10

11 **Abstract.** Vehicle emissions have become a major source of air pollution in urban areas, especially for near-road
12 environments, where the pollution characteristics are difficult to be captured by a single-scale air quality model
13 due to the complex composition of the underlying surface. Here we developed a hybrid model CMAQ-
14 RLINE_URBAN to quantitatively analyse the effects of vehicle emissions on urban roadside NO₂ concentrations
15 at a high spatial resolution of 50 m × 50 m. To estimate the influence of various street canyons on the dispersion
16 of air pollutants, a Machine Learning-based Street Canyon Flow (MLSCF) scheme was established based on
17 Computational Fluid Dynamic and **two machine learning methods**. The results indicated that compared with the
18 CMAQ model, the hybrid model improved the underestimation of NO₂ concentration at near-road sites with MB
19 changing from -10 μg/m³ to 6.3 μg/m³. The MLSCF scheme obviously increased upwind concentrations within
20 deep street canyons due to changes in the wind environment caused by the vortex. In summer, the relative
21 contribution of vehicles to NO₂ concentrations in Beijing urban areas was 39% on average, similar to results from
22 CMAQ-ISAM model, but increased significantly with the decreased distance to the road centerline, especially
23 reaching 75% on urban freeways.

24

27 **1 Introduction**

28 The accelerated urbanization leads to severe air pollution in China. As one of the indicators of air pollution, nitrogen
29 dioxide (NO₂) causes an adverse impact on human health and promotes the generation of ozone and particulate
30 matter (Pandey et al., 2005; Khaniabadi et al., 2017). During the last decade, benefiting from the implementations
31 of several air pollution control strategies by the Chinese government, the air quality has improved (Jin et al., 2016;
32 Zheng et al., 2018), and the vertical column densities of NO₂ displayed a decreasing trend after 2013 (Shah et al.,
33 2020; Cui et al., 2021). However, the economic development and nitrogen oxides (NO_x) emissions are not
34 decoupled in China (Luo et al., 2022a). In some megacities of China, such as Chengdu, the daily averaged
35 NO₂ concentration could reach 200 µg/m³ (Zhu et al., 2019), far exceeding the 24-h average air quality guideline
36 of 80 µg/m³ suggested by the Ministry of Environmental Protection of China.

37

38 The improvement of PM_{2.5} in China was mainly due to the emission reduction and control measures of industrial
39 and domestic sources (Zhang et al., 2019b), which also relieved the NO₂ pollution, but the reduction potential of
40 these sources has been gradually declining. Meanwhile, as the population of vehicles is growing rapidly, vehicle
41 emissions have become a major source of NO₂ pollution, especially in urban areas (Nguyen et al., 2018). Due to
42 the low release height of vehicle emissions, combined with the negative dispersion condition caused by nearby
43 buildings, air pollutants will be significantly accumulated near the street. According to roadside observations,
44 within the distance of about 100-200 m near roads, the concentrations of CO, NO₂, ultrafine particulate matter
45 (UFP), PM_{2.5}, PM₁₀, and other pollutants will increase with the decreased distance to the road centerline, especially
46 for the pollution levels of NO₂ and UFP increasing exponentially. Therefore, the gradient of concentration around
47 the road changes dramatically (Nayeb Yazdi et al., 2015; Hagler et al., 2012). Moreover, the dispersion of air
48 pollutants in the near-road environment is significantly affected by geometric characteristics of the street canyon.
49 For example, in a standard street canyon, when the external wind direction at the roof level is perpendicular to the
50 street axis, a clockwise vortex will be generated inside, resulting in the accumulation of pollutant concentrations at
51 the upwind grid receptors in the canyon (Oke, 1988; Manning et al., 2000). Consequently, how to quantitatively
52 identify urban vehicle-induced air pollution around roads affected by complex underlying surface conditions has
53 become an urgent scientific issue.

54

55 Regional-scaled air quality models, represented by Chemical Transport Models (CTMs) including Community
56 Multi-scale Air Quality (CMAQ) model (Byun and Schere, 2006), Comprehensive Air quality Model with

57 extensions (CAMx), and Weather Research and Forecasting/Chemistry model (WRF-Chem) (Grell et al., 2005),
58 **have** been used extensively in assessment on the impacts of vehicle emissions on the regional atmospheric
59 environment, focusing on the source apportionment (Luo et al., 2022b; Vara-Vela et al., 2016; Kheirbek et al.,
60 2016; Lv et al., 2020) and evaluation of control measures (Zhang et al., 2020; Yu et al., 2019; Cheng et al., 2019;
61 Ke et al., 2017). However, the spatial resolution of CTMs is generally larger than 1 km×1 km, so the significant
62 impacts of vehicle emissions on near-source air quality cannot be predicted by CTMs due to the grid
63 homogenization on vehicle emissions.

64

65 To avoid the aforementioned disadvantages, the local-scaled numerical models based on Gaussian diffusion theory
66 or computational fluid dynamic (CFD) are adopted by numerous researches to study at a finer spatial resolution
67 (Zhang et al., 2021b; Patterson and Harley, 2019; Soulhac et al., 2012), including Research LINE-source Dispersion
68 Model (RLINE) (Snyder et al., 2013), Operational Street Pollution Model (OSPM), AERMOD (Cimorelli et al.,
69 2005), and RapidAir® (Masey et al., 2018). However, the large uncertainties in predictions from Gaussian
70 dispersion models come from the provided meteorological conditions and background concentrations. The natural
71 logarithm function is usually used to characterize the vertical profile of wind speed in both the inertial and rough
72 sublayers, neglecting the influence of urban complex underlying surface compositions on the wind field (Cimorelli
73 et al., 2005; Masey et al., 2018; Snyder et al., 2013). Nevertheless, in standard and deep street canyons, the changes
74 of vertical wind profile cannot be described by the logarithmic form, otherwise the actual wind speed will be greatly
75 overestimated (Soulhac et al., 2008). Although the OSPM has performed a large number of comparisons with field
76 observations in shallow or standard street canyons, the validation of model performance in deep street canyons
77 with a large aspect ratio was still inadequate (Kakosimos et al., 2010). Moreover, OSPM overestimated the bottom
78 wind speed in a deep street canyon by about 10 times compared with the predictions from CFD, resulting in greatly
79 underestimating pollutant concentrations (Murena et al., 2009). Comparatively speaking, CFD model can
80 accurately simulate the air flow and pollutant concentration in complex street canyons, but the simulation domain
81 of CFD model is much smaller than the urban scale, and the influence of the long-term meteorological boundary
82 conditions cannot be considered.

