Abstract. ~~Although~~ water-soluble organic carbon (WSOC) in the cryosphere can significantly influence the global carbon cycle and radiation budget, ~~;~~ However, WSOC in the snowpack has received little scientific attention to date. This study reports the fluorescence characteristics, absorption properties, and radiative effects of WSOC based on 34 snow samples collected from sites in northeastern China.

~~Sampling sites were divided into five groups, comprising southeastern Inner Mongolia (SEIM), northeastern Inner Mongolia (NEIM), the south of northeastern China (SNC), the north of northeastern China (NNC), and the Changbai Mountain area (CBM). We found~~ Together, these groups represent a significant degree of regional WSOC variability, with concentrations ranging from ~~0.500.5 ± 0.190.2~~ to ~~5.705.7 ± 3.683.7~~ $\mu\text{g g}^{-1}$ (mean = ~~3.593.6 ± 3.193.2~~ $\mu\text{g g}^{-1}$). ~~We~~ Then ~~he~~ three principal fluorescent components of WSOC are identified ~~as the three principal fluorescent components: of WSOC as~~ (1) thea high-oxygen~~ated~~ humic-like substances (HULIS-1) of terrestrial origin, (2) thea low-oxygen~~ated~~ humic-like substances (HULIS-2) of mixed origin, and (3) and thea protein-like components substances (PRLIS) derived from autochthonous microbial activity. In southeastern Inner Mongolia (SEIM) ~~SEIM~~, a region dominated by desert and exposed soils, the WSOC ~~_content~~ exhibits the highest humification index (HIX) but the lowest fluorescence (FI) and biological (BIX) indices; the fluorescence signal is mainly attributed to HULIS-1, and thus implicates soil as the primary source. By

1 contrast, the HIX (FI and BIX) value ~~was is~~ the lowest (highest) and ~~percentage of~~ PRLIS ~~is the most~~
2 ~~intense~~~~highest~~ in the remote ~~grasslands and forested~~ areas of ~~the northeastern Inner Mongolia~~
3 ~~(NEIM)~~NEIM, suggesting a primarily biological source. For ~~south and north of northeastern China (SNC~~
4 ~~and NNC)~~SNC and NNC, both of which are characterized by intensive agriculture and industrial activity,
5 the fluorescence signal is dominated by HULIS-2, and the HIX, FI, and BIX values are all moderate,
6 indicating ~~the~~ mixed origins for WSOC (anthropogenic activity, microbial activity, and soil). We also
7 observed that, throughout northeastern China, the light absorption of WSOC is dominated by HULIS-1,
8 followed by HULIS-2 and PRLIS. The contribution of WSOC to albedo reduction (average concentration
9 $3.6 \mu\text{g g}^{-1}$) in the ultraviolet-visible (~~UV-vis~~) band is approximately half that of black carbon (BC:
10 average concentration $0.6 \mu\text{g g}^{-1}$); ~~R~~radiative forcing is $3.8 (0.8) \text{ W m}^{-2}$ in old (fresh) snow, equating to
11 19 % (17 %) of the radiative forcing of BC. These results indicate that WSOC has a profound impact on
12 snow albedo and the solar radiation balance.

13 1 Introduction

14 Seasonal snow plays a significant role in Earth's solar radiation energy budget owing to its high
15 reflectivity (Beniston et al., 2017; Usha et al., 2020; Xie et al., 2018). In recent decades, however, the
16 extent of snow-covered areas has trended downward, partially as a result of the presence of light-
17 absorbing particles (LAPs) in the snowpack (Barnett et al., 2008; ~~Dumont et al., 2014~~; Groisman et al.,
18 1994; ~~Dumont et al., 2014~~). ~~Black carbon (BC), organic carbon (OC), mineral dust (MD), and biota~~
19 ~~comprise the principal light absorbing particles in seasonal snow (Di Mauro, 2020; Qian et al., 2015),~~
20 ~~which together serve to lower surface albedo and impose a positive radiative forcing (Dumont et al.,~~
21 ~~2014; Hansen and Nazarenko, 2004; Warren and Wiscombe, 1980; Zhang et al., 2017). Concurrently,~~
22 ~~LAPs absorb solar radiation, thereby accelerating snow melt (Li et al., 2021b). Ultimately, the disruption~~

1 of the global radiative balance due to LAPs has important implications for regional and global climate
2 change (Skiles et al., 2018). The LAPs in seasonal snow, such as black carbon (BC), organic carbon
3 (OC), mineral dust (MD), and biota (Beres et al., 2020; Di Mauro, 2020; Els et al., 2020; Qian et al.,
4 2015; Wu et al., 2016), can strongly absorb solar radiation, which ~~together serves~~ to lower surface albedo
5 and impose a positive radiative forcing (Cui et al., 2021; Dumont et al., 2014; Hansen and Nazarenko,
6 2004; Shi et al., 2022b; Warren and Wiscombe, 1980; Zhang et al., 2017). Ultimately, LAPs can
7 accelerate snow melting (Li et al., 2021b) and disturb the global radiative balance, therefore, have
8 important implications for regional and global climate change (Shi et al., 2022a; Skiles et al., 2018; ~~Shi~~
9 ~~et al., 2022a~~).

10 Snowpack BC and MD have been the focus of considerable research in snow-covered regions worldwide
11 (~~Antony et al., 2014; Doherty et al., 2014; Hegg et al., 2010; Li et al., 2021a; Wang et al., 2014b; Zhang~~
12 ~~et al., 2018; Antony et al., 2014; Hegg et al., 2010; Doherty et al., 2014; Wang et al., 2014b~~). As the most
13 important LAP (Bond et al., 2013; Doherty et al., 2010; ~~Shi et al., 2020; Wang et al., 2014b; Shi et al.,~~
14 ~~2020~~), the radiative efficiency of snowpack BC can be more than three times greater than that of carbon
15 dioxide (Flanner et al., 2007). ~~and~~ MD, another important snowpack LAP, is also known to alter the
16 cryospheric environment owing to its light-absorbing properties (Di Mauro et al., 2015; Painter et al.,
17 2007; Sarangi et al., 2020; Shi et al., 2021). Recently, researchers have also begun evaluating the
18 influence of biomes on global snow albedo (Hotaling et al., 2021). In contrast, however, the role of OC
19 remains poorly understood because of its complex composition and a ~~relative dearth~~ lack of OC-focused
20 research. Consequently, substantial uncertainty surrounds the origins, optical properties, and radiative
21 effects of snowpack OC.

1 A recent study has reported that the storage of OC in mountain glaciers and ice caps (~ 11 % of Earth's
2 land surface) could be as high as 6 petagrams (Pg; Hood et al., 2015), the majority of which is water-
3 soluble organic carbon (WSOC). WSOC is one of the largest sources of bioavailable organic carbon in
4 aquatic ecosystems (Battin et al., 2009). ~~Moreover, The recent study has~~ A recent study has reported that
5 the storage of OC in mountain glaciers and ice caps (~11 % of Earth's land surface) could be as high as
6 6 petagrams (Pg, Hood et al., 2015), the majority of which is water-soluble organic carbon (WSOC)
7 (Hood et al., 2015; Yan et al., 2016). The substantial part of WSOC in the glacier is highly bioavailable
8 and can be a source of labile organic matter for downstream ecosystems (Singer et al., 2012). The
9 physical and photochemical processes can occur within various WSOC in snow cover and glaciers, and
10 therefore have a great effect on atmospheric and glacier chemistry (Antony et al., 2011; Domine, 2002;
11 Grannas et al., 2007; Antony et al., 2011). Moreover, WSOC has important influences on the energy
12 budget and radiative forcing of snow cover and glaciers (Kirillova et al., 2014; Ram et al., 2010; Yan et
13 al., 2016). Asas the chief absorber of WSOC, water-soluble brown carbon (WS-BrC) can absorb
14 significant measures of solar radiation in the ultraviolet–visible (UV–vis) wavelengths (Murphy et al.,
15 2008). For instance, in their analysis of 21 ~~snow samples from the~~ Arctic and Antarctic ~~snow samples,~~
16 Anastasio and Robles (2007) ~~observed that attributed~~ 50 % of the total light absorption coefficients at
17 wavelengths of > 280 nm ~~might be attributed~~ to organic chromophores of WSOC. ~~In surficial snow~~
18 ~~samples from Barrow, Alaska,~~ Beine et al. (2011) reported that WSOC occupies almost the entire
19 absorption spectrum of the photochemically active region (300–450 nm) in surficial snow samples from
20 Barrow, Alaska,; and ~~And~~ Feng et al. (2016) observed that absorption in cryoconite samples from the
21 central Tibetan Plateau is dominated by WSOC components in the 300–350 nm range. Similarly, Yan et
22 al. (2016) measured WSOC in glacial snow from Laohugou glacier, northern Tibetan Plateau, where they

1 found that the radiative forcing is ~10 % that of BC. Together, these studies indicate that WSOC plays a
2 key role in global snowpack energy absorption (Niu et al., 2018; Zhang et al., 2020). We note that recent
3 researches on cryospheric WSOC mainly focused on alpine glaciers and polar regions ([Guo et al., 2022;](#)
4 [Li et al., 2022;](#) ~~[Guo et al., 2022](#)~~), while the extensive mid-latitude regions impacted by seasonal snowpack
5 remain relatively understudied.

6 The composition of WSOC is typically complex, and ~~the~~ characteristics of fluorescence and absorption
7 can vary widely among the different components. Nonetheless, recent studies have tended to treat WSOC
8 as a single entity and focus on the overall impacts ([Barrett and Sheesley, 2017;](#) [D'Sa et al., 2014;](#) [Niu et](#)
9 [al., 2018;](#) [Wu et al., 2019](#)), such that the specific roles of individual components are poorly constrained.

10 One commonly used analytical method for distinguishing the components and properties of fluorescence
11 is the fluorescence excitation-emission matrixes (EEMs), which has the advantage of high sensitivity
12 and small sample size (Coble, 1996; Kowalczyk et al., 2005). First applied in oceanic contexts (Coble et

13 al., 1990), EEMs ~~has~~ have been gradually extended to lakes, fog water, ~~and~~ rainwater, ~~and atmospheric~~
14 ~~aerosols in addition to glacial meltwater, ice cores, and snow~~ (Birdwell and Valsaraj, 2010; Huguet et
15 al., 2009; McKnight et al., 2001). At present, the application of EEMs on atmospheric aerosols has

16 entered a mature stage. EEMs have been used to identify fluorescent WSOC components in aerosols
17 from polar regions or urban backgrounds, and it has been found that different structures of WSOC
18 fractions exhibit different oxidation properties, which may provide a clue to understand the chemical
19 formation or loss of organic chromophores in atmospheric aerosols (Chen et al., 2016; Fu et al., 2015).

20 Recently, this method has been gradually extended to the analysis of glacier samples and snow samples
21 (Feng et al., 2018; Guo et al., 2022; Zhou et al., 2019b). Concurrently, parallel factor analysis

22 (PARAFAC) is an effective approach for extracting from complex EEMs the individual fluorescence

1 components and their corresponding fluorescence information, thus making EEM-PARAFAC a direct
2 and viable means for exploring sources of WSOC. For example, Zhou et al., (2019b) used EEM-
3 PARAFAC to identify the multiple sources of WSOC measured in seasonal snow in northwestern China.
4 Accordingly, we have applied EEM-PARAFAC in our analysis of snow samples for this study.

