on nitrate depletion for NaNO₃/OA mixtures

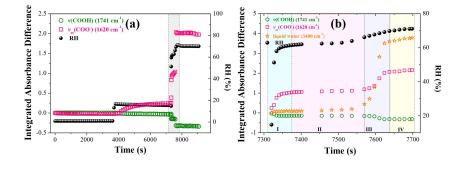

Figure 3. (a) Temporal changes in ΔA values of v(COOH) and $v_{as}(COO⁻)$ bands with stepwise increasing RH for 3:1 NaNO₃/OA mixed 190 particles. (b) Temporal changes in ΔA values of v(COOH), $v_{as}(COO⁻)$ and liquid water bands with increasing RH corresponding to the shaded period in (a).

To better understand the phase state effect on this acid-displacement reaction, 3:1 NaNO₃/OA mixtures are dried in vacuum and then exposed to stepwise increasing RH. The integrated absorbance difference (ΔA), derived from the deducted spectra of IR spectra at a certain time to that at the initial time, of 1741 cm⁻¹ band (assigned to COOH stretching mode, v(COOH)) and 1620 cm⁻¹ band (assigned to COO⁻ asymmetric stretching vibration, v_{as}(COO⁻)) as a function of time is determined and

- and 1620 cm⁻¹ band (assigned to COO⁻ asymmetric stretching vibration, v_{as} (COO⁻)) as a function of time is determined and shown in Fig. 3a. First, the ΔA remains almost unchanged at RH < 5%. As RH increases to ~ 15%, the ΔA of v_{as} (COO⁻) band exhibits a considerable increase, indicative of the occurrence of nitrate depletion. At the same time, the ΔA value of ~ 0.3 when the reaction equilibrium is reached implies that the nitrate depletion is limited at low RH. Note that the IR spectra changes with time at constant ~ 15% RH are supplied in Fig. S6. Almost no 1620 cm⁻¹ band is observed at the initial time,
- suggesting almost no $Na_2C_2O_4$ formation in the vacuuming process, potentially owing to the minimization of HNO₃ release arising from rapid water evaporation (Ma et al., 2013). Then, the 1620 cm⁻¹ band appears and becomes stronger with time, suggesting $Na_2C_2O_4$ can be continuously produced at constant ~ 15% RH. Considering the constant droplet water activity at constant 15% RH, these scenarios may provide more direct and powerful evidences for oxalate formation and associated nitrate depletion. Besides, coupled with the particle morphology changes shown in Fig. 2, we can infer the conversion of
- 205 amorphous NaNO₃ solids to highly viscous NaNO₃ semisolids due to the uptake of trace amounts of moisture. As RH continues to increase, the ΔA values of $v_{as}(COO^{-})$ and v(COOH) bands respectively increase or decrease. Finally, the ΔA values of the two bands remain constant with time.

Further, the variation in ΔA and water content as RH increases from ~ 14.8% to ~ 69.2% (shaded period in Fig. 3a) is processed and depicted in Fig. 3b. First, four stages are classed. In stage I, as RH increases from ~ 14.8% to ~ 61.0%, the 210 liquid water content (yellow pentagram) shows a very slight increase, while the ΔA of $v_{as}(COO^{-})$ band (pink pane) and v(COOH) band (green circle) increases or decreases significantly. This implies that the absorbed moisture with increasing RH is favourable for nitrate depletion. In stage II, the RH increases slightly, meanwhile, the water content and the ΔA values remain almost unchanged. As the RH increases to ~ 66.2%, the deliquescence of remaining NaNO₃ occurs, causing a sharp increase in liquid water content (stage III); meanwhile, the ΔA values of $v_{as}(COO^{-})$ and v(COOH) bands respectively increase

- 215 or decrease, indicating further nitrate depletion due to more available NO₃⁻ ions formation. In stage IV, the reaction equilibrium is reached and ΔA values remain unchanged. In addition, corresponding IR spectra changes of 3:1 mixtures during the shaded period are supplied in Fig. S7. At ~ 69.2% RH, the presence of 1741 cm⁻¹ band indicates the excess of liquid OA, suggesting this displacement reaction tends to reach equilibrium with comparable final concentrations of "reactants" and "products" (Wang and Laskin, 2014).
- For the quantitative evaluation of phase state effect, the kinetics of this displacement reaction should be further explored. For a given second-order reaction: $A + B \rightarrow P (P = \text{products})$, the reaction rate can be determined as

