Abstract

Hydroperoxide esters, formed in the reactions of carbonyl oxides (also called Criegee intermediates, CIs) with formic acid, play a crucial role in the formation of secondary organic aerosol (SOA) in the atmosphere. However, the transformation mechanism of hydroperoxide esters in the presence of stabilized Criegee intermediates (SCIs) is not well understood. Herein, the oligomerization reaction mechanisms and kinetics of distinct SCIs (CH_2OO, *syn*-CH_3CHOO, *anti*-CH_3CHOO and $(CH_3)_2COO$) reactions with their respective hydroperoxide esters as well as with hydroperoxymethyl formate (HPMF) are investigated in the gas phase using quantum chemical and kinetics modeling methods. The calculations show that the addition reactions of SCIs with hydroperoxide esters proceed through successive insertion of SCIs into hydroperoxide ester to form oligomers that involve SCIs as the repeated chain unit. The saturated vapour pressure and saturated concentration of the formed oligomers decrease monotonically as the number of SCIs is increased. The exothermicity of oligomerization reactions decreases significantly when the number of methyl substituents increases, and the exothermicity of *anti*-methyl substituted carbonyl oxides is obviously higher than that of *syn*-methyl substituted carbonyl oxides. The –OOH insertion reaction is energetically more feasible than the –CH insertion pathway in the SCIs oligomerization reactions, and the barrier heights increase with increasing the number of SCIs added to the oligomer except *syn*-CH_3CHOO. For the reactions of distinct SCIs with HPMF, the barrier of –OOH insertion pathway shows a dramatic decrease when a methyl substituent occurs at the *anti*-position, while it reveals a significant increase when a methyl group is introduced at the *syn*-position and dimethyl substituent. Compared with the rate coefficients of the CH_2OO + HPMF reaction, the rate coefficients increase by about one order of magnitude when a methyl substituent occurs at the *anti*-position, whereas the rate coefficients decrease by 1-2 orders of magnitude when a methyl group is introduced at the *syn*-position. These new findings advance our current understanding on the influence of Criegee-chemistry on the formation and growth processes as well as the

51 chemical compositions of SOA.

1. Introduction

53   Alkenes are an important class of volatile organic compounds (VOCs) that are
54 emitted into the atmosphere from large quantities of biogenic and anthropogenic
55 sources (Lester and Klippenstein, 2018). The reaction with ozone is one of the
56 dominant degradation pathways for alkenes in the atmosphere (Johnson and Marston,
57 2008; Atkinson and Arey, 2003). Ozonolysis of alkene proceeds through the
58 electrophilic 1,3-cycloaddition of ozone to C=C bond of alkenes to form a primary
59 ozonides (POZ), and then it rapidly decomposes into a carbonyl compound and a
60 carbonyl oxide (also called Criegee intermediates, CIs) (Criegee, 1975; Osborn and
61 Taatjes, 2015; Giorio et al., 2017). A part of the initially energized CIs ($\sim$ 37-50%)
62 may promptly dissociate to OH radicals, which are thought to be an important
63 nonphotolytic source of OH radicals in the atmosphere (Novelli et al., 2014; Liu et al.,
64 2014). The remaining CIs ($\sim$ 63-50%) are collisionally stabilized prior to the thermal
65 unimolecular decay (Lester and Klippenstein, 2018; Novelli et al., 2014; Anglada and
66 Solé, 2016). The stabilized Criegee intermediates (SCIs) can proceed bimolecular
67 reactions with various trace species such as H_2O, NO_2, SO_2, and HCOOH to generate
68 secondary organic aerosol (SOA), thus profoundly influencing air quality, global
69 climate and human health (Osborn and Taatjes, 2015; Khan et al., 2018; Lin and Chao,
70 2017; Liu et al., 2019; Chhantyal-Pun et al., 2018; Gong and Chen, 2021; Taatjes,
71 2017).