5 [EEM-PARAFAC can only provide plausible information about the component-specific influence of](#)
6 [WSOC on fluorescent properties, and the quantitative fractional contributions of specific components to](#)
7 [light absorption are still unknown. Recently, Chen et al. \(2019a\) collected atmospheric aerosol samples](#)
8 [in PM_{2.5} over Xi'an, China, and successfully attributed the dithiothreitol \(DTT\) activity levels to various](#)
9 [BrC components by coupling DDT and BrC datasets. A similar attribution method has been applied to](#)
10 [various research areas, including climate change, extreme weather, and atmospheric environments \(Cao](#)
11 [et al., 2015; Pokrovsky, 2019; Xin et al., 2016; Zhao et al., 2019\).](#) In this study, we applied a multiple
12 [linear regression method comparable to that of Chen et al. \(2019a\) to derive the fractional contribution](#)
13 [of each WSOC component to light absorption. Despite this method having been used elsewhere \(Wu et](#)
14 [al., 2022; Wu et al., 2021\), it remains a highly innovative approach to evaluating the light absorption of](#)
15 [snowpack WSOC.](#)

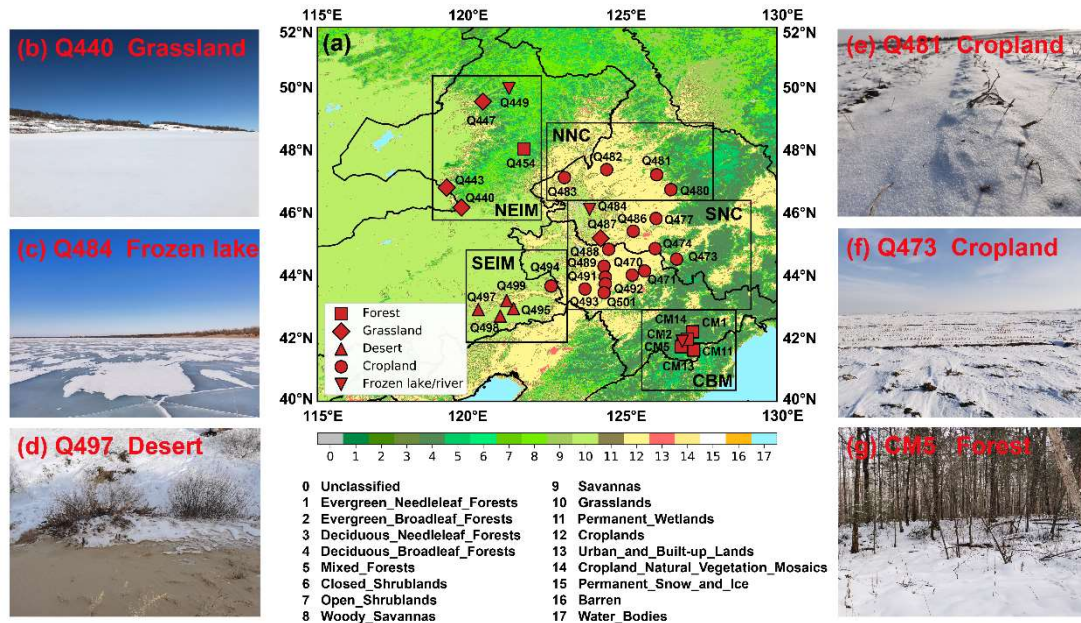

16 Northeastern China supports an extensive snowpack during winter and spring. As a major industrial and
17 agricultural center, this region is also the principal source of heavy airborne pollutants that are
18 incorporated into seasonal snow via wet and dry deposition (Wang et al., 2017). Coupled with intensive
19 tilling of farmland, the geographical proximity of northeastern China to [the](#) neighboring desert regions
20 also provides a source of soil organic matter that becomes entrained into the snowpack (Wang et al.,
21 2013b). Compared with research on BC-snow mixing ratios and their radiative impact in northeastern
22 China (Dang et al., 2017; Huang et al., 2011; Pu et al., 2019), studies of WSOC are still in their infancy.

1 To address this deficiency, we ~~analyzed 34 samples of seasonal snow collected in December 2020 and~~
2 ~~January 2021 to~~ ~~make~~ the ~~first~~primary~~first~~ investigation of the fluorescence characteristics,
3 absorption properties, and radiative effects of WSOC in seasonal snow samples in northeastern China.
4 Specifically, we applied EEM-PARAFAC to identify the origins and fluorescence characteristics of
5 snowpack WSOC, after which we derived individual absorption contributions for each WSOC
6 component using fluorescence data, an absorption data series, and an attribution method. Finally, we
7 estimated the reduction of snow albedo and radiative forcing caused by WSOC and BC via the Spectral
8 Albedo Model for Dirty Snow (SAMDS) radiative transfer model.

9 **2 Methods**

10 **2.1 Sample collection**

11 During ~~the months of~~ January and December 2020 and January 2021, we collected 34 snow samples
12 from sites across northeastern China, including the eastern part of Inner Mongolia and Heilongjiang and
13 Jilin provinces. Sample numbers were set following previous campaigns (Pu et al., 2017; Wang et al.,
14 2013b, 2017), with the exception that samples from the Changbai Mountain area are numbered
15 individually. The geographical distribution of sampling sites and respective land-cover types are shown
16 in Figure 1a.; ~~our~~The sites are characterized by five land-cover types, including forest, grassland, desert,
17 cropland, and frozen lake/river (Fig. 1b–g). On the basis of these geographical and environmental
18 classifications, we divided the sampling sites into five broad regions: southeastern Inner Mongolia (SEIM;
19 Q494–495, Q497–499), the south of northeast China (SNC; Q470–471, Q473–474, Q477, Q484, Q486–
20 Q489, Q491–Q493, Q501), the north of ~~n~~ortheast China (NNC; Q480–483), the Changbai Mountain
21 area (CBM; CM1–CM2, CM5, CM11, CM13–CM14), and northeastern Inner Mongolia (NEIM; Q440,
22 Q443, Q447, Q449, Q454).

1

2 **Figure 1: (a) Information on sampling site distributions in northeastern China, including the land cover type,**
 3 **site number, and grouping. Land cover types are derived from Collection 5.1 of the MODIS global land cover**
 4 **type dataset (MCD12Q1: <https://lpdaac.usgs.gov/products/mcd12q1v006/>) and are indicated by specific**
 5 **colors and symbols relative to sampling sites. Sampling sites are divided into ~~the~~ five groups defined by black**
 6 **rectangles. (b–g) Photographs depicting the typical snow and ground-cover conditions of our various sampling**
 7 **sites.**

8 ~~Our~~ The sample sampling sites were chosen at random but had to be located ≥ 20 km from cities and
 9 villages and at least 1a kmkilometer upwind of roads or railroads to minimize the influence of single-
 10 point pollution sources and to ensure the broadest regional representation. Furthermore, we performed
 11 sample collection oriented toward the wind to avoid contamination from personnel. At each site, we used
 12 a sterile disposable shovel to collect 0–5 cm-thick samples of surface snow, which were subsequently
 13 stored in sterile Whirlpak (Nasco, WI, USA) bags. For snow depths of < 5 cm, we determined the
 14 sampling depth according to the actual conditions to avoid inducting significant soil impurities during
 15 sampling. Snow samples were melted at room temperature (25 °C) and stored in a freezer at -20 °C until
 16 analysis in the laboratory. For more operational details, we refer the reader to Wang et al. (2013b).

1 2.2 Chemical species analysis

2 ~~After collection, samples were melted at room temperature (25 °C) before being filtered using a~~
3 ~~disposable sterile syringe (Jiangnan, Anhui, China) and 0.45 µm pore sized polytetrafluoroethylene~~
4 ~~(PTFE) filter (Jingteng, Tianjin, China) (Chen et al., 2019a). Prior to analysis, filtrates were stored in~~
5 ~~pre-baked (4 hours at 450 °C) glass vials in a freezer. For each sample, we used a total organic carbon~~
6 ~~analyzer (Aurora 1030W, OI Analytical, TX, USA) to measure the concentration of WSOC;~~
7 ~~measurement detection limits and relative standard deviations were 2 µg L⁻¹ and 1 %, respectively.~~
8 ~~Blank-corrected concentrations are provided in Table S1. All collected snow samples were stored in a~~
9 ~~freezer at -20 °C until ~~analyzed~~analysis in the laboratory. In the lab process, the samples were ~~firstly~~~~
10 ~~melted at room temperature (25 °C). Then 30 mL meltwater was taken for each sample with the clean~~
11 ~~disposable syringe (Jiangnan, Anhui, China) and injected into the pre-baked (4h, 450 °C) glass bottle~~
12 ~~passing through 0.45 µm pore-sized polytetrafluoroethylene filters (Jinteng, Tianjin, China). Finally, the~~
13 ~~concentration of WSOC was measured by the total organic carbon analyzer (Aurora 1030W, OI~~
14 ~~Analytical, TX, USA), and measurement detection limits and relative standard deviations were 2 µg L⁻¹~~
15 ~~and 1 %, respectively. Additionally, a blank sample prepared with ultrapure water was measured for~~
16 ~~blank correction before the sample measurement. The blank concentration of WSOC is 0.35 mg L⁻¹ and~~
17 ~~the blank-corrected WSOC concentrations are provided in Table S1. The concentration of WSOC for~~
18 ~~ultrapure water blank is 0.35 mg L⁻¹, and the value of each sample after blank subtraction is presented in~~
19 ~~Table S1.~~

20 We used 0.4 µm pore-sized polycarbonate filter membranes (Whatman, USA) to isolate BC and other
21 insoluble particles, following the protocols outlined by [Shi et al. \(2020\)](#) and [Wang et al. \(2014b\)](#) [Wang](#)
22 [et al. \(2020\)](#), after which we employed a custom-developed two-sphere integrating-sandwich (TSI) filter-

1 based spectrophotometer to measure particle absorption. Coupled with the mass of filtered meltwater,
2 these optical measurements were then converted to snowpack BC concentrations. To make these
3 calculations, we applied a BC mass-absorption coefficient (MAC) and absorption Ångström exponent
4 (AAE) of $6.3 \text{ m}^2 \text{ g}^{-1}$ (550 nm) and 1.1, respectively, after Pu et al. (2017). We note that TSI provides
5 greater accuracy and smaller overall uncertainties in the quantification of seasonal snow BC than do
6 thermo-optical carbon analysis (Wang et al., 2020), and thus it has been applied widely in this type of
7 research (Shi et al., 2020). For more detailed information, ~~we refer the reader to see~~ Wang et al. (2013b).