 $\frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = -k[\mathrm{A}][\mathrm{B}]$

(1)

where *k* refers to the second-order rate constant (cm³ molecule⁻¹ s⁻¹); [A] and [B] refer to the concentration of reactants A and B, respectively. Herein, during stepwise RH increasing, the concentration of reactant A, i.e., aqueous NO₃⁻, is limited and the concentration of reactant B, i.e., liquid OA, is in excess, and hence, this displacement reaction can be treated as a pseudo first-order reaction (He et al., 2017; Gao et al., 2018). The rate equation (1) can be rewritten as

$$\frac{d[A]}{dt} = -k_{app}[A]$$
And then,
(2)

 $[\mathbf{A}] = [\mathbf{A}_0]e^{-k_{\mathrm{app}}t}$

225

235

(3)

230 where k_{app} is the pseudo first-order rate constant (s⁻¹) and equals to k[B]. [A₀] refers to the initial concentration of reactant A. Based on this, the concentrations of reactant A and products P will change exponentially. As well, the integrated absorbance of 1620 cm⁻¹ ($v_{as}(COO^-)$) band can be used to describe the product concentration, thus the pseudo-first-order rate constant k_{app} can be determined by the exponential changes in absorbance difference of $v_{as}(COO^-)$ band, $\Delta \bar{A}$, as a function of reaction time (Hung and Ariya, 2007; Hung et al., 2005; Gao et al., 2018). Namely, $\Delta \bar{A} = A_{\infty}e^{-k_{app}t}$, where $\Delta \bar{A} = A_t - A_{\infty}$, A_t and

 A_{∞} represent the integrated absorbance at time *t* and time infinite, respectively.

As shown in Fig. 3, the HNO₃ release process can be divided into three stages, corresponding to three RH ranges, i.e., constant ~ 15%, sudden RH increase from ~ 14.8% to ~ 61.0%, and 66.2-69.2%. The measured k_{app} values are shown in Table 1 and the $\Delta \bar{A}$ changes with initialized reaction time are depicted in Fig. S8. As seen, the HNO₃ release is relatively slow with a k_{app} value of ~ 1.70 × 10⁻³ s⁻¹ at constant ~ 15% RH, possibly owing to limited NO₃⁻ concentration and mass

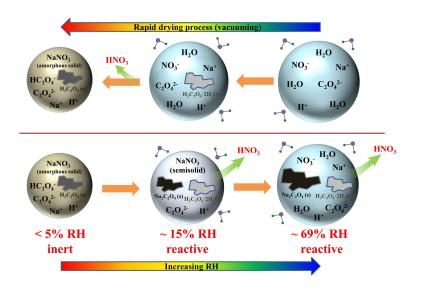

- transfer limitation within the particle phase; the humidification process at 14.8-61.0% RH exhibits the fastest HNO₃ release with the k_{app} value of ~ 7.45 × 10⁻² s⁻¹; during NaNO₃ deliquescence, the HNO₃ release rate slightly decreases but is still about one order of magnitude higher than that at constant ~ 15% RH. It is noteworthy that the R² of exponential fitting of $\Delta \bar{A}$ as a function of initialized reaction time at 66.2-69.2% RH is only 0.812, implying this displacement reaction may no longer obey to pseudo first-order reaction after NaNO₃ deliquescence due to the formation of large amounts of available NO₃⁻ ions,
- 245 in other words, the concentration of aqueous NO_3^- is no longer limited. Furthermore, the fractions of reacting liquid OA at the end of three RH ranges are measured by the ratio of integrated absorbance of 1741 cm⁻¹ (ν (COOH)) band at a certain time to that before the reaction, which show a value of ~ 32.3% before NaNO₃ deliquescence and reach ~ 71.0% after deliquescence. These results further confirm that aqueous NaNO₃ tends to be more reactive to liquid OA than amorphous and semisolid NaNO₃ due to the presence of large amounts of available NO₃⁻ ions.
- 250 **Table 1** The pseudo-first-order rate constant k_{app} and fractions of reacting liquid OA corresponding to different time periods and RH ranges.