83

84 **Considering the respective strengths and limitations of regional models and local models, several studies have been**
85 **carried out on coupling of air quality models applicable to different scales (Ketzler et al., 2012; Stocker et al., 2012;**
86 **Lefebvre et al., 2013; Jensen et al., 2017; Kim et al., 2018; Mallet et al., 2018; Hood et al., 2018; Benavides et al.,**
87 **2019; Kamińska, 2019; Mu et al., 2022). Although these models performed accurately in near-road simulation, the**

88 influence of street canyons is still hard to be considered. In some hybrid models (Stocker et al., 2012; Jensen et al.,
89 2017; Mallet et al., 2018), OSPM was still applied to calculate concentration levels within the street, where the
90 application of logarithmic wind profile probably overestimated the bottom wind speed in a deep street canyon as
91 abovementioned. Other models simply assumed that in street canyons, wind direction followed the street direction,
92 and wind speed was uniform, which was not sufficient to resolve the concentration gradient within street canyons
93 (Kim et al., 2018; Benavides et al., 2019). Berchet et al. (2017) proposed a cost-effective method for simulating
94 city-scale pollution taking advantage of high-resolution accurate CFD, while the primary NO_x was predicted due
95 to the lack of a chemical module. Therefore, it is essential to build an integrated model to predict long-term and
96 near-road air pollution suitable for the urban complex underlying surface environment.

97

98 In this paper, we developed a hybrid model CMAQ-RLINE_URBAN by offline coupling the local RLINE model
99 with the regional CMAQ model and some localized urban thermodynamic parameter schemes, to simulate the near-
100 road NO₂ pollution and quantify the impacts of vehicle emissions at a high spatial resolution. Specifically, in order
101 to predict the effects of urban street canyons on the diffusion of pollutants, we developed a Machine Learning-
102 based Street Canyon Flow (MLSCF) parameterization scheme, which was based on **two machine learning methods**
103 using wind data from 1,600 CFD simulations. To evaluate the performance of CMAQ-RLINE_URBAN,
104 simulations under several scenarios were conducted in Beijing urban areas from August 1st to 31th of 2019, and
105 validated through comparison with observations from monitoring sites. Furthermore, spatial distribution
106 characteristics of NO₂ concentrations in the near-road environment were also analysed in this study.

107

108 **2 Materials and Methods**

109 **2.1 Hybrid model framework**

110 Here, we established the MLSCF scheme based on R language, and modified the code of RLINE model to add
111 other parameterization schemes with FORTRAN language. Finally, a multiscale air quality hybrid model was
112 developed to achieve a high-resolution NO₂ pollution mapping in urban areas. The framework of CMAQ-
113 RLINE_URBAN is shown in Figure 1. The hybrid model was established based on RLINE model, offline coupling
114 with the gridded meteorological field provided by WRF model and the pollutant background concentrations from
115 non-vehicle sources provided by CMAQ model with the Integrated Source Apportionment Method (ISAM),
116 considering the thermodynamic effects caused by the complex underlying surface compositions of the city. In our
117 model, a NO₂ pollution map with a high temporal (1 h) and spatial resolution (**50 m×50 m**) can finally be obtained.

118

119 RLINE is a Gaussian line source dispersion model developed by Snyder et al. (2013) to predict pollutant
120 concentrations in near-road environments. In the RLINE model, the mobile source is considered as a finite line
121 source, from which the concentration is found by approximating the line as a series of point sources and integrating
122 the contributions of point sources using an efficient numerical integration scheme. The number of points needed
123 for convergence to the proper solution is a function of distance from the source line to the receptor, and each point
124 source is simulated using a Gaussian plume formulation. The RLINE model performs generally comparable results
125 when evaluated with other line source models for on-road traffic emissions dispersion (Snyder et al., 2013; Heist
126 et al., 2013; Chang et al., 2015), and has been successfully used in many studies to evaluate the impacts from traffic
127 emissions on air quality (Zhai et al., 2016; Valencia et al., 2018; Benavides et al., 2019; Filigrana et al., 2020;
128 Zhang et al., 2021a).

129

130 The simulation for local meteorological conditions in CMAQ-RLINE_URBAN included three steps: Estimation
131 for areas above the top of Urban Canopy Layer (UCL), inside of UCL, and inside of the street canyon. (1) In this
132 study, the configuration of WRF model referred to our previous study (Lv et al., 2020). The height of midpoint in
133 the bottom layer to the ground was set as 22.5 m, which was close to the average height of buildings near street
134 canyons, similar to the settings in the previous study (Benavides et al., 2019). Therefore, the meteorological field
135 simulated by the WRF model was used as the wind field and atmospheric stability at the top of UCL. During the
136 hybrid model running, the meteorological conditions over buildings near each road were obtained separately from
137 WRF model according to the road location. (2) Then, the surface roughness length (z_0) of each road was estimated
138 based on the surrounding building geometry and used to recalculate the localized meteorological parameters (e.g.
139 Monin-Obukhov length) within UCL according to the algorithm proposed by Benavides et al. (2019) (z_0 scheme).
140 The atmospheric turbulence intensity in urban areas around sunset in the afternoon was obviously enhanced
141 considering the influence of the urban heat island effect based on methods in the AERMOD model (Cimorelli et
142 al., 2005) (UHI scheme). The UHI scheme would affect the turbulent intensity based on the evaluation for the
143 upward surface heat flux and the urban boundary layer height due to convective effects, and then the mixing height,
144 convective velocity scale, surface friction velocity, and Monin-Obukhov length were all recalculated (details in the
145 Supplement Section S1). (3) Finally, the wind field within UCL was calculated according to different types of road
146 environments: open terrain and street canyon. The logarithmic wind profile based on Monin-Obukhov Similarity
147 Theory (MOST) (Foken, 2006) in the original RLINE model was still used when the grid receptor was located in
148 the open terrain (MOST scheme), while the MLSCF parameterization scheme was used for grid receptors within
149 the street canyon to quantitatively characterize the influence of the street canyon geometry and the external wind

150 environment at the top of the roof. The detailed introduction for street canyon geometry and the MLSCF scheme
151 was described in the following section.