8 **2.3 Fluorescence and absorption measurement**

9 We obtained absorbance and fluorescence EEMs for filtered meltwater samples via synchronous
10 absorption-3D Fluorescence scanning spectrometry (Aqualog, Horiba Scientific) with the following
11 measurement parameters: [fluorescence spectra excitation range](#) = 240–800 nm in 3 nm intervals;
12 [emission range](#) = 152.25–929.92 nm in 5.04 nm (8 pixels) intervals, scanning interval = 0.3 seconds.
13 Prior to sample measurement, we ~~analyzed~~[analysed](#) aliquots of filtered ultra-pure water (18.2 M ω cm,
14 Milli-q Purification System, Millipore) as analytical blanks. We normalized ~~the~~ fluorescence intensity to
15 that of the water Raman unit (RU), which exhibits a peak excitation wavelength of 350 nm, and deducted
16 this Raman signal from all subsequent sample tests (Lawaetz and Stedmon, 2009). ~~The inner filtration~~
17 ~~effect and Rayleigh scattering peaks were also dispelled following the methods reported by Kothawala~~
18 ~~et al. (2013) and Bahram et al. (2006), respectively. The inner filtration effect correction is based on the~~
19 ~~absorbance-based approach (Kothawala et al., 2013), using the measured absorbance at each pair of~~
20 ~~excitation and emission wavelengths across the EEMs to convert the observed fluorescence intensity into~~
21 ~~the corrected fluorescence intensity. Rayleigh scattering peaks were processed by interpolation algorithm~~
22 ~~in the EEMscat MATLAB toolbox (Bahram et al. 2006).~~ As fluorescence spectra with wavelengths

1 greater than 600 nm are primarily noise (Zhou et al., 2019b), they are not considered further in this study.

2 ~~Likewise, any samples with absorption spectra of >600 nm wavelengths were subtracted for the baseline~~
3 ~~correction (Chen et al., 2019b).~~

4 We used version 0.6.3 of the MATLAB drEEM toolbox (<http://dreem.openfluor.org/>; Murphy et al.,
5 2013) to perform PARAFAC analysis on EEMs. Comprising the consistency index, residuals, and visual
6 inspections, the 3-component model is considered more reliable and representative than ~~are~~ the 2–7-
7 component models (Fig. S1 ~~in the Supplement~~) and passes the S4C6T3 split scheme (Fig. S2; Murphy
8 et al., 2013). The contributions of these three components to the overall fluorescence signal are expressed
9 as relative percentages of F_{\max} in RU, and the total fluorescence volume (TFV; RU nm²) is calculated
10 from the EEMs (Song et al., 2019). Normalized TFV equates to NFV (RU nm² (mg L⁻¹)⁻¹), TFV
11 c(WSOC)⁻¹), where c(WSOC) is the concentration of WSOC in the snow (mg L⁻¹), and represents a
12 sample's fluorescence ability (Chen et al., 2019a).

13 We calculated three fluorescence-derived indices—the fluorescence index (FI), biological index (BIX),
14 and humification index (HIX)—from the ratio of fluorescence intensity at specific excitation and
15 emission wavelengths. As demonstrated by previous studies (Birdwell and Valsaraj, 2010; Huguet et al.,
16 2009; McKnight et al., 2001), these ratios can help characterize potential sources of WSOC. Specifically,
17 the FI is taken to represent the relative amount of DOM derived from terrestrial and microbial/algae
18 sources (McKnight et al., 2001); high values correspond to terrestrially derived organics, and low values
19 reflect microbial sources. The HIX describes the degree of humification of soluble organic matter
20 (Zsolnay et al., 1999). During humification, the aromaticity of organic matter increases as microbial
21 availability decreases, such that higher HIX values correspond to more strongly humified and/or higher
22 aromaticity organics (principally of terrestrial origin), whereas lower values indicate autochthonous or

1 microbial origins. As a measure of autochthonous productivity (Huguet et al., 2009), elevated BIX values
 2 are associated with increased contributions of microbial-derived fluorescent organic matter. The three
 3 indices are calculated by the following equations ([Feng et al., 2016](#); [Huguet et al., 2009](#); [McKnight et al.,
 4 2001](#); [Ohno, 2002](#); [Huguet et al., 2009](#); [McKnight et al., 2001](#); [Feng et al., 2016](#)):

$$5 \quad FI = \frac{I(\text{Ex} = 370, \text{Em} = 470)}{I(\text{Ex} = 370, \text{Em} = 520)}, \quad \text{_____} \quad \text{---} \quad (1)$$

$$6 \quad BIX = \frac{I(\text{Ex} = 310, \text{Em} = 380)}{I(\text{Ex} = 310, \text{Em} = 430)}, \quad \text{_____} \quad (2)$$

$$7 \quad HIX = \frac{I(\text{Ex} = 254, \text{Em} = 435 - 480)}{I(\text{Ex} = 254, \text{Em} = 300 - 345) + I(\text{Ex} = 254, \text{Em} = 435 - 480)}, \quad \text{_____} \quad (3)$$

8 where I is the fluorescence intensity, and Ex and Em represent the excitation and emission wavelengths,
 9 respectively. To ensure a direct comparison with prior results, we recalculated published HIX data using
 10 the same calculation methods as in our ~~own~~ analyses. [According to a previous study, FI values of \$\leq 1.4\$
 11 correspond to terrestrial sources, and values of \$\geq 1.9\$ denote a primarily microbial origin. The values of
 12 \$1.4-1.9\$ suggest a mixed origin \(McKnight et al., 2001\).](#)

13 [The absorption spectra of WSOC were derived from 240 to 800 nm in 3 nm intervals. The baseline shifts
 14 and scattering effects of the measurement for the absorption spectra were corrected by subtracting the
 15 average absorbance above 600 nm from the whole spectrum \(Chen et al., 2019b\).](#) We converted sample
 16 absorbance to an absorption coefficient using the following equation:

$$17 \quad a_{\text{WSOC}}(\lambda) = \ln(10) \cdot \text{Abs}(\lambda) \cdot L^{-1}, \quad \text{_____} \quad (4)$$

18 where Abs is absorbance, λ is [the](#) wavelength, L is the path length of the cuvette (0.01 m), and a_{WSOC} is
 19 the absorption coefficient (m^{-1}).

20 Owing to the absorption characteristics of WSOC, we selected the absorption coefficient at 280 nm
 21 ($a_{\text{WSOC}}(280)$) to characterize the absorption intensity of WSOC [for comparison with other studies](#)
 22 [\(Zhang et al., 2010\).](#)

1 To investigate the wavelength dependence of WSOC absorption, we obtained the Absorption Ångström
2 exponent (AAE) via the following equation (Doherty et al., 2010; Niu et al., 2018; Wang et al., 2013b;
3 Yan et al., 2016):

$$4 a_{\text{WSOC}}(\lambda) = K \cdot \lambda^{-\text{AAE}}, \quad (5)$$

5 where K is a constant related to WSOC concentration.

6 We calculated the mass absorption coefficient (MAC_λ , $\text{m}^2 \text{g}^{-1}$) of our samples using the equation (Chen
7 et al., 2019b; Yan et al., 2016):

$$8 \text{MAC}_\lambda = a_{\text{WSOC}}(\lambda) / c(\text{WSOC}), \quad (6)$$

9 where a_{WSOC} is the absorption coefficient derived from Equation (4) and $c(\text{WSOC})$ (mg L^{-1}) is the
10 concentration of WSOC.

11 2.4 Snow albedo modeling and radiative forcing calculations

12 To ~~revealestablish~~ the radiative effect impact of snowpack WSOC in northeastern China, we used
13 SAMDS to simulate spectral snow albedo. This model is based on ~~the~~ asymptotic radiative transfer theory,
14 which has been verified ~~by-in~~ previous studies (Li et al., 2021b; Wang et al., 2017), ~~and described in~~
15 ~~detail by Wang et al. (2017), and it involves parameters including solar zenith angle, impurity~~
16 ~~concentrations, snow radius, and equivalent particle size.~~ As described in detail by Wang et al. (2017),
17 the model involves parameters including solar zenith angle, impurity concentrations, the mass absorption
18 coefficient of impurities, and snow grain radius. Measured values include the concentration of BC and
19 ~~the~~ absorption coefficients of WSOC. To quantify the influence of pollutants on snow albedo, we
20 assumed a semi-infinite snow layer and ~~a~~ uniform snow grain ~~radiusradii~~ of 100 μm for fresh snow and
21 1000 μm for old snow, consistent with previous studies (Pu et al., 2021). With the solar zenith angle
22 fixed at 60°, ~~consistent within line with~~ our sampling dates and locations, we calculated the reduction

1 [\(\$\Delta\alpha_i\$, \$i\$ represents BC only, WSOC only, and BC + WSOC, similarly hereinafter.\)](#) in spectral snow albedo
 2 derived from different types of impurities for the UV–vis (280–400 nm) and ultraviolet–near infrared
 3 (UV–NIR; 280–1500 nm) bands. ~~Radiative forcing was then derived by multiplying the albedo reduction~~
 4 ~~value by the incident solar radiation (Painter et al., 2013), permitting us to evaluate radiative forcing~~
 5 ~~under four scenarios: pure snow, WSOC only, BC only, and WSOC + BC. The radiative forcing resulting~~
 6 ~~from either BC or WSOC in snow (RF_i) was then derived by multiplying the albedo reduction value by~~
 7 ~~the incident solar radiation (Painter et al., 2013):~~

$$8 \quad RF_i = E \cdot (\alpha_{pure} - \alpha_i) = E \cdot \Delta\alpha_i, \text{-----} (7)$$

9 ~~where α_{pure} is snow albedo for pure snow and E is the average daily downward shortwave solar radiation~~
 10 ~~flux acquired from NASA’s Clouds and the Earth’s Radiant Energy System (CERES) product “CERES~~
 11 ~~SYN1deg” (<https://ceres.larc.nasa.gov/products.php?product=SYN1deg>).~~

12 3 Results and discussion

13 3.1 Characteristics of chemical species

14 Figure 2a shows the spatial distribution of measured WSOC in seasonal snow across northeastern China.
 15 ~~Averaged across our entire study area, t~~The ~~averaged~~mean WSOC concentration (arithmetic mean \pm
 16 standard deviation) is ~~3.593.6~~ \pm ~~3.193.2~~ $\mu\text{g g}^{-1}$, with a maximum of ~~17.9918.0~~ $\mu\text{g g}^{-1}$ and a minimum of
 17 ~~0.290.3~~ $\mu\text{g g}^{-1}$. Among ~~all~~the five regions, WSOC concentrations are highest in SNC (average $5.7 \pm$
 18 ~~3.683.7~~ $\mu\text{g g}^{-1}$), likely reflecting the greater degree of agricultural and industrial activity there compared
 19 with other regions (Lu et al., 2011; Wang et al., 2013b). We highlight that both agricultural and industrial
 20 sources are considered anthropogenic. In contrast, ~~the~~~~our~~ second highest measured concentrations
 21 (~~3.353.4~~ \pm ~~1.491.5~~ $\mu\text{g g}^{-1}$) are from SEIM, where desertification occurs (Fang et al., 2007) and is

1 **Figure 2: Spatial distributions of concentrations of (a) WSOC and (b) BC in snow samples. Sampling sites are**
2 **divided into the five groups defined in Figure 1. Bubble sizes are proportional to concentrations of WSOC**
3 **and BC.**