72   Formic acid (HCOOH), one of the most abundant carboxylic acids, has a
73 significant influence on rainwater acidity in remote areas, where pH reduces by
74 0.25-0.5 in the presence of HCOOH (Stavrakou et al., 2012; Wang et al., 2020;
75 Chaliyakunnel et al., 2016). It also plays an important role in the formation of cloud
76 condensation nuclei (CCN), indirectly influencing radiative forcing and climate
77 change (Yu, 2000). The primary sources of HCOOH include biomass burning, human
78 activities, tropical and boreal forests, as well as the secondary sources involve the
79 photochemical oxidation of non-methane hydrocarbons, such as ketene-enols, vinyl

alcohol, isoprene, and terpenoids (Stavrakou et al., 2012; Wang et al., 2020; Chaliyakunnel et al., 2016; So et al., 2014; Paulot et al., 2011). According to satellite measurements, the production of HCOOH is up to 100-120 Tg yr^{-1}, and the value is expected to increase due to the acceleration of industrialization and urbanization (Stavrakou et al., 2012). Recent kinetics measurements have revealed that the reaction with HCOOH is a more important loss process for SCI than is presently assumed, especially in terrestrial equatorial areas and in high SCI concentration areas (Welz et al., 2014; Chung et al., 2019). The formed hydroperoxide esters have been identified as the low-volatility and high-oxygenated compounds, contributing to the formation and growth of SOA (Welz et al., 2014; Vansco et al., 2021; Sakamoto et al., 2017; Riva et al., 2017).

Welz et al. (2014) directly determined the rate coefficients for the reactions of CH_2OO and CH_3CHOO with formic and acetic acid by employing multiplexed photoionization mass spectrometry and cavity-enhanced broadband ultraviolet absorption spectroscopy. They found that the measured rate coefficients are in the excess of 1.0×10^{-10} cm^3 molecule^{-1} s^{-1}, which are several orders of magnitude greater than those derived from previous experimental studies (Johnson et al., 2001; Tobias and Ziemann, 2001). Sipilä et al. conducted a competitive reaction kinetics experiment to investigate the reactions of acetone oxide ((CH_3)$_2$OO) with SO_2, HCOOH and CH_3COOH, and they concluded that the rate coefficients of the ((CH_3)$_2$OO + HCOOH/CH_3OOH reactions are faster than that of the ((CH_3)$_2$OO + SO_2 system by about three times (Sipilä et al., 2014). These high rate coefficients could make the reaction with carboxylic acids a substantial dominant chemical sink for carbonyl oxides in the atmosphere (Welz et al., 2014; Taatjes et al., 2019; Chhantyal-Pun et al., 2017). Quantum chemical calculations show that the reaction of CH_2OO with HCOOH proceeds through a facile transfer of hydrogen atom from the acidic OH group to the terminal oxygen of CH_2OO to form hydroperoxymethyl formate (HPMF) (Long et al., 2009; Vereecken, 2017; Porterfield et al., 2019). Chen et al. (2018) concluded the same by investigating the reactions of various carbonyl oxides with HCOOH that the barrierless 1,4-insertion reaction is the most favorable

pathway, and the primary products are hydroperoxide esters. Caravan et al. (2020) employed high-level ab initio CCSD(T)-F12 methods to study the reaction of methyl vinyl ketone oxide (MVK-oxide) with HCOOH, and they found that the barrierless net insertion of MVK-oxide into HCOOH leading to the formation of a functionalized hydroperoxide is dominant over fragmentation to produce an alkoxy radical and OH radicals. Moreover, oligomerization reactions with hydroperoxides and peroxy radicals are identified as one of the dominant loss processes for carbonyl oxides under atmospheric conditions (Sakamoto et al., 2013; Sadezky et al., 2008; Zhao et al., 2015; Chen et al., 2017 and 2019). All the above milestone investigations provide important information for understanding the chemistry of Criegee intermediate in the presence of carboxylic acids. However, to the best of our knowledge, there are few studies on the oligomerization reactions of SCIs with hydroperoxide esters, which are important with regard to organic new particle and cloud condensation nuclei formations. Moreover, the relationship between the reactivity of SCIs and the nature of substituents remains uncertain in the SCIs oligomerization reactions.