Time periods (s)	RH ranges (%)	$k_{\rm app}$ (s ⁻¹)	R^2	Fractions of reacting liquid OA (%)
4042-5731	~ 15 (constant)	1.70×10^{-3}	0.991	6.9

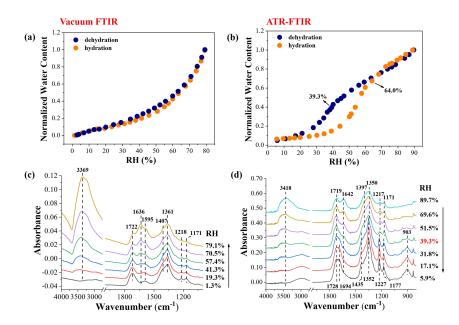

7320-7374	14.8-61.0	7.45×10^{-2}	0.958	32.3
7570-7651	66.2-69.2	2.77×10^{-2}	0.812	71.0

A summary of phase state changes and chemical compositional evolution of NaNO₃/OA mixed particles is shown in Fig. 4. During the rapid drying (i.e., vacuuming process), mixed droplets release water and then OA dihydrate forms. After that, mixed particles are effloresced to produce amorphous NaNO3 solids, and OA dihydrate is converted into anhydrous OA. At the same time, the aqueous NaHC2O4 is formed accompanied by the release of gaseous HNO3. For the humidification 255 process, first, amorphous NaNO3 solids at < 5% RH are inert to liquid OA, due to the unavailable dissociative NO3⁻ ions for HNO3 liberation. As RH increases to around 15% (or even lower), amorphous solids are converted into viscous semisolids, which can exhibit chemical reactivity to liquid OA causing nitrate depletion. When the NaNO3 is deliquesced, more available NO3⁻ ions are formed, and thus aqueous NaNO3 is more reactive to liquid OA causing higher nitrate depletion 260 extent. In previous studies, Li et al. (2017) indicated that the reaction between MA and NaCl could occur when aqueous H⁺ from MA and CI ions from NaCl were available for HCl liberation, meanwhile, the reaction would slow down or stop once the amount of available H⁺ became small or the particles were effloresced. Besides, Kuwata and Martin (2012) investigated the phase state effect of atmospheric SOM on its reactivity upon ammonia exposure. They found that the semisolid adipic acid and a-pinene SOM could take up small amounts of ammonia even at low RH. At high RH, the particles existed in liquid 265 state, and the absorbed water could act as a plasticizer which decreased the viscosity of particles and increased the diffusion coefficient of ammonia, thereby leading to extensive ammonia uptake. It was noteworthy that the ammonia uptake was also thermodynamic or kinetically limited, showing that aqueous SOM particles were not fully neutralized even for the highest

thermodynamic or NH₃ concentration.

270 Figure 4. Schematic diagram of phase state changes and chemical compositional evolution of NaNO₃/OA mixed particles in the vacuuming and humidification processes.

3.3 Hygroscopic growth and chemical composition evolution of NaNO₃/MA mixtures

Figure 5. Hygroscopic growth curves of 1:1 mixed NaNO₃/MA particles measured by vacuum FTIR (a) and ATR-FTIR (b), as well as
 corresponding IR spectra during the humidification in vacuum FTIR measurement (c) and during the dehumidification in ATR-FTIR measurement (d).

Figure 5a and 5b display the hygroscopic behaviour of mixed NaNO₃/MA particles deposited on CaF₂ windows and Ge substrate measured by vacuum FTIR and ATR-FTIR, respectively. Correspondingly, the IR spectra upon hydration and upon dehydration are shown in Fig. 5c and 5d. Note that the IR spectra upon dehydration in vacuum FTIR measurement and upon hydration in ATR-FTIR measurement are shown in Fig. S9a and S9b, respectively. In vacuum FTIR measurement, the water content of mixed particles increases or decreases continuously with changing RH without distinct phase transitions (seen Fig. 5a). In other words, the addition of MA can totally inhibit the NaNO₃ crystallization. Likewise, Braban and Abbatt (2004) and Parsons et al. (2004) did not observe the efflorescence of (NH₄)₂SO₄ or MA in 1:1 mixed (NH₄)₂SO₄/MA particles under dry conditions. Also, no efflorescence was observed by Ghorai et al. (2014) for 1:1 NaCl/MA mixed system. In Fig. 5c, the