152

153 The real-time vehicle emission inventory based on Street-Level On-road Vehicle Emission (SLOVE) Model
154 developed in our previous study (Lv et al., 2020), which was based on the real-time traffic condition data from
155 AMap, was used in both regional and local air quality models. In our simulation, the concentrations of NO, NO₂,
156 and O₃ excluding contributions from vehicle emissions were used as background concentrations at the roof level,
157 avoiding the double counting in the coupling process. These background concentrations were simulated by CMAQ-
158 ISAM model, in which the emissions were divided into mobile and other four emission groups to trace their
159 contributions separately, and details were presented in our previous study (Lv et al., 2020). In addition, the influence
160 of atmospheric turbulence and building geometry on the vertical mixing of background concentration was
161 considered (vertical mixing scheme). The ratios of wind speed at surface and roof levels were used as a proxy to
162 calculate the contribution of background concentration over street canyons to the near-ground level (Benavides et
163 al., 2019). **In this scheme, the surface wind was from MLSCF scheme when the gird receptor is located within the**
164 **street canyon, and otherwise the logarithmic wind profile was used to calculate the wind speed at the specified**
165 **height, and details were showed in the Supplement Section S2.** Finally, combined with the vehicle-induced primary
166 NO_x concentration calculated by the RLINE kernel, the high spatial resolution NO₂ map could be simulated
167 considering the photochemical process of NO_x. **In this study, a simplified two-reaction scheme, including the**
168 **photolysis of NO₂ and the oxidation of NO, was incorporated into the model to characterize the photochemical**
169 **process of NO_x (details in the Supplement Section S3), which has been successfully applied in the SIRANE**
170 **dispersion model (Soulhac et al., 2017).**

171

172 **2.2 Development for MLSCF scheme**

173 **2.2.1 The database of street canyon geometry**

174 We first established a database of street canyon geometry for 15,398 roads in urban areas of Beijing based on the
175 three-dimensional building data obtained from our previous study (Lv et al., 2020) using Geographic Information
176 System (GIS). Three typical parameters to represent street canyon geometry were investigated, including height
177 ratio (H_l/H_r) (H_l is the building height on the left side, while H_r is the building height on the right side), aspect
178 ratio (H/W) (H is set to be the average height, and W is the width of the street canyon), the canyon length to height
179 ratio (L/H) (L is set to be the length of the street canyon). In this study, the extremely special geometry of canyons
180 was not considered, and the typical street canyons were selected as the following conditions: (1) The proportion of

181 actual street canyon length (the length of road where the buildings nearby) was greater than 0.5; (2) H/W was
182 greater than 0.2; (3) H_l/H_r was between 0.3 and 3.3. Finally, the total number of the typical street canyon was
183 1,889, with a total length of 787 km. The spatial distributions of canyon geometry are shown in Figure S1 in the
184 Supplement. In urban areas of Beijing, street canyon was generally wide with the averaged width of 50.3 m, and
185 buildings on both sides were relatively low with a mean of 23.6 m. Most street canyons were obviously located in
186 areas within the fourth ring road. The shallow ($H/W \leq 0.5$) canyons and long canyons ($L/H > 7$) were dominated,
187 accounting for 54% and 84% of the total number of street canyons.

188

189 **2.2.2 Description of CFD cases**

190 **Here**, to predict air flow in street canyons comprehensively, CFD simulations were conducted under combinations
191 of different values of controlling factors based on ANSYS FLUENT (v19.2). The controlling factors included the
192 aforementioned three typical parameters to represent canyon geometry, the background wind speed at the height of
193 $H(V(H))$ and the angle between wind direction and street axis (α) to describe the external wind environment. The
194 selected values of each factor were listed in Table 1, and total 1600 (i.e., $5 \times 4 \times 4 \times 5 \times 4$) simulations were
195 implemented.

196

197 In this study, the computational domain of three-dimensional (3D) full-scale CFD simulations is shown in Figure
198 2. The average building height H of the street canyon was always set to 21 m in different simulations, which was
199 similar to the mean street canyon height in Beijing. Other actual size of street canyons (e.g. street canyon width W)
200 was calculated according to the ratio of each specific simulation. Distances between urban canopy layers (UCL)
201 boundaries and the domain top, domain inlet and domain outlet were set as $5H$, $6H$, and $20H$, respectively.

202

203 **The turbulence closure schemes for CFD include the Reynolds-Averaged Navier-Stokes (RANS) and the Large-**
204 **Eddy Simulation (LES), and the choice of them depends on the computational cost, the accuracy required and the**
205 **purpose of application. The RANS resolves the mean time-averaged properties with all the turbulence motions to**
206 **be modelled, while LES adopts a spatial filtering operation and consequently resolves large-scale eddies directly**
207 **and parameterizes small-scale eddies (Zhong et al., 2016). Compared with the LES, the RANS is more easily**
208 **established and computationally faster (Xie and Castro, 2006). However, the LES can provide a better prediction**
209 **of air flow than that from the RANS when handling complex geometries (Dejoan et al., 2010; Santiago et al., 2010).**

210 In this study, considering the huge computational burden of a large number of simulations and the relatively simple
211 geometry of street canyons in our modelling, the RANS was selected to characterize the air flow.

212

213 Following the CFD guideline (Tominaga et al., 2008; Franke et al., 2011), zero normal gradient conditions or
214 pressure outlet conditions were applied at the domain outlet, and symmetry boundary conditions were adopted at
215 the domain top and two lateral domain boundaries. For near-wall treatment, no-slip wall boundary conditions with
216 standard wall functions were used (Fluent, 2006). All governing equations for the flow and turbulent quantities
217 were discretized by the finite volume method with the second-order upwind scheme. The SIMPLE scheme was
218 used for the pressure and velocity coupling. The residual for continuity equation, velocity components, turbulent
219 kinetic energy, and its dissipation rate were all below 10^{-5} . Meanwhile, the CFD simulation would also stop when
220 the iteration steps exceeded 10,000, due to the large computing cost of so many simulations. The selected turbulence
221 model and grid arrangement are discussed in the following section.

222

223 At the domain inlet, the power-law velocity profile (Brown et al., 2001), vertical profiles of turbulent kinetic energy
224 k_{in} and its dissipation rate ε_{in} at the domain inlet (Lien and Yee, 2004; Zhang et al., 2019a), were described below:

225

$$U_0(z) = U_{ref} \left(\frac{z}{H_{ref}} \right)^\alpha$$

226

$$k_{in}(z) = (I_{in} \times U_0(z))^2$$

227

$$\varepsilon_{in}(z) = \frac{C_\mu^{3/4} k_{in}^{3/2}}{\kappa z}$$

228 Here, $U_0(z)$ stood for the stream-wise velocity at the height z . U_{ref} represented the reference speed. The reference
229 height H_{ref} was 21m. The power-law exponent of $\alpha=0.22$ denoted underlying surface roughness above medium-
230 dense urban area (Kikumoto et al., 2017). Turbulence intensity I_{in} was 0.1, Von Karman constant κ was 0.41 and
231 C_μ was 0.09.

232

233 2.2.3 The CFD validation

234 In this study, the stream-wise and vertical velocity predicted by CFD within street canyons was compared with
235 wind tunnel data in previous researches. For buildings of the cube arrays model, wind tunnel data from Brown et
236 al. (2001) was used to evaluate the reliability of CFD results by measuring vertical profiles of velocity. In this
237 experiment, street canyon was perpendicular to the wind direction at the roof level. For long-street models, we

238 predicted horizontal profiles of velocity along the street centerline at the height of $z=0.11H$ or vertical profiles at
239 some points and then validated CFD simulations using wind tunnel data from Hang et al. (2010). In this validation
240 case, the wind direction at the roof level was parallel to the axis of street canyons. The description and validation
241 results are shown in Figure S2-S3, and Table S1 in the Supplement, respectively.