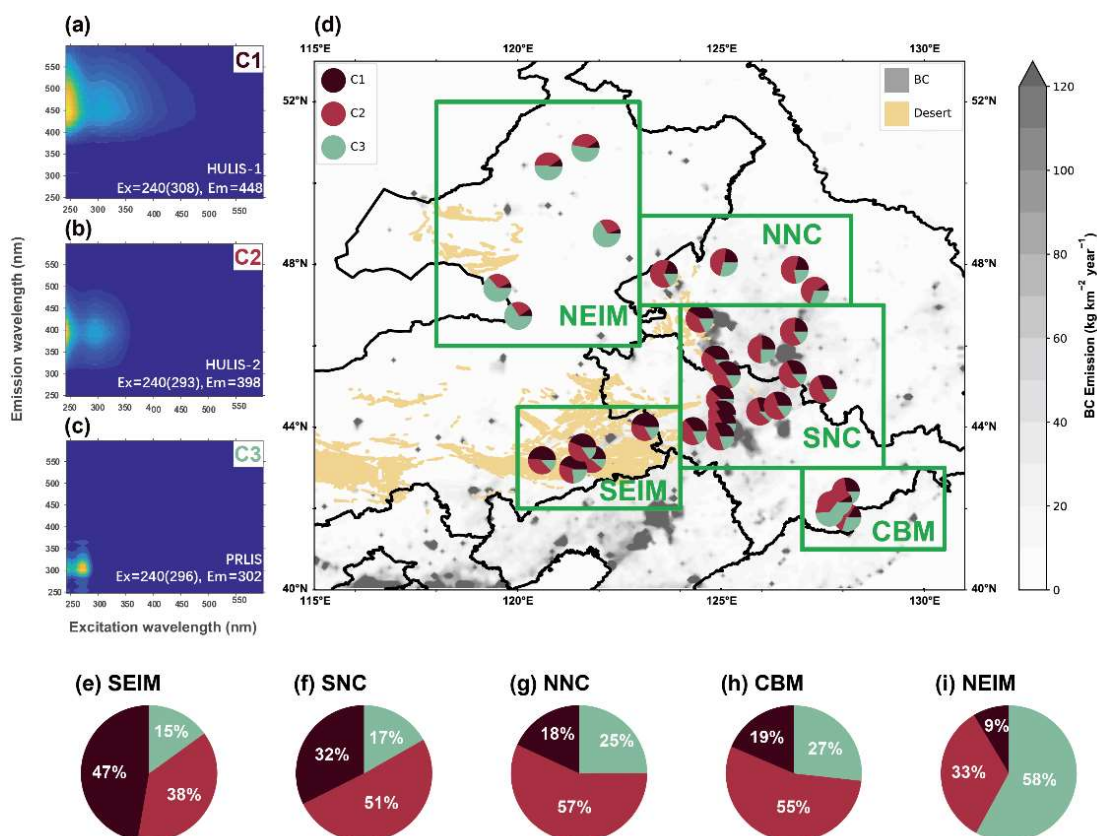

4 In comparison with previous studies, we observed that, with the exception of NEIM, our measured
5 WSOC concentrations are significantly higher than those reported for snow/ice from the Tibetan Plateau
6 (TGL; $\sim 0.71\text{--}1.02 \mu\text{g g}^{-1}$; Feng et al., 2016), the Alps ($\sim 0.14\text{--}0.78 \mu\text{g g}^{-1}$; Vione et al., 2021), North
7 America ($\sim 0.1\text{--}0.3 \mu\text{g g}^{-1}$; Fellman et al., 2015), and polar regions ($\sim 0.12\text{--}0.27 \mu\text{g g}^{-1}$; Antony et al.,
8 2014), but comparable to values in Laohugou glacier ice from the Tibetan Plateau ($\sim 1.02\text{--}2.6 \mu\text{g g}^{-1}$;
9 Feng et al., [2016](#), [2018](#)) and seasonal snowpack in northwestern China ($0.48\text{--}7.07 \mu\text{g g}^{-1}$;
10 Zhou et al., 2021). This finding implies that snowpack WSOC in northeastern China is significantly
11 contributing significantly to regional and global climate change (Domine, 2002).

12 A similar spatial pattern is exhibited by snowpack BC (Fig. 2b). For example, of all five regions, the
13 regional mean BC concentration is highest for SNC (mean: $922.99923 \pm 512.10512 \text{ ng g}^{-1}$), followed by
14 SEIM ($659.17659 \pm 581.85582 \text{ ng g}^{-1}$), NNC ($494.13494 \pm 223.81224 \text{ ng g}^{-1}$), and the CBM (391.38391
15 $\pm 312.49312 \text{ ng g}^{-1}$). BC concentrations are lowest in NEIM ($59.7960 \pm 18.6819 \text{ ng g}^{-1}$), in agreement
16 with the values in remote areas reported by Doherty et al. (2010).

17 **3.2 Fluorescence characteristics of WSOC**

18 Three fluorescent components (C1–C3) were captured by resolving the EEMs ~~spectras~~; all fluorescence
19 information is summarized in Table S2. C1 exhibits a primary peak at $\text{Ex} = 240 \text{ nm}$, $\text{Em} = 448 \text{ nm}$,
20 indicating the high-oxygenated humic-like substance (HULIS) found primarily in aromatic conjugated
21 macromolecules (Chen et al., 2016). The weaker secondary peak occurs at longer excitation wavelengths
22 ($\text{Ex} / \text{Em} = 308 / 448 \text{ nm}$), implying a higher aromatic content and greater molecular weight (Coble et
23 al., 1998). Wen et al. ([2021](#)) concluded that C1 is probably derived from natural terrestrial sources, such

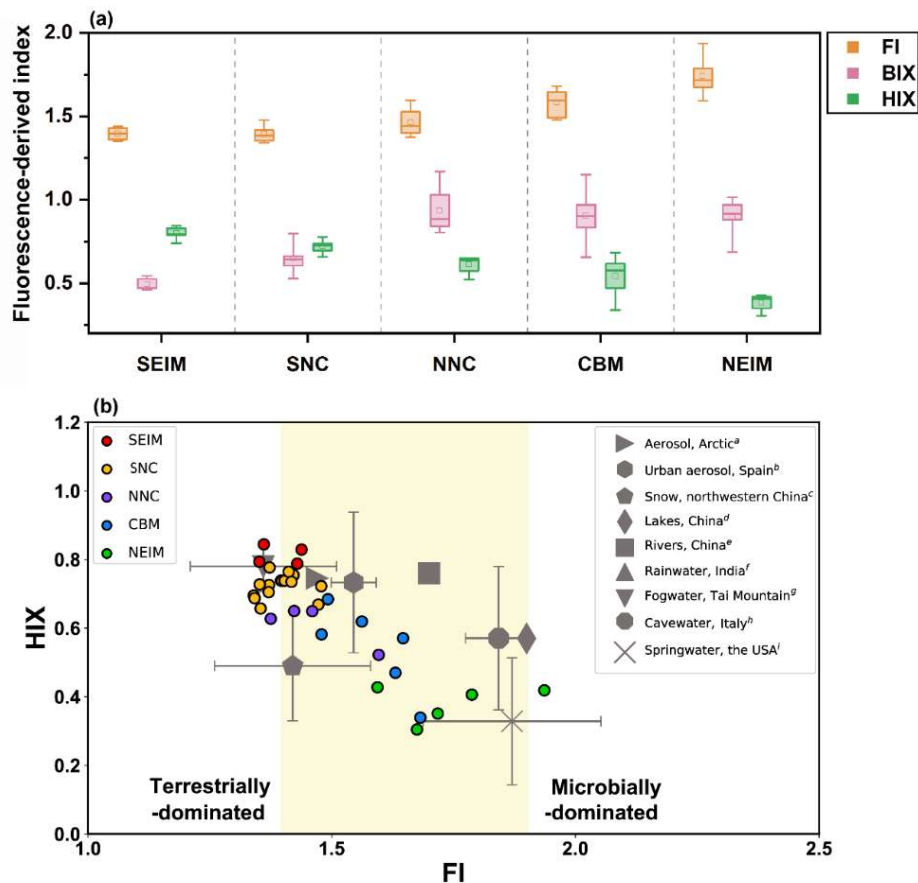

1 as dust and soil, as proposed originally by Stedmon et al. (2003) and Osburn et al. (2016). Accordingly,
2 we classified C1 as a terrestrial, humic-like substance, hereafter referred to as HULIS-1.
3 C2 exhibits a primary (secondary) peak at Ex = 240 (293) nm, Em = 398 nm, suggestive of the
4 lower-oxygenated HULIS (Chen et al., 2016). Observed in a variety of sources, Stedmon et al. (2003)
5 reported this component in terrestrial end-member samples. Whereas, both Murphy et al. (2011) and
6 Osburn et al. (2016) have since linked C2 to anthropogenic sources, such as urban runoff and sewage.
7 Microbial activity and the degradation of phytoplankton in natural aquatic systems are also thought to
8 contribute to this component (Yamashita et al., 2008; Zhang et al., 2009). Accordingly, we classified C2
9 as humic-like substances with complex origins in terrestrial, anthropogenic, and/or microbial sources,
10 hereafter termed HULIS-2. Unlike HULIS-1 and HULIS-2, C3 is recognizable as a UVB-like protein or
11 tyrosine-like fluorescence (hereafter PRLIS) with a primary (secondary) peak at Ex = 240 (293) nm, Em
12 = 398 nm (Osburn et al., 2016; Stedmon and Markager, 2005). PRLIS reflects autochthonously labile
13 DOM produced by biological processes (Stedmon et al., 2003) and has been reported in previous studies
14 of seasonal snow (Zhou et al., 2019b).

1
2 **Figure 3: (a–c) Three fluorescent components identified by PARAFAC analysis. (d) Relative contributions of**
3 **the three components to total fluorescence at each site. HULIS-1, HULIS-2, and PRLIS are represented by**
4 **the specific colors shown in the legend (top left corner). The distributions of BC emissions and desert areas in**
5 **our study area are indicated by gray and light yellow, respectively, with darker gray colors indicating higher**
6 **black carbon concentrations. (e–i) Average contributions of the three components in different groups of**
7 **samples. BC emission data are derived from the research group at Peking University**
8 **(<http://inventory.pku.edu.cn/home.html>, Wang et al., 2014a); the Chinese desert (sand) distribution dataset**
9 **is provided by the National Tibetan Plateau Data Center ([http://poles.tpdac.ac.cn/zh-hans/data/122c9ac2-53ee-](http://poles.tpdac.ac.cn/zh-hans/data/122c9ac2-53ee-4b9a-ae87-1a980b131c9b/)**
10 **4b9a-ae87-1a980b131c9b/; Wang et al., 2013a).**

11 Figure 3d depicts the spatial distribution of the relative contribution of three components to fluorescence,
12 with the regional averages given in Figure 3e–g. In SEIM, the greatest contribution is that of HULIS-1
13 (47%), followed by HULIS-2 (38%) and PRLIS (15%), indicating that the signal is dominated by local
14 soil/dust sources, consistent with the local environment (Figs. 2 and 3d). HULIS-2 plays a greater role
15 in SNC, where it accounts for half of the total fluorescence signals; ~~of the remaining half, with~~ HULIS-
16 1 is being next most important. This difference in key components between SEIM and SNC illustrates
17 the change in the primary source of fluorescence intensity. ~~Indeed, with the most intensive human activity~~