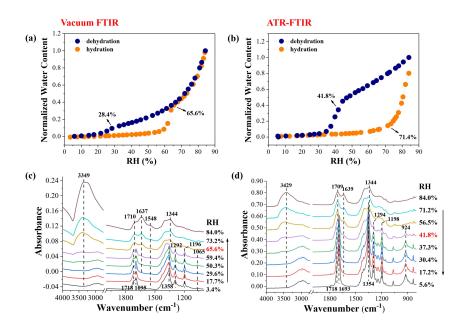

285 1722 cm⁻¹ band is assigned to v(C=O) of aqueous MA, and the 1407, 1218 and 1171 cm⁻¹ bands are also the characteristics of aqueous MA (Shao et al., 2017). The 1361 cm⁻¹ band is assigned to $v_3(NO_3^-)$ of NaNO₃ solution phase. More importantly, a new band located at 1595 cm⁻¹ indicates the formation of monosodium malonate (HOOCCH₂COONa) (Wang et al., 2019;

Shao et al., 2018). Thus, the displacement reaction between NaNO₃ and MA is confirmed by vacuum FTIR measurement as follows:

290 HOOCCH₂COOH(aq) + NaNO₃(aq) → HOOCCH₂COONa(aq) + HNO₃(g)(↑) (R3) The production of monosodium malonate has also been observed in mixed NaCl/MA aerosols by Li et al. (2017). They explained that the first acid dissociation constant (*K*_{a1}) of MA was about 1.5 × 10⁻³, which was ~ 3 orders of magnitude larger than the second one (*K*_{a2} = 2.0 × 10⁻⁶), resulting in much more HOOCCH₂COO⁻ dissociated from MA than CH₂(COO)₂²⁻ (Li et al., 2017). Besides, no disodium salts are observed in the NaNO₃/MA system, differing from the NaNO₃/OA system, which may be due to the higher acidity of OA (*pK*_{a2} = 4.19) than MA (*pK*_{a2} = 5.70). To further validate this displacement reaction, the IR spectra of NaNO₃/MA mixtures before and after the RH cycle are supplied in Fig. S10. It is clear that the 1722 cm⁻¹ band assigned to *v*(COOH) of MA becomes weaker, meanwhile, the 1595 cm⁻¹ band assigned to

 $v_{as}(COO^{-})$ of HOOCCH₂COO⁻ ions dissociated from monosodium malonate becomes stronger after the RH cycle.

- In ATR-FTIR measurement, deposited particles on the Ge substrate show distinct efflorescence and deliquescence 300 transitions during the RH cycle. The initial efflorescence relative humidity (ERH) is ~ 39.9% and the RH where the particles are fully deliquesced is ~ 64.0%. As shown in Fig. 5d, the IR features of mixtures at 89.7% RH are comparable to that measured by vacuum FTIR. Whereas, as RH decreases to 39.3%, the 1719 cm⁻¹ band, assigned to v(COOH) of aqueous MA, is split into two shoulder peaks located at 1728 and 1694 cm⁻¹. Furthermore, the 1397, 1217, and 1171 cm⁻¹ bands red-shift to 1435, 1227, and 1177 cm⁻¹, respectively. A new peak located at 903 cm⁻¹ appears. All these scenarios indicate the liquid-
- solid phase transition of MA (Shao et al., 2017). The 1350 cm⁻¹ band assigned to $v_3(NO_3^-)$ of aqueous NO_3^- turns into a sharp peak at 1352 cm⁻¹, suggesting the formation of NaNO₃ solids. In other words, the efflorescence of MA and NaNO₃ occurs synchronously at ~ 39.3% RH. As compared to vacuum FTIR results, we can infer that the heterogeneous efficacy of Ge substrate is much higher than CaF₂ windows, resulting in heterogeneous nucleation of MA and NaNO₃ upon dehydration (Ma et al., 2021b). As shown in Fig. 5b and S9b, the solid-liquid phase transition of crystalline MA and NaNO₃ ends at ~
- 310 64.0% RH, which is lower than the deliquescence points of pure components. Specially, no IR features of malonate sodium salts are observed, indicative of no nitrate depletion in ATR-FTIR measurement, which is differed from the vacuum FTIR observation. The causes for this discrepancy will be discussed detailed in Sec. 3.5. Besides, the chlorine depletion in 1:1 mixed NaCl/MA particles with two different RH changing rates is also experimentally detected to further probe the influence factors for acid-displacement reactions, and the detailed discussion is presented in the Supplement. Briefly, the disodium
- 315 malonate is produced in 1:1 mixed NaCl/MA particles during the dehumidification with the RH changing rate of 0.04% RH·s⁻¹, while in the faster dehumidification process (2.20% RH·s⁻¹), no malonate sodium salts are formed and the mixtures are effloresced completely. There are two probable causes for no chloride depletion observed in the fast drying process. One is the minimization of HNO₃-HCl release caused by rapid water evaporation (Ma et al., 2013). Another cause is the efflorescence transition of mixed droplets at relatively high RH arising from lower temperature of droplets caused by rapid
- 320 water evaporation (Ma et al., 2019c).
- 14

3.4 Hygroscopic growth and chemical composition evolution of NaNO₃/GA mixtures

Figure 6. Hygroscopic growth curves of 1:1 mixed NaNO₃/GA particles measured by vacuum FTIR (a) and ATR-FTIR (b), as well as
 325 corresponding IR spectra during the humidification in vacuum FTIR measurement (c) and during the dehumidification in ATR-FTIR measurement (d).