242

243 We identified the influence of different minimum sizes of hexahedral cells near wall surfaces (fine: 0.1m, medium:
244 0.2m, and coarse: 0.5m) and turbulence models (standard k- ϵ model and RNG k- ϵ model) on the predicted velocity,
245 to evaluate the grid independence and turbulence model accuracy (Figure S3 in the Supplement). The results
246 indicated that the predictions from the standard k- ϵ model could well match the variations of observed velocity
247 within the street canyon, of which performances were much better than that of the RNG model. In addition, different
248 grid resolutions used in simulations would not obviously affect the predicted results. We finally adopted the
249 standard k- ϵ model to characterize turbulence, and the grid with an expansion ratio of 1.1 was applied in which the
250 minimum size of hexahedral cells near wall surfaces was 0.5 m to save the computing cost.

251

252 Moreover, the averaged wind speed from CFD in street canyons with different aspect ratios and external wind
253 direction was compared with predictions from other empirical methods used in SIRANE model (Soulhac et al.,
254 2012) and MUNICH model (Kim et al., 2018). Similar predictions using different methods also proved the
255 reliability of CFD simulation in this study (Figure S4 in the Supplement).

256

257 **2.2.4 Machine learning**

258 Data driven method, such as machine learning and deep learning, is now a successful operational geoscientific
259 processing schemes and has co-evolved with data availability over the past decade (Reichstein et al., 2019).
260 Specially, these models have been used as computationally efficient emulators of explicit mechanism models, to
261 explore uncertainties (Aleksankina et al., 2019) and sensitivities or replace complex gas-phase chemistry schemes
262 (Keller and Evans, 2019; Conibear et al., 2021). In addition, meta-models (Fang et al., 2005) such as neural
263 networks and Gaussian process (Beddows et al., 2017) are also used to produce a quick to run model surrogate and
264 show reliable performance. Random Forest (RF) model algorithm is an ensemble learning method that generates
265 many decision trees and aggregates their results, which has been developed to solve the high variance errors typical
266 of a single decision tree (Breiman, 2001). Multivariate Adaptive Regression Splines (MARS) is a nonparametric
267 and nonlinear regression method, which can be regarded as an extension of the multivariate linear model (Friedman,
268 1991). RF and MARS are common machine learning methods which run efficiently on large data sets, and are

269 relatively robust to outliers and noise. Furthermore, they never require the specification of underlying data model
270 and the complex parameter tuning, and they can still provide efficient alternatives and generally show a high
271 accuracy in applications for predict air pollutant concentrations (Hu et al., 2017; Chen et al., 2018; Kamińska, 2019;
272 Geng et al., 2020).

273

274 Here, based on the database including 42,880 samples obtained from 1600 CFD simulations, the RF and MARS
275 were both used to simulate the wind vector along X-axis (V_x) and Y-axis (V_y) at different heights within the street
276 canyon respectively. The input predictor variables included H/W , L/W , H_l/H_r , the grid receptor relative height
277 (z/H), the background wind vector at the height of H along X-axis ($Vbg_x = V(H) \times \sin \alpha$) and Y-axis ($Vbg_y =$
278 $V(H) \times \cos \alpha$). We finally combined the advantages of these two machine learning models and developed the
279 MLSCF scheme to predict wind environment in street canyons and incorporated into the hybrid model, which is
280 discussed in the section 3.1.

281

282 In RF model, the number of predictors randomly sampled at each split node in the decision tree (m_{try}) and the
283 number of trees to grow ($NumTrees$) are two important hyperparameters that determine the performance of the
284 model. Similarly, in MARS model, the two important hyperparameters are the total number of terms ($nprune$) and
285 the maximum number of interactions ($degree$). By comparing the mean squared error (MSE) for testing datasets
286 across models with candidate parameter combinations, we set m_{try} and $NumTrees$ as 6 and 200 in RF,
287 respectively, and $nprune$ and $degree$ as 23 and 3 in MARS, respectively. Additionally, the 10-fold cross-
288 validation (CV) repeated ten times were considered to evaluate the prediction performance of our models. The total
289 dataset was randomly divided into 10 subsets, where 9 subsets was used to train model and another was applied for
290 validation. The fitted coefficients of MARS are shown in Table S2-S3 in the Supplement.

291

292 In order to identify the sensitivity and response relationship between prediction variables and results in RF model,
293 we used the MSE for out-of-bag (OOB) to evaluate the relative importance of each feature to V_x and V_y , by
294 randomly replacing the value of a single prediction variable one by one (Liaw, 2002). Higher values of increase in
295 MSE indicated that the predictor was more important. In addition, Partial Dependence Plots (PDPs) was applied to
296 establish the response relationship between the change of a single predictive variable and the predicted results,
297 considering the average influence of other variables (Greenwell, 2017).

298

299 2.3 Configuration of CMAQ-RLINE_URBAN

300 The near-ground NO₂ concentrations were simulated from August 1st to 31th in 2019 when the average of daily
301 high temperatures was higher than 30 °C and sunlight duration was longer than 13 hours, leading to strong
302 photochemical reactions. The simulation domain for the hybrid model covered the core urban areas within and
303 surrounding the fifth ring road, shown in Figure 3. The receptors included both grid receptors and monitor receptors.
304 The grid receptors were set at a spatial resolution of 50 m×50 m, and the height above the ground was 1.5 m, which
305 was equivalent to the height of the human breathing. We used data from 10 observation stations (monitor receptors)
306 located in the normal urban environment and 5 near-road monitoring sites for validation (Beijing Ecological
307 Environment Monitoring Center, available at <http://zx.bjmemc.com.cn/>) (DSH, NSH, QM, XZM, and YDM) in the
308 simulation domain (Figure 3), which were 10 meters and 3 meters above the ground respectively. The QM and
309 XZM sites were located in shallow street canyons, and details for the morphometric of near-road measurement sites
310 were shown in Table S4 in the Supplement.

311

312 In general, compared to the RLINE model, CMAQ-RLINE_URBAN has the following improvements:

313 (a) The gridded meteorological parameters provided by WRF model were used.

314 (b) Gridded non-vehicle-related concentrations provided by CMAQ-ISAM model were used as background
315 concentrations.

316 (c) A simple NO_x photochemical scheme was incorporated to simulate NO₂ concentrations.

317 (d) Thermodynamic effects caused by the special underlying surface structures of the city were considered,
318 including UHI effects, the influence of local buildings on turbulence intensity and vertical mixing of
319 background concentrations.

320 (e) A newly developed MLSCF scheme was applied to predict wind environment in street canyons.