1 (e.g., agriculture, industrial emissions) being located in SNC (Figs. 1a and 3d; Guo and Hu, 2022),
2 HULIS-2 might be derived from any combination of terrestrial, anthropogenic, and microbial sources.
3 Nonetheless, in agreement with previous studies (Zhou et al., 2019b), our combined analysis suggests
4 that anthropogenic activity is the main contributor to seasonal snow in northeastern China. Indeed,
5 although HULIS-2 might be derived from any combination of terrestrial, anthropogenic, and microbial
6 sources (Osburn et al., 2016; Stedmon et al., 2003; Yamashita et al., 2008; Zhang et al., 2009), human
7 activity (e.g., agriculture, industrial emissions) is most intensive in SNC. Therefore, our combined
8 analysis suggests that anthropogenic source is the main contributor to seasonal snow in SNC (Figs. 1a
9 and 3d; Guo and Hu, 2022). The conclusion is also in good agreement with the previous study (Zhou et
10 al., 2019b). As in SNC, HULIS-2 also represents approximately half of the fluorescence signal in both
11 NNC and the CBM. The background environment of NNC is similar to that of SNC, with dense urban
12 cities and populations. In the latter CBM, which is although heavily forested (Fig. 1a; Guo and Hu, 2022),
13 the long-range transport of anthropogenic pollutants is responsible for the dominance of HULIS-2, as
14 discussed in Sect. 3.1. HULIS-1 accounts for less than PRLIS in both NNC and the CBM, which we
15 posit reflects the concealment of bare soil surfaces by deep snow and the importance of biological
16 processes due to the heavy vegetation cover. PRLIS accounts for >50 % of the total fluorescence signal
17 in NEIM, followed by HULIS-2; HULIS-1 contributes relatively little in this region. We attribute this
18 pattern to both the extensive grassland and forest cover, which obscures bare soil surfaces, and the
19 distance from anthropogenic pollution. These together serve to amplify the importance of biological
20 processes (Zhou et al., 2019a). Taken as a whole, the respective contributions of HULIS-1, HULIS-2,
21 and PRLIS to the fluorescence signals in our study area are ~30 %, ~50 %, and ~20 %, respectively. We
22 note that these findings correspond well with the background environmental conditions.

 5 **samples (colored dots) from northeastern China, together with the average and standard deviation of different**
 6 **types of WSOC (grey markers) adapted from: Arctic aerosols (^a Fu et al., 2015), Spanish urban aerosols (^b**
 7 **Mladenov et al., 2011), seasonal snowpack in northwestern China (^c Zhou et al., 2019b), Chinese lakes and**
 8 **rivers (^{d, e} Zhou et al., 2017), rainwater from Rameswaram, India (^f Salve et al., 2012), fog water from Tai**
 9 **Mountain, China (^g Birdwell and Valsaraj, 2010), cave water from Frasassi Caves, Italy (^h Birdwell and Engel,**
 10 **2010), and spring water in the USA (ⁱ Birdwell and Engel, 2010). Shaded areas represent mixed WSOC**
 11 **signatures.**

12 The FI, BIX, and HIX indices reveal spatial variability in fluorescence characteristics and thus permit
 13 the tracing of potential sources. Regionally averaged FI, BIX, and HIX values are depicted in Figure 4a.

14 Our results show that, ~~in general, the~~ FI values ~~are varies in the range of~~ 1.34–1.94 (mean = 1.49), BIX
 15 ~~between are~~ 0.46 and 1.17 (mean = 0.74), and HIX ~~between are~~ 0.30 and 0.84 (mean = 0.64). By
 16 comparison, reported mean FI, BIX, and HIX values for seasonal snow in Xinjiang (northwestern China)
 17 are 1.42, 0.76, and 0.55, respectively (Zhou et al., 2019b), suggesting that the impacts of humification

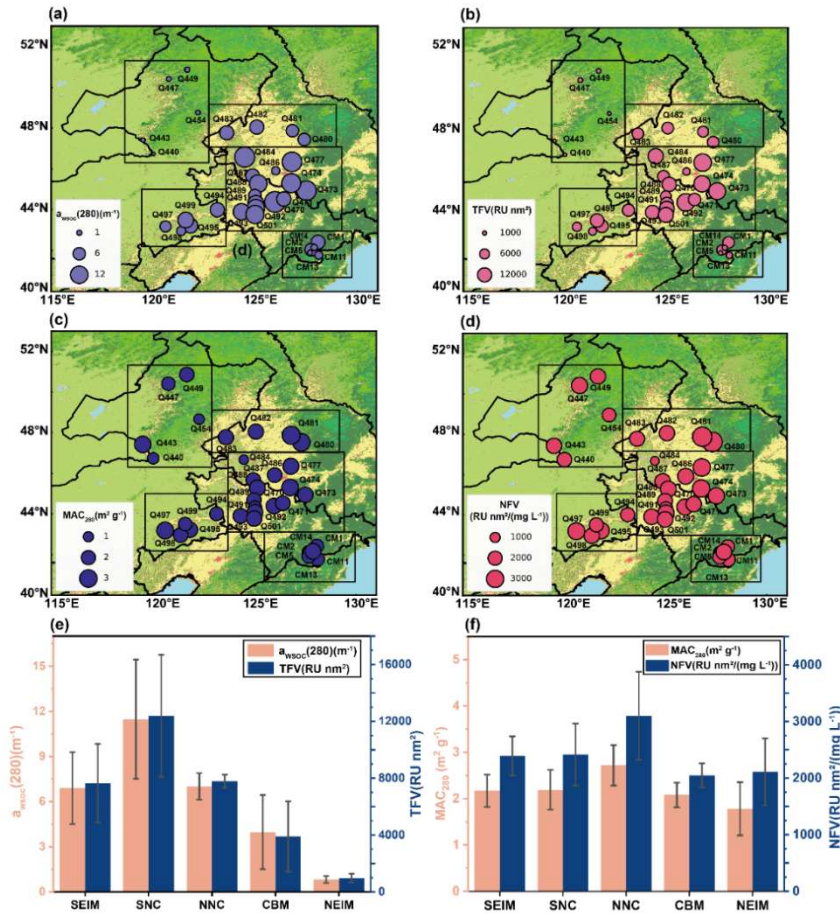

1 and WSOC aromaticity are slightly ~~higher-greater~~ in ~~our-the~~ study area than in Xinjiang. This outcome
2 implies a relatively strong terrigenous signal and correspondingly weaker biogenic signal in the seasonal
3 snowpack of northeastern China. Regionally, SEIM exhibits the lowest FI (mean = 1.40) and BIX (mean
4 = 0.49) values but the largest HIX value (mean = 0.80), further confirming the strong influence of highly
5 aromatic, terrestrially derived WSOC in this region relative to the others. In contrast, NEIM returns the
6 highest FI (mean = 1.74) and BIX (mean = 0.89) values, but the lowest HIX value (mean = 0.38),
7 indicating the dominance of low-aromatic WSOC of microbial origin. Intriguingly, our results reveal that
8 FI and BIX rise ~~monotonously~~generally with decreasing (increasing) fractional contributions of HULIS-
9 1 (PRLIS), whereas HIX exhibits a similar but contrasting pattern. Together, the comprehensive dataset
10 described above verifies the regional variability in the terrestrial contributions to WSOC, ~~within which~~
11 SEIM > SNC > NNC > CBM > NEIM; this pattern is reversed for microbially sourced WSOC.

12 Figure 4b illustrates HIX versus FI as a scatterplot, compared with published data for different sample
13 types; the shaded area depicts the region in which the FI value is >1.4 but <1.9. ~~As FI values of ≤1.4~~
14 ~~correspond to terrestrial sources and values of ≥1.9 denote a primarily microbial origin, values of 1.4–~~
15 ~~1.9 suggest a mixed origin.~~ In general, FI exhibits a rising trend with declining HIX across northeastern
16 China. For both SEIM and SNC, FI occupies a narrow range centered on 1.4, indicating either a
17 predominantly terrestrial or mixed origin. We note that these results are comparable to those of fog water
18 from the Tai Mountain, Arctic atmospheric aerosols, and seasonal snow in northwestern China (Birdwell
19 and Valsaraj, 2010; Fu et al., 2015; Zhou et al., 2019b). Further, we highlight that HIX values are
20 marginally higher in SEIM than elsewhere, suggesting a stronger influence from highly humified WSOC
21 that probably reflects the extensive deserts and exposed earth in this region. FI values for NNC and the
22 CBM fall within the range of 1.4–1.7 and thus reflect a mixed origin, in line with previous data from

1 urban aerosols in Spain and Chinese river water samples (Mladenov et al., 2011, Zhou et al., 2017).
2 When combined, the FI and HIX values for NNC and CBM snowpack indicate that WSOC in these
3 regions bears a stronger terrestrial signature than do water samples from Chinese lakes and Italian caves
4 (Birdwell and Engel, 2010; Zhou et al., 2017). Finally, FI values for NEIM fall within a range of 1.6–
5 2.0, comparable to values ~~from~~ for spring water in the USA (Birdwell and Engel, 2010), thus implying a
6 predominantly microbial or mixed origin.

7 **3.3 Comparisons of fluorescence and absorption characteristics**

8 ~~Figure 5a depicts TFV as a measure of the spatial distribution of absolute WSOC fluorescence intensity~~
9 ~~in the snowpack of northeastern China; a_{WSOC(280)} is shown in Figure 5b for comparison. Figure 5a~~
10 ~~describes the spatial distribution of a_{WSOC(280)} as WSOC absorption in the snowpack of northeastern~~
11 ~~China; Figure 5b depicts TFV as a measure of the spatial distribution of absolute WSOC fluorescence~~
12 ~~intensity for comparison.~~ In general, TFV and ~~a_{WSOC}a_{WSOC}~~(280) both exhibit large spatial variability in
13 the range of 690–18600 RU nm² and 0.42–16.98 m⁻¹, respectively. Regional mean values are 7700 ±
14 2800 RU·nm² (TFV) and 6.90 ± 2.39 m⁻¹ (~~a_{WSOC}a_{WSOC}~~(280)) for SEIM, 12400 ± 4300 RU·nm² (TFV)
15 and 11.48 ± 3.96 m⁻¹ (~~a_{WSOC}a_{WSOC}~~(280)) for SNC, 7800 ± 500 RU·nm² (TFV) and 7.02 ± 0.88 m⁻¹
16 (~~a_{WSOC}a_{WSOC}~~(280)) for NNC, 3900 ± 2500 RU·nm² (TFV) and 3.97 ± 2.46 m⁻¹ (~~a_{WSOC}a_{WSOC}~~(280)) for
17 the CBM, and 1000 ± 300 RU·nm² (TFV) and 0.83 ± 0.23 m⁻¹ (~~a_{WSOC}a_{WSOC}~~(280)) for NEIM. We note
18 that both distributions are consistent in space (Fig. 5e), with the highest concentrations in SNC and the
19 lowest in NEIM. Moreover, the ~~a_{WSOC}a_{WSOC}~~(280) value for SNC is an order of magnitude larger than
20 that for NEIM, implying that the impact of WSOC on snow albedo at UV wavelengths is significant in
21 SNC but less notable in NEIM in general (see Sect. 3.5). Previous work has reported a similarly broad
22 range of snowpack ~~a_{WSOC}a_{WSOC}~~(280) (0.15–10.57 m⁻¹) in northwestern China (Zhou et al., 2019b).