The hygroscopic growth curve and corresponding IR spectra of 1:1 mixed NaNO₃/GA particles measured by vacuum FTIR are shown in Fig. 6a and 6c, respectively. Routinely, mixed particles are first dried in vacuum and then undergo a RH cycle. In Fig. 6c, at ~ 3.4% RH, the shoulder peaks located at 1718 and 1695 cm⁻¹ are attributed to ν (C=O) of crystalline GA, and

- 330 the v(C-O) band at 1292 cm⁻¹ and rocking vibration mode of CH₂ (γ (CH₂)) located at 1196 cm⁻¹ are also the characteristics of GA solids (Wu et al., 2019a). The 1358 cm⁻¹ band is attributed to v_3 (NO₃⁻) of NaNO₃ solids. Indeed, mixed NaNO₃/GA particles exhibit distinctly different efflorescence behaviour compared with NaNO₃/MA mixtures, considerably consistent with the observation by Ghorai et al. (2014) for NaCl/GA(MA) mixed systems. This may be attributed to weaker inhibiting effect of GA than MA on inorganic salt crystallization (Ma et al., 2021b). In addition, a weak peak located at 1548 cm⁻¹
- appears upon hydration, indicating the formation of dissociated glutarate sodium salts. The weaker intensity compared with NaNO₃/MA system indicates the substantially weaker chemical reactivity of GA ($pK_{a1} = 4.32$) than MA ($pK_{a1} = 2.83$) (Ghorai et al., 2014). As RH increases to 65.6%, mixed NaNO₃/GA particles are fully deliquesced, and corresponding IR feature changes are consistent with the observation by Wu et al. (2019b). During the dehumidification, aqueous droplets are

effloresced at ~ 28.4% RH, judged mainly from the IR feature changes of mixtures shown in Fig. S12a. It should be noted

- 340 that only v₃(NO₃⁻) band experiences a red shift from 1344 to 1358 cm⁻¹, implying only NaNO₃ component effloresces and GA cannot be crystallized upon dehydration. The particle morphology of partial crystallization for mixtures of GA and nitrates was also observed by Wang and Laskin (2014). Braban (2004) found that GA would not effloresce upon drying for (NH₄)₂SO₄/GA mixed system, potentially owing to the residual (NH₄)₂SO₄ in solution phase added extra barrier to the formation of GA crystalline germ (Braban and Abbatt, 2004). Wu et al. (2019b) studied the stepwise efflorescence process
- 345 of 1:1 mixed NaNO₃/GA particles in the pulsed RH mode with vacuum FTIR method. They found that effloresced particles reversibly absorb and release water with pulsed RH changes when the minimal RH values were below 10%, suggesting there were still small amount of water retained in mixed particles, i.e., the mixed particles were partially crystallized. In addition, the crystallization of GA in the vacuuming process can be explained by the lower temperature of droplets arising from rapid water evaporation, as discussed in the Supplement.
- 350 In ATR-FTIR measurement, the efflorescence of mixed NaNO₃/GA particles occurs at ~ 41.8% RH, showing an abrupt decrease of water content with decreasing RH (seen Fig. 6b). For the humidification process, mixed particles obviously take up water at ~ 71.4% RH. The water content cannot match with that in the dehumidification process even until ~ 84.0% RH, suggesting the GA component cannot be deliquesced completely due to its high DRH (Marcolli et al., 2004; Yeung et al., 2010). This is further confirmed by corresponding IR features shown in Fig. S12b. As seen, the feature bands at 1207 and
- 355 924 cm⁻¹ assigned to GA crystals are still observed at RH as high as 84.0%. Likewise, partial dissolution of GA was also observed for the (NH₄)₂SO₄/GA system by Ling and Chan (2008). More importantly, there are no IR features of glutarate sodium salts observed during the RH cycle, which will be further explained in Sec. 3.5.