321

322 In our simulation, the model configurations in the base scenario CMAQ-RLINE_URBAN included all (a)-(e)
323 schemes, and the other two control scenarios were set to investigate the sensitivity of urban schemes on predictions,
324 where all input data was set to be the same. The scenario CMAQ-RLINE only including (a)-(c) schemes was set to
325 analyze the impacts of urban thermodynamic schemes, and the scenario CMAQ-RLINE_URBAN_nc including
326 (a)-(d) schemes was set to identify the impacts of the MLSCF scheme.

327

328 3 Results

329 3.1 Fitting results of machine learning

330 In this study, the 10-fold cross-validation (CV) repeated ten times was considered to evaluate the prediction
331 performances of RF and MARS models. As shown in Figure 4 and Figure S5, both models performed acceptable
332 robustness in CV, indicating that neither RF nor MARS model overfitted the data. In general, the performances of
333 both models in predicting V_y was better than that in V_x of which the absolute value was relatively small, especially
334 for MARS model. Since V_x was responsible for the formation of the vortex within street canyons and affected by
335 multiple factors, it was more difficult to be simulated. The averages of mean absolute error (MAE), root mean
336 square error (RMSE), and correlation coefficient (R) in the CV of the RF model for V_x and V_y were 0.04 m/s and
337 0.05 m/s, 0.02 m/s and 0.03 m/s, and 0.99, respectively. **Although the average of the relative error (RE) were a little**
338 **high (42.5% and 43%), particularly when the predicted wind speed was low, the median RE were relatively low**
339 **with 9.8% and 2.7%, respectively, indicating an acceptable performance.** Compared with the advanced non-linear
340 RF algorithm, the MARS model performed not very well, especially when the absolute value of V_x was greater than
341 1 m/s and V_y was less than 3 m/s. However, when the predicted wind speed by machine learning methods was
342 compared with observations from wind tunnel experiments, we found that the performance of the MARS model
343 was obviously better than that of RF model in one of validation cases (see Figure 5). The decision tree model like
344 RF failed to respond to the parts beyond the range of prediction variables ($Vbg_y=17$ m/s \gg 5 m/s), while the more
345 reasonable predictions can be obtained by the MARS model which used piecewise linear function essentially.
346 Therefore, the MLSCF scheme was established based on a method to combine the advantages of each model. The
347 RF model was used when the input value was within the range of predictors shown in Table 1, otherwise the
348 predictions from the MARS model were used.

349
350 In addition, the importance of each predictor variable in the RF model was investigated to explain their impacts on
351 predictions. As shown in Figure 6, the background wind speeds on x and y axis played vital roles in predictions of
352 V_x and V_y , respectively, followed by the relative height (z/H). Among the geometric parameters of the street
353 canyon, the impact of L/W was least. Since V_x was the main driving force for the formation of vortices in street
354 canyons, it was more affected by the geometry of street canyons especially H_l/H_r , comparing to V_y . This feature
355 importance ranking was basically consistent with the conclusion in a previous study (Fu et al., 2017). Figure S6 in
356 the Supplement **shows** the PDPs of each predictor variable in RF model for V_x and V_y . As z/H grew, V_x and V_y
357 showed linear and logarithmic increase patterns, respectively. And the resistant effect of windward buildings on

358 wind speed enhanced with the increasing of H_l/H_r , resulting in a significant decrease in V_x particularly when
359 H_l/H_r was lower than 1.25. The relationship between predictors and results in the model was consistent with the
360 actual mechanism, indicating our model could provide an accurate description of the wind field in the street canyon.
361

362 **3.2 Impacts of MLSCF on simulations in street canyons**

363 We compared the differences between monthly mean wind profile in different street canyons including QM
364 (shallow canyon: $H/W = 0.22$), XZM (shallow canyon: $H/W = 0.35$), SZJ (standard canyon: $H/W = 1$) and
365 JTDL (deep canyon: $H/W = 1.93$), calculated by the default logarithmic function based on MOST in the original
366 RLINE model (Foken, 2006), and the MLSCF scheme developed in this study. As shown in Figure 7(a)-(d), the
367 wind profile estimated by MOST showed a logarithmic change at the height above displacement height (d_h) with
368 a decrease to 0 at d_h , and remained constant below d_h (the d_h is calculated by multiplying surface roughness length
369 (z_0) times a factor which is recommended to be set as 5). Compared with the MOST, the simulated wind speeds
370 near the ground and at the top of canyons were generally lower based on the MLSCF scheme in shallow and
371 standard street canyons. In the deep street canyon, the significant reduction in ventilation volume led to the mean
372 wind speed simulated by the MLSCF scheme much lower than that of MOST at all heights. Although the aspect
373 ratios of the street canyon located in QM and XZM were similar, their orientations were quite different, resulting
374 in significant differences under prevailing external winds in different directions. Since the prevailing northerly and
375 southerly wind was observed in Beijing during the study period, the resistance effect of the buildings on both sides
376 of the east-west street canyon located in QM was more obvious.

377

378 We also investigated the impacts of the MLSCF on hourly wind direction at the bottom ($z = 3m$) of different street
379 canyons by comparing the roof-level predictions from WRF model (see Figure 7(e)-(f)). In the shallow street
380 canyon like QM, the simulated wind direction at the bottom was consistent with the background on the whole, with
381 the R reaching 0.8. When the background wind direction was less than 180° , the averaged wind direction at the
382 bottom simulated by MLSCF was 91.8° , which was basically consistent with the angle between the street and the
383 south direction (84.5°). When the background wind direction was greater than 180° , the average wind direction
384 predicted by MLSCF (257.4°) was similar to that in the opposite direction of the street (264.5°), which was in line
385 with the theory proposed by Soulhac et al. (2008) that the average wind direction in street canyons was assumed to
386 be consistent with the (opposite) orientation of the street. While in the deep street canyon of SZJ, when the external
387 wind perpendicularly blew to the street, the wind direction at the bottom was completely opposite to that at the top
388 due to the formation of vortex, with the R reaching -0.97. In conclusion, compared with the traditional MOST

389 method, the newly developed MLSCF scheme could well simulate the influence of the external wind environment
390 and geometry on the wind field inside the street canyon.