1
 2 **Figure 5: Spatial distribution of (a) $a_{wsoc}(280)$ (m^{-1}), (b) TFV ($RU\ nm^2$)-, (c) MAC_{280} ($m^2\ g^{-1}$) and (d)**
 3 **NFV ($RU\ nm^2\ (mg\ L^{-1})^{-1}$). Regional averages for (e) $a_{wsoc}(280)$, TFV , and (f) MAC_{280} , and NFV for the**
 4 **five groups. Error bars in (e) and (f) represent the standard deviations of $a_{wsoc}(280)$, MAC_{280} , TFV ,**
 5 **and NFV for the five groups, respectively.**

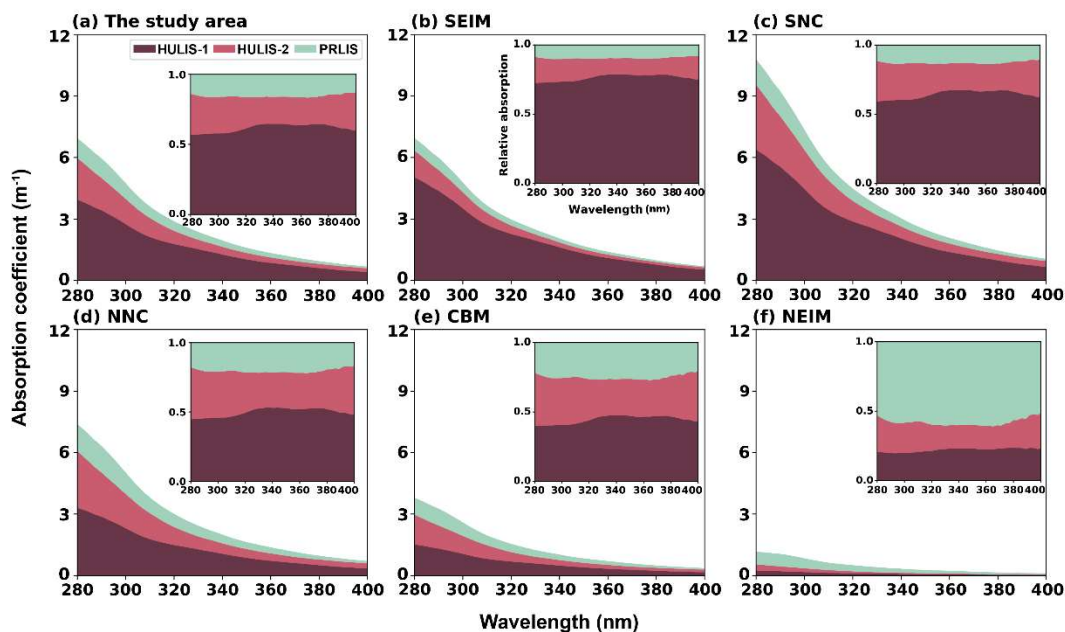

6 Two additional fluorescence and absorption capacity indices, identified as NFV and MAC_{280} , are proven
 7 tools for revealing $WSOC$'s fluorescence and absorption characteristics and they are related to chemical
 8 composition, structure, and source (Chen et al., 2019a). For the present our study area as a whole, mean
 9 NFV and MAC_{280} values are $2411.572412 \pm 373.63374$ $RU\ nm^2\ (mg\ L^{-1})^{-1}$ and $2.172.2 \pm 0.490.5$ m^2
 10 g^{-1} , respectively. Both indices exhibit a narrow range, with regional means ranging from 2100 ± 600 to
 11 3100 ± 800 $RU\ nm^2\ (mg\ L^{-1})^{-1}$ and from $1.781.8 \pm 0.570.6$ to $2.722.7 \pm 0.440.4$ $m^2\ g^{-1}$, respectively, in
 12 contrast to the broad inter-regional disparities in TFV and $a_{wsoc}(280)$. Moreover, the spatial
 13 patterns of NFV and MAC_{280} are similar, with the highest values in NNC . We speculate that this result

1 reflects the comparatively high low-oxygenated HULIS-2 fraction measured in the NNC samples (Fig.
2 3g), as the lower-oxygenated BrC (e.g., HULIS-2) has a higher absorption capacity (Browne et al., 2019).
3 Scatterplots ~~for of~~ $a_{\text{WSOC}}(280)$ ~~versus with~~ TFV, $F_{\text{max}}(\text{HULIS-1})$, $F_{\text{max}}(\text{HULIS-2})$, and $F_{\text{max}}(\text{PRLIS})$
4 are provided in Figure S4 to further demonstrate the close relationship between fluorescence and the
5 absorption characteristics of WSOC in our snow samples. As samples Q480, Q484, and Q477 deviate
6 considerably from the respective confidence intervals, we did not include them in our analyses.
7 Surprisingly, we found that TFV is closely correlated to $a_{\text{WSOC}}(280)$, with $P < 0.001$ and all
8 datapoints located close to the line of best fit, indicating that the three components (HULIS-1, HULIS-
9 2, PRLIS) contributing to the total fluorescence are also responsible for the majority of absorption. For
10 each component, our data show that $F_{\text{max}}(\text{HULIS-1})$ is most closely correlated with $a_{\text{WSOC}}(280)$,
11 followed by $F_{\text{max}}(\text{HULIS-2})$. The correlation between $F_{\text{max}}(\text{PRLIS})$ and $a_{\text{WSOC}}(280)$ is the
12 ~~poorestweakest~~, yet it is still significant ($P < 0.001$). Together, our results imply that HULIS-1 is
13 probably the greatest contributor to light absorption, with PRLIS being the least important.

14 3.4 Fractional contributions of different WSOC components to light absorption

15 ~~Previous studies of atmospheric aerosols, water, and snow/glacier ice have typically regarded WSOC as~~
16 ~~a whole when discussing its impact on light absorption (Barrett and Sheesley, 2017; D'Sa et al., 2014;~~
17 ~~Niu et al., 2018; Wu et al., 2019). Yet, depending on environmental conditions, the various components~~
18 ~~of WSOC play measurably different roles in light absorption according to their concentrations and optical~~
19 ~~properties (Zhou et al., 2022). Although the qualitative analysis described above have provided plausible~~
20 ~~information about the component specific influence of WSOC on light absorption, the quantitative~~
21 ~~fractional contributions of specific components to light absorption are still unknown. Recently, Chen et~~
22 ~~al. (2019a) collected atmospheric aerosol samples in $\text{PM}_{2.5}$ over Xi'an, China, and successfully attributed~~

1 ~~the dithiothreitol (DTT) activity levels to various BrC components by coupling DDT and BrC datasets.~~
2 ~~A similar attribution method has been applied to various research areas, including climate change,~~
3 ~~extreme weather, and atmospheric environments (Cao et al., 2015; Pokrovsky, 2019; Xin et al., 2016;~~
4 ~~Zhao et al., 2019).~~ In this study, we applied a multiple linear regression method comparable to that of
5 Chen et al. (2019a) to derive the fractional contribution of each WSOC component to light absorption.
6 ~~We note that, despite this method having been used elsewhere (Wu et al., 2022; Wu et al., 2021), it~~
7 ~~remains a highly innovative approach to evaluating the light absorption of snowpack WSOC.~~ Table S3
8 lists the statistical results of the fitted light absorption coefficient, based on the F_{\max} data for three
9 fluorescent components of EEM analysis. As the fitted results can explain ~94 %–99 % of the variance
10 in measured light absorption within the 280–400 nm range, we conclude that the fusion of multiple
11 fluorescent components is an effective means of describing most of the spatial features of WSOC light
12 absorption throughout northeastern China. Accordingly, the wavelength-dependent fractional
13 contributions of each component of light absorption in this band (280–400 nm) are reported in Figure 6.
14 For ~~the our~~ entire study area, light absorption is dominated by high-oxygenated HULIS-1, which accounts
15 for ~56 %–65 % of the contribution across UV wavelengths. Further~~more~~, ~~with increasing wavelength~~
16 ~~the contribution of we observed that the~~ HULIS-1 ~~first increases from~~ contribution rises slightly from
17 280 to ~340 nm, ~~after which there is a and then~~ decreases~~ing trend as wavelength increases~~. In contrast,
18 HULIS-2 exhibits a valley-type pattern in ~~terms of its~~ fractional contribution ~~at wavelengths~~ between
19 280 and 400 nm and is responsible for ~19 %–30 % of all light absorption.

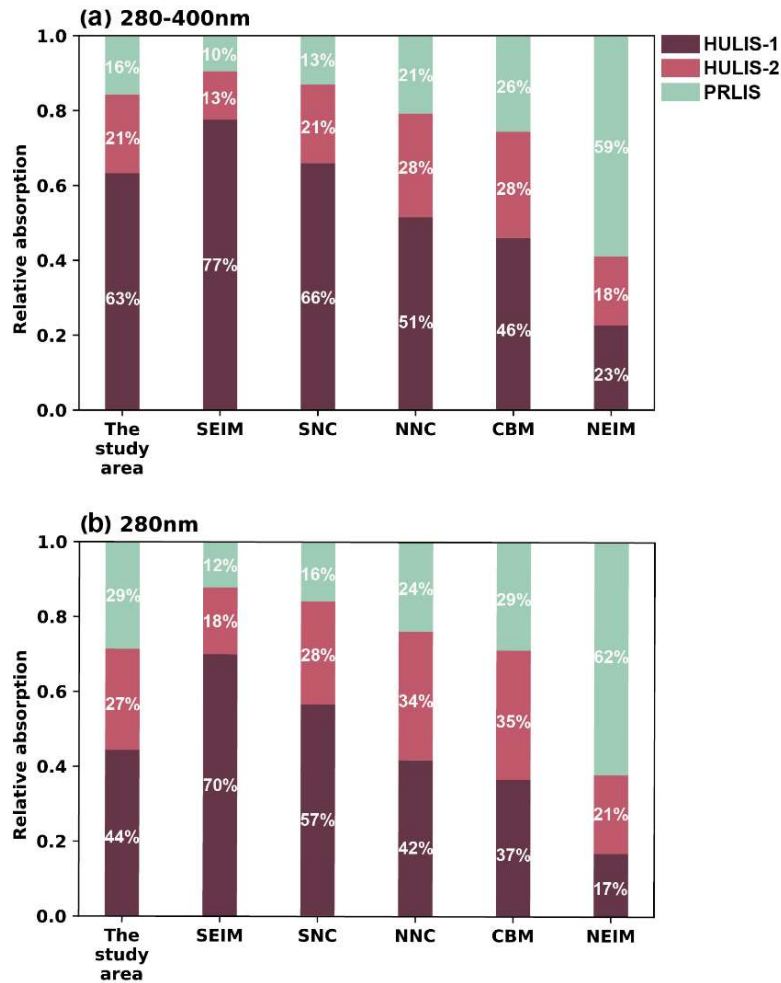

1
2 **Figure 6: Relative contributions of the three components to the total absorption of samples in (a) the whole**
3 **study area and (b–f) each of the five groups.**

4 PRLIS contributes the least (~12 %–17 %) to light absorption and exhibits a similar wavelength-
5 dependent pattern to HULIS-1. These results are consistent with the qualitatively comparative analysis
6 described in Sect. 3.3. Previous studies have also highlighted this dominance of high-oxygenated
7 compounds in WSOC light absorption, based on samples impacted by naturally and anthropogenically
8 derived soils (Zhou et al., 2022). Conversely, the total absorption coefficient of WSOC decreases with
9 the increasing wavelength between 280 and 400 nm, in accord with previous studies (Andreae and
10 Gelencser, 2006; Chakrabarty et al., 2010; Gustafsson et al., 2009; Wu et al., 2019). The AAE lies
11 primarily between 5.0 and 8.0 (mean = 6.6) in the range of 280–400 nm, which is in agreement with
12 results from snow collected from the Arctic, the northern Tibetan Plateau, and northwestern China
13 (Voisin et al., 2012; Yan et al., 2016; Zhou et al., 2021).