3.5 Influence factors for acid-displacement reactions

As already indicated, the driving out of gaseous HCl/HNO₃ from chloride/nitrate and organic acids mixtures is mainly
dominated by two factors, i.e., K_{a1} and K_H of organic acids (Wang and Laskin, 2014; Laskin et al., 2012). Note that the acid dissociation constant (*pK*_{a1}, *pK*_{a2}), equilibrium constant K₁, K₂ and K₃ utilized in the pH change simulation, as well as Henry's law constant (*K*_H) at 298 K for different acids involved in this study are listed in Table 2. In our previous review, the chlorine depletion in mixed NaCl/diacids systems was suggested to be related to the acidity and environmental concentration of organic acids, as well as ambient RH and particle size of mixtures (Chen et al., 2021). First, stronger acidity would cause
more available H⁺ in aqueous phase, favouring the acid-displacement reaction. The acidity of diacids followed the order of

OA > MA > SA > GA. Then, the higher acid concentration and lower RH would lead to greater HCl partial pressure, which was favourable for the partitioning of HCl into the gas phase. Finally, the chlorine depletion extent, ξ , was determined to be inversely proportional to r^2 where r was the droplet radius. In other words, the depletion extent ξ would increase greatly with decreasing droplet size. 370 As known, the driving out of volatile species such as HNO₃ from aqueous droplets can be quantified by Maxwell steady-state diffusive mass transfer equation (Chen et al., 2021; Cai et al., 2014; Ray et al., 1979). The mass flux of HNO₃ partitioning from particle to gas phase can be determined as

$$-\frac{dm}{dt} = \frac{4\pi r M D}{RT} (p_{\infty} - p_r) \tag{4}$$

where *m* denotes the mass of HNO₃ within the droplets (g); *t* denotes the evaporation time (s); *M* and *D* represent the 375 molecular weight (g mol⁻¹) and diffusion coefficient of HNO₃ in the air (m² s⁻¹), respectively; *R* is the ideal gas constant (J mol⁻¹ K⁻¹); *T* is the temperature (K); *r* is the droplet radius (m); p_{∞} and p_r represent the partial pressure of HNO₃ (Pa) at infinite distance and droplet surface, respectively.

When the RH decreases continuously, the evaporation rate of HNO₃ at a certain RH, k_{RH} (g s⁻¹), can be expressed as (assuming $p_{\infty} = 0$)

 $380 \quad k_{\rm RH} = \frac{dm}{dt} = \frac{4\pi r M D p_r}{RT}$ (5)

In the ATR-FTIR measurement, the diffusion coefficient of HNO₃ in the air is (1.18 ± 0.03) × 10⁻⁵ m² s⁻¹ under the condition of T = 298 K and P = 1 atm (Durham and Stockburger, 1986). Assuming that the droplet radius at 90% RH is ~ 1.5 µm, the droplet size r at any RH can be determined according to the size growth factors predicted by the Extended Aerosol Inorganic Model (E-AIM). p_r can also be estimated by the E-AIM model. Note that the E-AIM predictions are performed by 385 UNIFAC model with parameters modified by Peng et al. (2001). In addition, the RH can be converted to water activity, a_w, by Köhler equation to minimize the Kelvin curvature effect, as shown in the Supplement (Jing et al., 2016). Based on these, the k_{RH} for 1:1 mixed NaNO₃/OA, NaNO₃/MA, and NaNO₃/GA systems as a function of a_w in ATR-FTIR measurement can

be estimated and shown in Fig. 7a. Note that the solid phase formation is prevented to obtain the simulation data of supersaturated droplets at low RH.

390 Besides, according to Chapman-Enskog method, the diffusion coefficient of HNO₃ in the gas phase can be expressed as (Reid et al., 1987)

$$D = \frac{0.0026}{PM_{\rm AB}^{1/2} \sigma_{\rm AB}^2 \alpha_{\rm D}}$$
(6)

where subscripts A and B denote species A and B; *P* is the ambient pressure (bar); $M_{AB} = 2[(1/M_A) + (1/M_B)]^{-1}$ (g mol⁻¹); σ_{AB} represents the characteristic length (Å); Ω_D is the diffusion collision integral. Thus, the HNO₃ diffusion coefficient in 395 vacuum FTIR measurement, *D**, is much higher than that in ATR-FTIR measurement, due to the much lower ambient pressure in vacuum FTIR, *P**, which can be expressed as

$$P^* = P_0 * RH$$

(7)