391

392 As shown in Figure 8, the impacts of the MLSCF scheme on simulated NO₂ concentration were identified by the
393 differences between CMAQ-RLINE_URBAN and CMAQ-RLINE_URBAN_nc scenario during a clean day
394 (August 24th). When the atmosphere was stable at night, in street canyons with a large aspect ratio, the wind
395 direction at the bottom changed to the opposite to that at the top, combined with the decreased wind speed affected
396 by the MLSCF scheme, the NO₂ concentrations at upwind **grid receptors** increased by up to 80 µg/m³. Meanwhile,
397 the changes in wind direction would also decrease the concentrations at downwind **grid receptors** by up to 20 µg/m³.
398 For example, in the SZJ standard canyon, the background wind direction over the street was 79° (easterly), and
399 the wind direction at the bottom changed to 291° affected by the MLSCF scheme (westerly). Therefore, the upwind
400 NO₂ concentrations increased, and the location of peak NO₂ concentration shifted to the windward. Since the
401 changes in NO₂ concentrations were also influenced by the local on-road emissions, the increase was only up to
402 2.1 µg/m³ in SJZ street, where the traffic flow and vehicle emissions were small at night. However, a little influence
403 was observed during the day in the convective boundary layer. During this period, although the wind direction at
404 the bottom was not changed obviously due to the parallel background wind in SZJ street, the increased surface
405 wind speed was beneficial for the dispersion, resulting in the decreased concentration in **grid receptors** within both
406 sides of the street canyon. In summary, the MLSCF scheme enabled the characterization of the concentration
407 distribution in street canyons.

408

409 **3.3 Performance of near-road simulations from different models**

410 The performances in predicting NO₂ concentrations at all **monitor receptors** from different models were first
411 compared, including CMAQ-RLINE_URBAN, CMAQ-RLINE and CMAQ model. The mean bias (MB), RMSE,
412 normalized mean bias (NMB), normalized mean gross error (NMGE), the fraction of predictions within a factor of
413 two (FAC2), Index of agreement (IOA), and *R* between simulations and observations were all selected as statistical
414 indicators for the evaluation (Table 2). In general, the performance of CMAQ-RLINE_URBAN was the best at all
415 urban sites. Compared to the CMAQ model, the averaged MB and NMB at urban sites in the hybrid model
416 decreased from 8 µg/m³ to 1.3 µg/m³ and 27% to 4%, respectively.

417

418 Diurnal variations of observed and predicted hourly averaged NO₂ concentrations at near-road sites from different
419 models were mainly compared and shown in Figure 9. The comparison of hourly and daily averaged concentrations

420 is shown in Figure 10. Overall, the CMAQ-RLINE_URBAN performed best with the smallest deviations. By
421 comparing the performances of the CMAQ and CMAQ-RLINE scenario, we found the direct coupling between the
422 CMAQ and RLINE models could reproduce the high NO₂ concentrations at near-road sites in daytime, and
423 significantly improve the underestimation of near-source concentrations due to grid dilution on emissions in
424 CMAQ model. The averaged MB and NMB at all sites changed from -10 µg/m³ to 25.6 µg/m³, and from -20% to
425 51%, respectively. However, a significant overestimation was found in the CMAQ-RLINE at night (0:00-6:00) and
426 around sunset in the afternoon (16:00-23:00), of which the peak could exceed the observed concentrations by more
427 than 1 times. This overestimation was reduced in the CMAQ-RLINE_URBAN, where the urban thermodynamic
428 schemes were implemented. The averaged MB and NMB decreased to 6.3 µg/m³ and 12%, respectively, due to the
429 following reasons: (1) The increased surface roughness length slightly enhanced local turbulence intensity near
430 roads; (2) The UHI scheme enhanced the intensity of atmospheric turbulence in urban areas before and after sunset
431 in the afternoon; (3) The effect of turbulence intensity on the local vertical mixing of background concentrations
432 was considered, significantly reducing the mixing ratio of concentrations over UCL and near the ground at nights
433 in the stable boundary layer (Figure S7 in the Supplement), which was probably the main driving force of decreased
434 predictions in the hybrid model (Benavides et al., 2019). However, the CMAQ-RLINE_URBAN slightly
435 overestimated the nighttime NO₂ concentration of all observation stations except the DSH, which was probably
436 caused by overestimations of background concentrations from CMAQ-ISAM and vehicle emissions.

437

438 The accuracy of model performances at each traffic site showed a little difference affected by the variations in the
439 traffic flow and emissions of nearby roads, as well as the geometry of surrounding buildings and street canyons. At
440 DSH and NSH sites, which were adjacent to ring roads as the main urban freight corridors with a high traffic flow
441 including a large proportion of trucks, the high NO_x emissions led to the highest roadside NO₂ observations among
442 all sites. The CMAQ model would significantly underestimate the high NO₂ concentration at sites nearby ring roads,
443 with MB and NMB lower than -15 µg/m³ and -28% (Table S5 in the Supplement), respectively, which was
444 improved using CMAQ-RLINE_URBAN. However, the hybrid model performed a minor overestimation at the
445 NSH site, since the monitor was actually positioned in the road centerline but assumed to be located downwind in
446 the model, resulting in a relatively large systematic error (Snyder et al., 2013). In total, CMAQ-
447 RLINE_URBAN performed best among all models, especially improving the estimation of NO₂ concentrations
448 near roads by the original regional model.

449

450 Additionally, Figure S8 in the Supplement **shows** the comparison between simulated and observed roadside hourly
451 and daily maximum 8-hour average O₃ concentrations by different models, and their diurnal variations **are** shown
452 in Figure S9. Generally, the hybrid model significantly improved the overestimation of daytime O₃ concentrations
453 by the CMAQ model when considering the titration effect of high NO concentration near roads on O₃. In the hybrid
454 model, the peak time was delayed to about 15:00, which was closer to the observation, but still 1-2 hours earlier
455 than the actual time, which may be related to the uncertainty in NO₂ photolysis rate.

456

457 **3.4 Spatial distribution characteristics of simulated concentrations**

458 We investigated the differences between the spatial distribution of the monthly averaged NO₂ concentration
459 simulated by the CMAQ and CMAQ-RLINE_URBAN models, as shown in Figure 11. Since the urban
460 thermodynamic schemes were considered in the hybrid model, the overestimation of most urban environmental
461 **grid receptors** by CMAQ model was relieved. Within the fourth ring road and its surrounding areas, the mean
462 concentration of NO₂ from CMAQ-RLINE_URBAN was 30.1 µg/m³, lower than that from the CMAQ model (39.5
463 µg/m³). The overall spatial distribution characteristics of NO₂ predictions from both models showed that the
464 concentrations in south regions were high due to the pollution transport from Hebei province (An et al., 2019).
465 However, near-road hotspots for the NO₂ pollution were identified in the hybrid model where the spatial resolution
466 of results increased to 50 m×50 m. The NO₂ concentrations nearby ring roads with high traffic flow and emissions
467 were up to 120 µg/m³, much higher than the maximum prediction from CMAQ model (52.4 µg/m³). In addition,
468 the simulated near-road concentrations from the hybrid model during traffic peak hours (18:00-19:00) were
469 significantly higher than those at noon (12:00-13:00), while there were few changes in results from CMAQ model
470 (Figure S10 in the Supplement).