14 For each component, the wavelength-dependent variability in light absorption is similar among all five
15 regions, although the magnitude of each contribution varies from region to region. Moreover, compared
16 with the spectral results, ~~we found~~ that the solar-radiation-weighted broadband light absorption is was a

1 more meaningful parameter for researchers studying climate change and atmospheric radiation.
2 Therefore, the broadband results in Figure 7a for 280–400 nm absorption contributions—HULIS-1
3 (62 %), HULIS-2 (21 %), and PRLIS (17 %)—are average values for the whole study area. On a regional
4 scale, the HULIS-1 contribution to light absorption (280–400 nm) follows the spatial pattern SEIM >
5 SNC > NNC > CBM > NEIM. We note that HULIS-1 dominates light absorption in SEIM, SNC, and
6 NNC but has a minor impact in NEIM compared with the other two components. In contrast, the impact
7 of HULIS-2 varies only slightly among the five regions, with the greatest contributions in NNC and
8 CMB, and the lowest in NEIM. The contribution of PRLIS is essentially opposite to that of HULIS-1,
9 being dominant in NEIM but of relatively minor importancet elsewhere. As shown in Figure 7b, light
10 absorption contributions at 280 nm are consistent with the broadband results (Fig. 7a) in terms of the
11 regional pattern, although specific values differ because of the different wavelength-dependent properties
12 of light absorption for the three WSOC components.

1

2 **Figure 7: Regional averages for the relative contributions of the three fluorescent components to light**
 3 **absorption at wavelengths of (a) 280 nm–280–400 nm and (b) 280–400 nm–280 nm.**

4 We find it noteworthy that, for each component, the overall regional pattern of its contribution to light

5 absorption aligns with its impact on fluorescence signals, thereby confirming the viability of the

6 attribution analysis employed in [this](#) study. Nonetheless, we observed that the magnitude of each

7 component’s contribution varies relative to its respective fluorescence signal. For instance, HULIS-1

8 returns a greater contribution to light absorption than its fluorescence signal, in contrast to HULIS-2.

9 One plausible explanation for this discrepancy is that the [apparent](#) fluorescence quantum yields (AQYs),

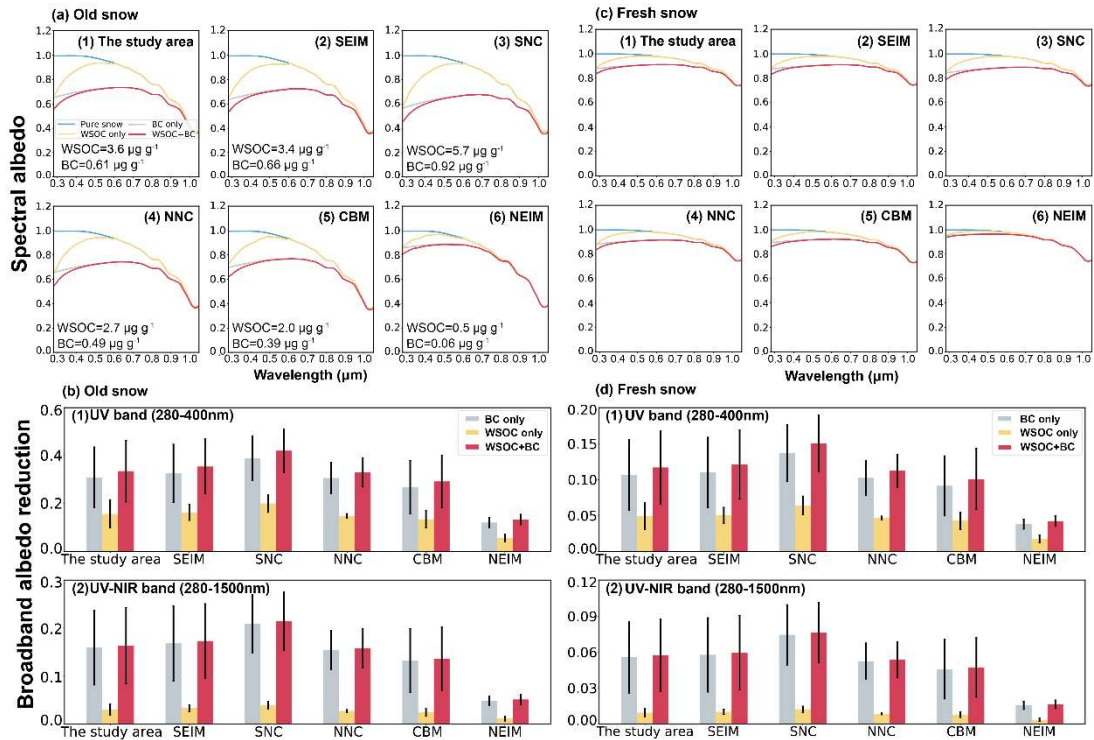

10 which are essentially the ratio of fluorescence intensity versus absorption intensity, are different for each

11 component. Indeed, in their comprehensive field-based study of BrC fluorescence and absorption

1 properties in northern China, Wen et al. (2021) reported that the AQYs of WSOC decreases with
2 increasing HIX, meaning that components with higher HIX values. Such as HULIS-1, have lower AQYs
3 than HULIS-2. Thus, the contribution of HULIS-1 to the fluorescence signals will be smaller than
4 its contribution to light absorption, and vice versa for HULIS-2.

5 **3.5 Albedo reduction and radiative forcing attributed to snowpack WSOC**

6 The strong light absorption of WSOC in UV bands has important ramifications for snow albedo and
7 radiative forcing throughout northeastern China. However, owing to the chemical and optical complexity
8 of WSOC components, quantitative estimates for snowpack light absorption remain poorly understood.
9 For example, although prior work in northeastern China has focused on BC (Wang et al., 2013b) and
10 other water-insoluble light-absorbing particles (Wang et al., 2017; Zhao et al., 2014) via field
11 measurements, model simulations, and satellite remote sensing (Pu et al., 2019), the specific impacts of
12 WSOC have not been studied. Consequently, ours is the first study to report on the impact of WSOC on
13 snow albedo and radiative forcing in northeastern China and to compare these data with BC results to
14 highlight the non-negligible role of WSOC.

1

2 **Figure 8: (a) and (b): Simulated snow spectral albedo and broadband albedo reductions—under various**
 3 **contamination scenarios and for different regions—for old snow (radius = 1000 μm). (c), (d) Simulated snow**
 4 **spectral albedo and broadband albedo reductions—under various contamination scenarios and for different**
 5 **regions—for fresh snow (radius = 100 μm). Colors represent the different types of snow (pure snow, BC- or**
 6 **WSOC-contaminated snow, and snow polluted by both WSOC and BC).**

7 Figure 8 shows the regional-mean spectral snow albedo as well as the reduction in albedo due to WSOC,
 8 BC, and WSOC + BC. We assume a snow radius of 100 μm for fresh snow and 1000 μm for old snow.

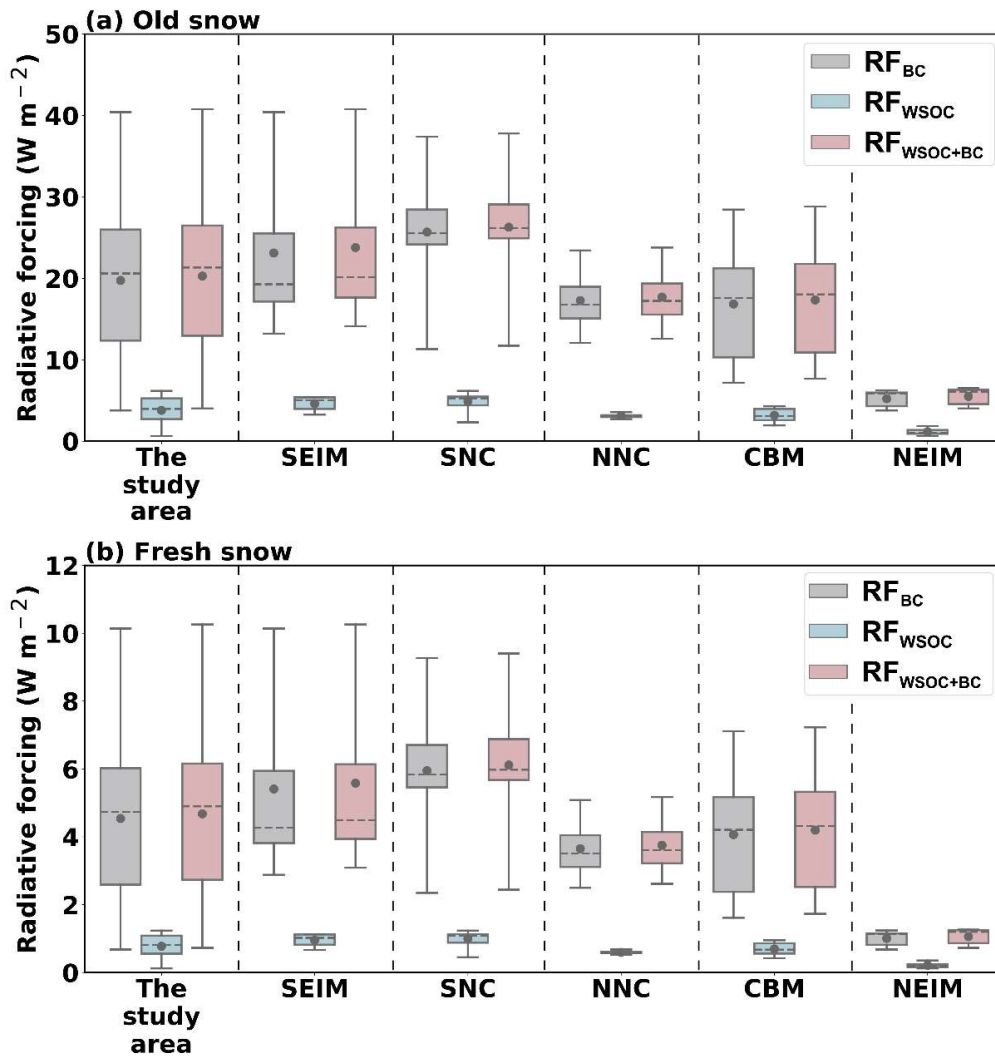

9 Our findings reveal that WSOC induces a marked decline in albedo within the UV and short-wave VIS
 10 bands, with the magnitude of albedo reduction growing rapidly as wavelength shrinks owing to the large

11 AAE value of WSOC. In comparison, BC induces a widespread albedo reduction spanning the UV to
 12 NIR bands, and wavelength-dependent variations are significantly smaller than those of WSOC. For VIS

13 and NIR, the reduction in albedo is dominated by BC, whereas the impacts of WSOC and BC are
 14 comparable ~~at~~ UV wavelengths, a pattern that is consistent with the results of studies of atmospheric

15 aerosols (Shamjad et al., 2016). We note that these characteristics persist throughout northeastern China
 16 despite regional variability in environmental conditions and snowpack types (old vs. fresh snow).