where P_0 denotes the saturated water vapor pressure at 298 K (bar). Based on equations (6) and (7), the D^* value at any RH can be determined. Accordingly, the $k_{\rm RH}$ values in vacuum FTIR measurement can also be calculated for comparison, as shown in Fig. 7a. The $k_{\rm RH}$ values in vacuum FTIR measurement are ~ 35 times higher than those in ATR-FTIR measurement at $a_w = 0.9$, due to much lower ambient pressure in vacuum FTIR. Based on this, the discrepancies among the two

measurements for nitrate depletion in NaNO₃/MA(GA) systems can be mainly attributed to the higher HNO₃ release rate arising from faster HNO₃ gas phase diffusion in vacuum FTIR. Previous studies have indicated that numerous atmospheric processes involved aerosol particles were often carried out at high altitudes with significantly lower pressure than the ground level (Zhao et al., 2009; Rosenberger et al., 2018; Schilling and Winterer, 2014), and aerosol properties such as

- hygroscopicity under reduced pressure should be further characterized (Tang et al., 2019). Furthermore, mixed NaNO₃/OA systems exhibits higher HNO₃ release rate than NaNO₃/MA(GA) systems due to the higher acidity of OA. Meanwhile, the HNO₃ release rate for NaNO₃/OA system in ATR-FTIR measurement is comparable to that for NaNO₃/GA system in vacuum FTIR measurement. These indicate that the lower acidity and hence lower reactivity of MA and GA also contribute
- 410 to the unobserved nitrate depletion in ATR-FTIR measurement. In addition, all the k_{RH} values increase significantly with decreasing droplet water activity. Specifically, the k_{RH} at $a_w = 0.1$ is about two orders of magnitude higher than that at $a_w = 0.9$. It should be noted that in ATR-FTIR measurement, HNO₃ release from NaNO₃/MA(GA) aqueous droplets at very low RH would exhibit comparable levels to that for NaNO₃/OA system at relatively higher RH. Therefore, considerable HNO₃ release from NaNO₃/MA(GA) mixtures can be expected in case of no complete efflorescence of mixtures in ATR-FTIR

415 measurement. In other words, the crystallization of mixed droplets induced by the Ge substrate, causing the lack of aqueous H⁺ and NO₃⁻ ions available for HNO₃ liberation, tends to be another cause for negligible or even no HNO₃ release from NaNO₃/MA(GA) mixtures.

Besides, the pH changes of 1:1 NaNO₃/DCAs aqueous droplets with initial concentration of 0.1 mol/L as a function of nitrate depletion fraction are calculated and shown in Fig. 7b. The calculation method is similar to that for ammonium
depletion simulation proposed by Wang et al. (2019) (shown in the Supplement). As the NO₃⁻ in aqueous phase is depleted, the conversion of DCAs to their sodium salts proceeds, leading to the continuous reduction in droplet acidity.

Table 2 The acid dissociation constant (pK_{a1} , pK_{a2}), equilibrium constant K_1 , K_2 and K_3 utilized in the pH change simulation, as well as Henry's law constant (K_H) at 298 K for different acids involved in this study.

Species	pK_{a1}^{a}	pK_{a2}^{a}	$K_1(K_{a1})$	$K_2 (K_{a2})$	$K_3 (1/K_{a1})$	$K_{\rm H} \left({ m M/atm} ight)^{ m b}$
HNO ₃	-1.27		$> 2 \times 10^{1}$		5×10 ⁻²	$> 2 \times 10^{5}$
Oxalic acid	1.23	4.19	5.9×10 ⁻²	6.5×10 ⁻⁵		$(0.06-6.2) \times 10^8$
Malonic acid	2.83	5.70	1.5×10 ⁻³	2.0×10 ⁻⁶		$(0.26-3.3) \times 10^{10}$

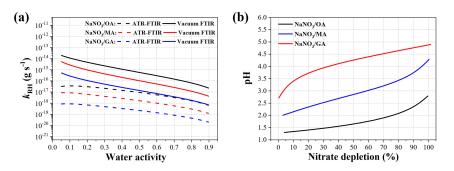

Figure 7. (a) The k_{RH} values for 1:1 mixed droplets of NaNO₃ and DCAs as a function of water activity at 298 K in the two measurements, i.e., ATR-FTIR (dashed lines) and vacuum FTIR (solid lines). Note that the droplet radius is assumed to be ~ 1.5 µm at $a_w = 0.9$. (b) The droplet pH of 1:1 NaNO₃/DCAs mixtures with initial concentration of 0.1 mol/L as a function of nitrate depletion fraction at 298 K.