471

472 The NO₂ concentrations estimated by CMAQ-RLINE_URBAN at all **grid receptors** grids followed a two-mode
473 Gaussian distribution (Figure S11 in the Supplement), which was similar to Zhang's results (Zhang et al., 2021b).
474 The NO₂ concentrations as a result of vehicle emissions were further calculated by the differences between the total
475 and background concentrations. In general, the vehicle-induced NO₂ concentrations in urban areas was 11.8 µg/m³,
476 accounting for 39% of the total concentrations, which was similar to the predicted contribution from the CMAQ-
477 ISAM model (42.5%).

478

479 Figure 12 **shows** the changes in NO₂ concentrations simulated by the hybrid model with distance from the **grid**
480 **receptors** to its nearest road centerline. The concentrations at **grid receptors** within 200 m from road were

481 significantly affected by vehicle emissions. Within 50 m around the road, as the distance from **grid receptors** to the
482 road centerline gradually increased, the NO₂ concentrations decreased exponentially. The total NO₂ concentrations
483 decreased from 53.1 µg/m³ to 30 µg/m³, and the vehicle-induced concentrations also dropped from 34.7 µg/m³ to
484 12.6 µg/m³. The concentrations near roads with different types were highly dependent on the emission intensity.
485 The NO₂ concentration was highest in the center of the urban freeway, which was 76 µg/m³ and about 1.9 times
486 higher than that on local roads. The relative contribution of vehicle emissions to NO₂ concentration reached up to
487 75.3% on urban freeways, as well as 71.9% and 65.5% on artery roads and freeways, but only 51.1% on local roads.
488 It was worth noting that although the NO₂ concentrations at far **grid receptors** to the road on highways were slightly
489 higher than those on other road types, the contribution of vehicle emissions was the least. It was since the NO_x
490 emission intensity of freeways was as high as that on artery roads, but the density and height of buildings around
491 freeways were usually low, resulting in a high vertical flux of background concentrations from the top of UCL to
492 the ground. In conclusion, the results from the hybrid model accurately reflected not only the impacts of local on-
493 road emissions, but also the pollution characteristics affected by non-vehicle sources at the regional scale.

494

495 **4 Conclusion and Discussions**

496 In this study, we developed a hybrid model CMAQ-RLINE_URBAN to quantitatively analyse the effects of vehicle
497 emissions on urban roadside NO₂ concentrations at a high spatial resolution of 50 m × 50 m. The main conclusions
498 of this study are as follows:

499

500 The developed MLSCF scheme revealed that affected by the geometry of buildings on both sides of the road, the
501 wind filed in the street canyon sometimes was quite different from that in the environmental background. In deep
502 street canyons, the wind speed at the bottom decreased obviously due to the resistant effect of buildings, and the
503 directions of horizontal flow at bottom and top of the canyon were completely opposite due to the formation of
504 vortex. The application of MLSCF scheme in the hybrid model led to increase NO₂ concentrations at upwind **grid**
505 **receptors** within deep street canyons due to changes in the wind environment. **However, the influence of the**
506 **turbulence induced by street canyon effects on the mixing of air pollution was not considered on which we will**
507 **make effort in the future.**

508

509 The comparison between observations and predictions showed that the hybrid model significantly improved the
510 underestimation of near-source concentrations due to grid dilution on emissions in CMAQ model. The
511 implementation of the urban thermodynamic schemes in the hybrid model also relieved the overestimation in night-

512 time NO₂ concentrations from the CMAQ directly coupled with RLINE model. The predictions from CMAQ-
513 RLINE_URBAN model could accurately reflect not only the impact of road local emissions, but also the pollution
514 characteristics of non-vehicle sources at regional level. It revealed that in summer, the average contribution of
515 vehicle emission to NO₂ concentrations in urban areas of Beijing was 11.8 μg/m³, and the relative contribution
516 accounted for approximately 39%. Moreover, the vehicle-induced NO₂ pollution increased significantly with the
517 decreased distance to the road centerline, especially reaching 76 μg/m³ (75%) on urban freeways.

518

519 On the basis of this study, the following perspectives are proposed for future research: (1) **At present, considering**
520 **the running cost, the grid resolution of area in Beijing 5th ring road and its surroundings can reach 50 m×50 m. We**
521 **will make efforts to develop a parallel computing method to reduce the computing time, in order to improve the**
522 **grid resolution of a relatively large-scale simulation. (2) In our study, a simplified two-reaction scheme was**
523 **incorporated into the model to characterize the photochemical process of NO_x, since it performed similar**
524 **predictions and less computational time compared with those of the complicated CB05 gas phase chemical**
525 **mechanism (Kim et al., 2018). However, another study pointed that the impact of nonlinear O₃-NO_x-VOC**
526 **chemistry on NO₂ concentrations in the deep canyon was nonnegligible (Zhong et al., 2017). The influence of**
527 **different chemistry schemes on near-road simulation will be investigated in the future. (3) The long-term site-**
528 **observation of wind environment and pollutant concentrations in various street canyons were suggested to be**
529 **compared with modelling results, especially in deep street canyons with large aspect ratio. The navigation**
530 **monitoring technology would be applied in the model verification, which can carry out large-scale observation of**
531 **concentration along streets. (4) Here, we considered the dynamic impact of idealized building structure on wind**
532 **environment in street canyons. However, there are many other influencing factors, such as building layout and**
533 **arrangement, roof shape, green vegetation, and thermodynamic effect, which are suggested to be considered in**
534 **future studies. (5) In this study, we mainly focused on the NO₂ concentrations. In fact, the concentration of**
535 **particulate matter, especially UFP, will also have an obvious peak near the road centerline. In the future, the process**
536 **of physical and chemical changes of particulate matter near the vehicle exhaust outlet should be further investigated.**

537

538 **Data availability**

539 Data are available upon request from the corresponding author Huan Liu (liu_env@tsinghua.edu.cn).

540

541 **Code availability**

542 The RF and MARS model for MLSCF are both available on Github ([https://github.com/claus0224/MLSCF-RF-](https://github.com/claus0224/MLSCF-RF-MARS)
543 [MARS](https://github.com/claus0224/MLSCF-RF-MARS)), and other codes are available from the corresponding author on reasonable request.

544

545 **Acknowledgment**

546 We would like to acknowledgment professor Jian Hang from Sun Yat-sen University for supports for CFD
547 simulations and Dr. Jaime Benavides from Barcelona Supercomputing Center for the application of urban
548 thermodynamic schemes. This work is supported by the National Natural Science Foundation of China (grant nos.
549 41822505 and 42061130213 to H.L.), the Tsinghua–Toyota General Research Center. H.L. is supported by the
550 Royal Society of the United Kingdom through a Newton Advanced Fellowship (NAF\R1\201166).

551

552 **Author contributions**

553 Z. Lv and Z. Luo contributed equally. Z. Lv and Z. Luo designed the research and wrote the manuscript. H.L., Y.Z.
554 and K.H. provided guidance on the research and revised the paper. Z. Lv, Z. Luo, and F.D. provided multiple
555 analytical perspective on this research. X.W., J.Z., and L.X. helped collect and clean the data. T.H. helped on
556 language modification.