1 For broadband wavelengths, our results indicate that the WSOC-induced (mean = 3.6 $\mu\text{g g}^{-1}$) albedo
2 reduction for 280–400 nm wavelengths in old (fresh) snow is 0.16 (0.05) across the whole study area,
3 which corresponds to approximately ~~5050.3~~ % (~~4646.3~~ %) the impact of BC (mean = 0.6 $\mu\text{g g}^{-1}$).
4 Regionally, the greatest decline in albedo occurred in SNC, where a mean WSOC of 5.7 $\mu\text{g g}^{-1}$ resulted
5 in a reduction of 0.20 (0.06) in the 280–400 nm range for old (fresh) snow. In contrast, the smallest
6 decline in albedo was observed in NEIM, with reductions of 0.06 (0.02) resulting from an average WSOC
7 concentration of 0.5 $\mu\text{g g}^{-1}$. Compared with the UV bands, a WSOC-induced albedo reduction of 0.03
8 (0.009) over the UV–NIR range (280–1500 nm) accounts for only ~~~1918.8~~ % (~~1716.7~~ %) of that due to
9 BC in ~~the our~~ study area. The regional mean for old (fresh) snow falls in the range of 0.01–0.04 (0.003–
10 0.012), with the highest (lowest) values occurring in SNC (NEIM). However, we observed the highest
11 ratio of WSOC- to BC-induced albedo reduction in NEIM. Together, these results indicate that WSOC
12 plays a potentially important role in altering UV snow albedo in NEIM, despite its relatively low
13 concentrations in the regional snowpack.

1

2 **Figure 9: Radiative forcing due to different pollutants in (a) old or (b) fresh snow. Gray, blue, and red indicate**
 3 **the radiative forcing of BC, WSOC, and BC + WSOC, respectively.**

4 Radiative forcing is an important index that directly reflects the impact of snowpack WSOC on the

5 regional radiation balance and climate (Beres et al., 2020). Previous studies have tended to focus on

6 calculating instantaneous radiative forcing values; however, in reality, time-averaged results are more

7 valuable for climate research. Here, we present data on the daily mean radiative forcing due to WSOC,

8 BC, and WSOC + BC (Fig. 9), ~~calculated using the methodology of Wang et al. (2017).~~ ~~In general, f~~or

9 northeastern China ~~we found~~ the mean radiative forcing of WSOC in old (fresh) snow ~~to be~~s 3.783.8

10 (0.770.8) $W m^{-2}$, with regional mean values varying from 1.151.2 (0.210.2) to 4.884.9 (1.0) $W m^{-2}$. Zhou

1 et al. (2021) reported daily mean radiative forcing by regional WSOC ($0.6\text{--}7.1 \mu\text{g g}^{-1}$) of between ~ 0.04
2 and $\sim 0.60\text{--}59 \text{ W m}^{-2}$ for northwestern China, which is comparable to our values in fresh snow.
3 Furthermore, the ratio of WSOC-driven to BC-driven radiative forcing varies within the range of
4 $1040.3\% \text{--} 32.0\%$ ($109.8\% \text{--} 3130.8\%$) for old (fresh) snow, which is consistent with the results of our
5 calculated albedo reductions. These results confirm that the role of WSOC must not be ignored in
6 discussions about radiative balance in northeastern China. Similarly, the sizeable impact of WSOC on
7 the absorption of UV radiation has the potential to influence biogeochemistry (Helms et al., 2013; Seekell
8 et al., 2015), and snow photochemical processes (e.g., photolysis of nitrate (NO_3^-) and nitrite (NO_2^-) in
9 snow, in addition to the release of NO_x ($\text{NO} + \text{NO}_2$ and HONO). Snow photochemistry is beyond the
10 scope of this study, however, the high concentrations of WSOC and nitrate (not shown) pollution in
11 northeastern China make this a logical next step for research in this field.

12 **4 Conclusions and atmospheric implications**

13 During 2020 and 2021, we collected 34 surface samples of seasonal snow from sites throughout
14 northeastern China to investigate the fluorescence characteristics, optical properties, and radiative effects
15 of snowpack WSOC. With an average concentration of WSOC of $3.593.6 \pm 3.19\text{--}3.2 \mu\text{g g}^{-1}$, our results
16 returned regional mean values of $3.353.4 \pm 1.49\text{--}1.5 \mu\text{g g}^{-1}$ (SEIM), $5.73\text{--}5.7 \pm 3.68\text{--}3.7 \mu\text{g g}^{-1}$ (SNC),
17 $2.702.7 \pm 0.75\text{--}0.8 \mu\text{g g}^{-1}$ (NNC), $1.952.0 \pm 1.281.3 \mu\text{g g}^{-1}$ (CBM), and $0.500.5 \pm 0.190.2 \mu\text{g g}^{-1}$ (NEIM),
18 indicating a considerable degree of regional variability of WSOC mass loadings. Measured values of
19 WSOC fluorescence intensity ($690\text{--}18600 \text{ RU nm}^2$) and light absorption ($0.4\text{--}17.0 \text{ m}^{-1}$) are also highly
20 variable.

21 [In the first study of its kind](#) Moreover, we [also](#) used EEMs and PARAFAC to identify three fluorescence
22 WSOC components prevalent in northeastern China [and analyzed their regional differences](#). [Specifically,](#)

1 ~~these include the high-oxygenated HULIS-1, which is a terrigenous, humic-like component, and the low-~~
2 ~~oxygenated HULIS-2, which is a humic-like component derived from mixed sources, such as~~
3 ~~anthropogenic activity, microbial processes, and soil. The third component, PRLIS, is a protein-like~~
4 ~~substance derived from autochthonous biological activity.~~ In SEIM, which is characterized by desert and
5 bare soil surfaces, the signal of high-oxygenated and terrigenous HULIS-1 is dominant (47 %) ~~and HIX~~
6 ~~values the highest, whereas FI and BIX are the lowest. Together, these findings reveal a~~ The high degree
7 of humification and minimal bioavailability of WSOC, ~~indicating~~ indicate that snowpack WSOC
8 originates primarily from soil sources. In contrast, the autochthonous PRLIS signal (58 %) dominates in
9 remote and clean NEIM, ~~which also exhibits the lowest HIX values and highest FI and BIX values. We~~
10 ~~propose that the elevated bioavailability of this remote, forested region indicates a predominantly~~
11 ~~biological origin for NEIM snowpack WSOC.~~ Low-oxygenated and anthropogenic HULIS-2 dominates
12 the densely populated and intensively farmed SNC (51 %) and NNC (57 %) regions, ~~where HIX, FI, and~~
13 ~~BIX values are moderate~~, leading us to conclude that the snowpack WSOC is of mixed origin in SNC
14 and NNC are influenced more by anthropogenic sources. In CBM of the forest environment, the impact
15 of long-distance transport of pollutants is greater than that of the background environment. The above
16 conclusions are also verified by fluorescence-derived indices.
17 ~~We employed multiple regression analysis to estimate the fractional contributions of different WSOC~~
18 ~~components to snowpack light absorption. Throughout our study area, HULIS-1 tends to be the greatest~~
19 ~~contributor (~56%–65%) over the 280–400 nm range, followed by HULIS-2 (~19%–30%) and PRLIS~~
20 ~~(~12%–17%). On a more regional basis, light absorption remains dominated by HULIS-1 in SEIM,~~
21 SNC, NNC, and the CBM, whereas PRLIS takes a leading role in NEIM. In contrast to its primary role

1 in fluorescence, the contribution of HULIS 2 to light absorption is relatively low across all regions,
2 potentially reflecting the variable fluorescence quantum yields (AQYs) of the different components.
3 Finally, we compared the impact on snow albedo and radiative forcing of WSOC relative to BC. With
4 an average concentration of $3.6 \mu\text{g g}^{-1}$, our results indicate that WSOC induces an albedo reduction
5 across northeastern China of 0.16 (0.05) in old (fresh) snow over the 280–400 nm range, and thus
6 represents approximately 50 % (46 %) of the albedo reduction due to BC (average concentration = 0.6
7 $\mu\text{g g}^{-1}$). We note, however, that the WSOC-driven reduction in the UV–NIR spectrum (280–1500 nm) is
8 only 0.03 (0.009), corresponding to 19 % (17 %) that of BC. The average radiative forcing of WSOC in
9 old (fresh) snow in northeastern China is 3.8 (0.8) W m^{-2} , equating to 19 % (17 %) of the BC-induced
10 radiative forcing. Ultimately, our findings indicate that WSOC (1) plays an important role in the regional
11 radiation balance and (2) might significantly affect biogeochemical and photochemical processes in
12 snow. We employed multiple regression analysis to estimate the fractional contributions of different
13 WSOC components to snowpack light absorption. Throughout our study area, HULIS-1 tends to be the
14 greatest contributor (~56 %–65 %) over the 280–400 nm range, followed by HULIS-2 (~19 %–30 %)
15 and PRLIS (~12 %–17 %). In contrast to its primary role in fluorescence, the contribution of HULIS-2
16 to light absorption is relatively low across all regions, potentially reflecting the variable molecular
17 structure of different components. Finally, we highlighted that the average RF due to WSOC in old (fresh)
18 snow in northeastern China is 3.8 (0.8) W m^{-2} , which is equal to 19 % (17 %) of the BC-induced radiative
19 forcing. Therefore, we demonstrated the important impacts of WSOC on the snow energy budget and
20 potentially on triggering snow photochemistry.

21 We indicate that our study could contribute to the understanding of carbon cycling processes, regional
22 air quality, hydrological processes, and climate change in the earth systems. For example, the abundant

1 ~~WSOC~~ WSOC concentrations measured in this study implied the significant carbon input from the
2 atmosphere to the snowpack through wet or dry depositions in northeastern China. While the complex
3 chemical compositions of snowpack WSOC could further influence the carbon balance of the snow
4 environment by affecting microbial activities (Stedmon et al., 2007). The strong absorption properties of
5 WSOC in the UV-Vis band also implied its important role in initiating snow photochemistry (McNeill
6 et al., 2012). ~~It~~ which will change the composition of organic compounds in the snow in turn (Grannas
7 et al., 2007), and affect the surrounding air quality by releasing oxidizing gas like NO_x into the
8 atmosphere (Zatko et al., 2013). Moreover, the non-negligible influence of WSOC on the snow albedo
9 and radiative effect indicated that it could not only accelerate snow melting, ~~but~~ change the periods and
10 mass of water and carbon exchange between snowpack and underlying soils or vegetation (Meyer and
11 Wania, 2008), but also potentially affect regional climate through changing the surface radiative balance
12 (Beres et al., 2020).