430 4 Conclusions and atmospheric implications

The conversion of organic acids to organic acid salts and the internal heterogeneity can significantly alter the hygroscopic properties, acidity, optical properties, viscosity, and chemical reactivity of mixed aerosols (Ma et al., 2013, 2019b; Peng et al., 2016; Ghorai et al., 2014). However, the formation and precipitation of organic acid salts have not been considered by the current version of E-AIM. In this work, the hygroscopic behaviour and chemical composition modification of

- 435 NaNO₃/DCAs mixtures during the RH cycle were investigated by vacuum FTIR and ATR-FTIR techniques. First, OA could react with nitrate causing considerable nitrate depletion in both the measurements. Indeed, substantial metal oxalate complexes, which could not contribute to the CCN activity of aerosols, were frequently detected mixed in tropospheric aerosols (Furukawa and Takahashi, 2011). At the same time, the nitrate phase state would play a critical role in determining the occurrence and extent of nitrate depletion, e.g., amorphous NaNO₃ solids were inert to liquid OA; at around 15% RH,
- 440 some moisture was absorbed to form semisolid NaNO₃ accompanied by HNO₃ liberation; the nitrate depletion extent and HNO₃ release rate increased with increasing RH; during NaNO₃ deliquescence, the displacement reaction proceeded due to more available NO₃⁻ ions formation. In addition, dried NaNO₃ particles can be treated as a surrogate for a broad class of amorphous or semisolid species existing in tropospheric aerosols, which undergo homogeneous or heterogeneous reactions causing secondary inorganic or organic aerosols formation. Therefore, the phase state effect may also be suitable for relevant aerosol reaction systems.

MA and GA exhibited weaker chemical reactivity to nitrate than OA in vacuum FTIR measurement. More importantly, almost no sodium salts of MA and GA were produced in ATR-FTIR measurements, differing from the vacuum FTIR observations. This discrepancy was confirmed to be mainly dominated by the faster HNO₃ gas phase diffusion arising from much lower ambient pressure in vacuum FTIR. Besides, the weaker acidity of MA and GA, lower HNO₃ release rate at

- 450 higher RH, as well as the occurrence of efflorescence transition of aqueous droplets also contributed to the unobserved nitrate depletion in ATR-FTIR measurements. These scenarios indicate that organic acids have a potential to deplete nitrate based on the comprehensive consideration of acidity, particle-phase state, droplet water activity, as well as HNO₃ gas phase diffusion (influenced by ambient pressure and so on). Our results reveal that faster HNO₃ gas phase diffusion, higher acidity of organic acids, lower droplet water activity, as well as the absence of efflorescence transition upon drying would be
- 455 favourable for HNO₃ partition into the gas phase. In atmospheric environmentaerosols, insoluble materials such as mineral dust inclusions frequentlyeonstantly induce the heterogeneous nucleation of aerosol_droplets at relatively high RH, and thus displacement reactions between MA or GA and nitrates may rarely contribute to the nitrate depletion in mineral dust and sea salt aerosol_aerosolss. Indeed, in supermicrometer sea-salt aerosols, the chloride depletion was mainly attributed to sulfate and nitrate, followed by methanesulfonate and oxalate, while malonate and glutarate played a minor role in Cl⁻ loss (Kerminen et al., 1998).

Besides, this work will help us understand the discrepancies among previous observations on chloride/nitrate depletion. For instance, in Ghorai's study, the submicrometer NaCl/MA(GA) particles deposited on Si₃N₄ windows and TEM grids tended to stay metastable state under dry conditions, leading to no or partial crystallization of mixtures which facilitated the HCl liberation (Ghorai et al., 2014). Likewise, the micron-sized NaNO₃/MA(GA) particles deposited on carbon-filmed grids

- 465 and Si₃N₄ windows would exist in amorphous liquid or viscous semisolid state after drying, causing significant HNO₃ liberation (Wang and Laskin, 2014). In contrast, Ma et al. (2013) did not observe the chlorine depletion in mixed NaCl/MA(GA) particles placed in aluminum sample holder and deposited on Ge substrate, which might be attributed to the heterogeneous nucleation of mixed droplets in the fast drying process. Also, the formation of Na₂C₂O₄ was observed in internally mixed NaCl/OA particles due to the higher acidity of OA (Ma et al., 2013).