557

558 **Competing interests**

559 The authors declare that they have no conflict of interest.

560

561 **Additional information**

562 The supplement is available for this paper at online resources.

563 Correspondence and requests for materials should be addressed to H.L.

Figure 5: Performances of machine learning on velocity profile in wind tunnel experiments. The street canyon was perpendicular (a) or parallel (b) to the wind direction at the roof level in different experiments. The detailed description of each experiment was introduced in Section 2.2.3.

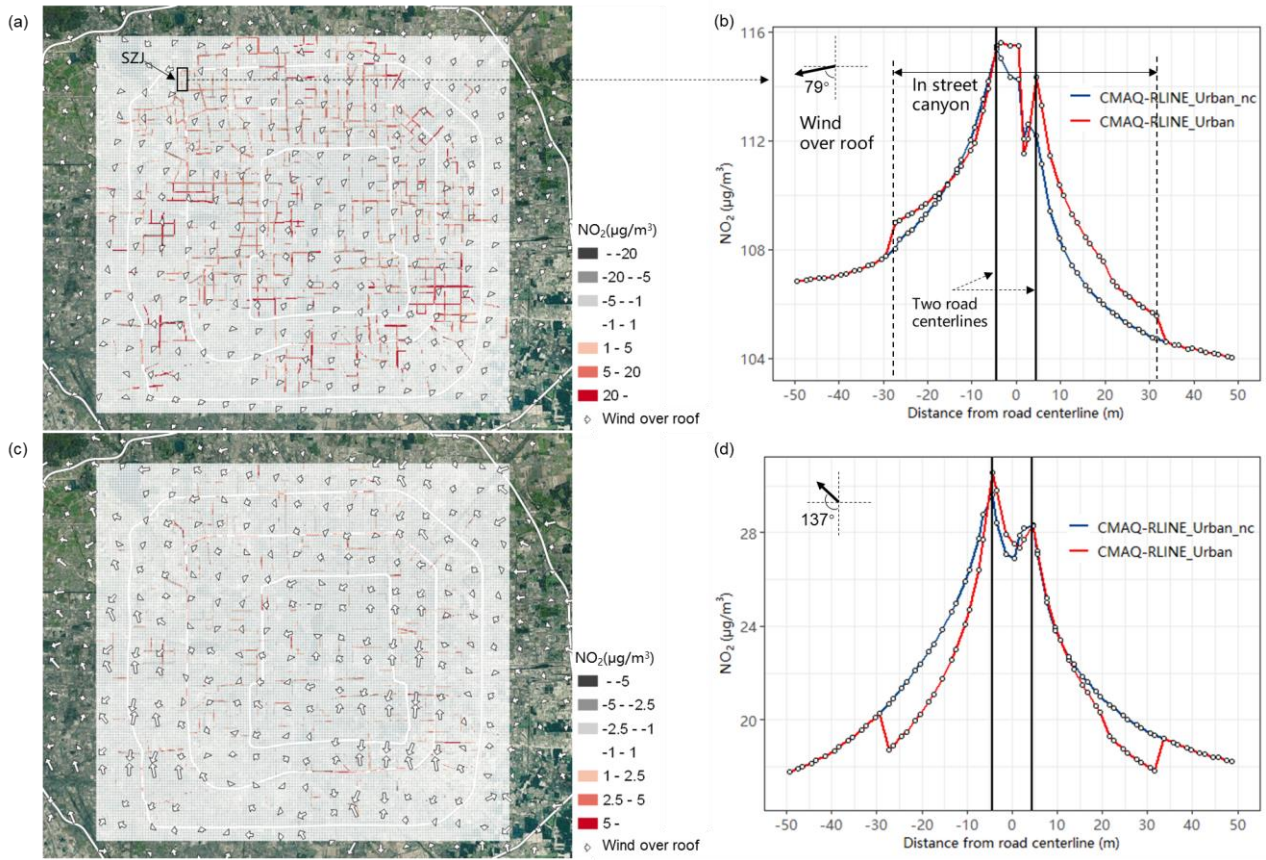

800
 801 **Figure 6: Variable importance ranking in the RF model for (a) V_x and (b) V_y .**

802

803
 804 **Figure 7: Influence of MLSCF on wind filed in the street canyon. Monthly averaged vertical profile of wind**
 805 **speed from MOST and MLSCF method in different street canyons: (a) QM (H/W=0.22); (b) XZM**
 806 **(H/W=0.35); (c) SZJ (H/W=1); (b) JTDL (H/W=1.93). The gray shade represents the standard deviation in**
 807 **results of all hours. Hourly wind direction from WRF model (at roof level) and MLSCF method (at ground**
 808 **level) in different street canyons: (e) QM (H/W=0.22); (f) SZJ (H/W=1). As the gray and green shade shown,**
 809 **the background wind over the street canyon provided by WRF model was divided into four main directions:**
 810 **east, west, south and north.**

832
 833 **Figure 12: Monthly averaged NO₂ concentrations attributed to all emission sources or vehicles with distance**
 834 **from the receptor to its nearest road centerline. (a) NO₂ attributed to all emission sources near all roads; (b)**
 835 **NO₂ attributed to all emission sources near different road types; (c) Relative contribution of vehicles to NO₂**
 836 **near different road types. The shade area in (a) represents the standard deviation in results of all receptors.**
 837

838 **Table 1: Values of controlling factors used in the simulations.**

Controlling factor	Value				
H_l/H_r (unitless)	0.50	0.75	1.00	1.33	2.00
H/W (unitless)	0.25	0.50	1.00	2.00	-
L/H (unitless)	3	5	10	20	-
$V(H)$ (m/s)	1	2	3	4	5
α (°)	0	30	60	90	-

839

840

841 **Table 2: Model performances under different scenarios**

Sites	Scenario	MB	RMSE	NMB	NMGE	FAC2	IOA	<i>R</i>
All	CMAQ	3.1	25.6	9	53	0.65	0.45	0.52
	CMAQ-RLINE	18.5	46.6	53	77	0.67	0.19	0.55
	CMAQ-RLINE_URBAN	4.6	25.8	13	49	0.75	0.49	0.57
Urban	CMAQ	8.0	24.3	27	58	0.68	0.40	0.59
	CMAQ-RLINE	12.3	35.8	43	76	0.64	0.20	0.50
	CMAQ-RLINE_URBAN	1.3	23.1	4	51	0.71	0.47	0.49

842 *MB: Mean bias; RSME: Root mean squared error; NMB: Normalized mean bias; NMGE: Normalized mean gross
843 error; FAC2: Fraction of predictions within a factor of two; IOA: Index of agreement; R: correlation coefficient.