In the present study, we mainly focus on the oligomerization reaction mechanisms and kinetics of four carbonyl oxides reactions with their respective hydroperoxide esters as well as with HPMF by employing quantum chemical calculations and kinetics modeling methods. For the initiation reactions of carbonyl oxides with formic acid, four kinds of pathways including 1,4 O-H insertion, 1,2 O-H insertion, C-H insertion, and C=O cycloaddition are considered. For the oligomerization reactions of the successive insertion of carbonyl oxides into hydroperoxide esters, two types of reactions involving –OOH and –CH insertions are taken into account. The selected carbonyl oxides, including CH_2OO, *syn*-, *anti*-CH_3CHOO and $(CH_3)_2CHOO$, are anticipated upon the ozonolysis of ethylene, propylene, and 2,3-dimethyl-2-butene, whereas the hydroperoxide esters are assumed to arise from the bimolecular reactions of carbonyl oxides with formic acid in the atmosphere.

2. Computational details

2.1 Electronic structure and energy calculations

The geometries of all stationary points, including reactants (R), intermediates (IM), transition states (TS), and products (P), are optimized at the M06-2X/6-311+G(2df,2p) level of theory, since the M06-2X functional has the reliable performance for predicting thermochemistry, kinetics and hydrogen bonding interactions (Zhao and Truhlar, 2008). Harmonic vibrational frequencies are performed at the same level to verify the nature of transition state (NIMAG = 1) and minimum (NIMAG = 0), and to provide zero-point vibrational energy (ZPVE) and Gibbs free energies corrections (G_{corr}), which are scaled by a factor of 0.98 (Alecu et al., 2010). Intrinsic reaction coordinate (IRC) calculations are carried out to verify that each transition state is connected to the desired reactant and product (Fukui, 1981). The single point energy (SPE) calculations are performed at the M06-2X/ma-TZVP level of theory based on the M06-2X/6-311+G(2df,2p) optimized geometries. Moreover, the basis set superposition error (BSSE) is performed by using the counterpoise method proposed by Boys and Bernardi (1970) to evaluate the stability of the pre-reactive complex (RC). Herein, the Gibbs free energy (G) is defined as the sum of SPE and Gibbs correction ($G = E + G_{corr}$). Electronic energy ($\Delta E^{\neq}$) and Gibbs free energy ($\Delta G^{\neq}$) barriers are defined as the difference in energy between a TS and a RC ($\Delta E^{\neq} = E_{TS} - E_{RC}$ and $\Delta G^{\neq} = G_{TS} - G_{RC}$). Reaction Gibbs free energy (ΔG) is defined as the difference in energy between a P and a R ($\Delta G = G_P - G_R$).

To further assess the reliability of the selected M06-2X/ma-TZVP method for SPE calculations, the single point energies of all stationary points involved in the initiation reactions of distinct SCIs with HCOOH are recalculated at the high-accuracy CCSD(T)/6-311+G(2df,2p) and QCISD(T)/6-311+G(2df,2p) levels of theory. The calculated results are summarized in Table S1. This table shows that the $\Delta E^{\neq}$ and $\Delta G^{\neq}$ obtained using the QCISD(T) method are in excellent agreement with those obtained using the CCSD(T) approach. It is therefore that the energies obtained using the CCSD(T) method are used as the benchmark for comparation. The mean

168 absolute deviations (MAD) of $\Delta E^{\neq}$ and $\Delta G^{\neq}$ between the CCSD(T) and M06-2X

169 methods are 0.43 and 0.41 kcal mol^{-1}, respectively; the largest deviations of $\Delta E^{\neq}$ and

170 $\Delta G^{\neq}$ are 1.0 and 1.1 kcal mol^{-1}, respectively. These results reveal that the energies

171 obtained using the M06-2X method are close to those obtained using the CCSD(T)

172 approach. Therefore, the M06-2X/ma-TZVP method is suitable to investigate the

173 SCIs oligomerization reactions. In the following discussion, the energies are applied

174 in terms of Gibbs free energy to describe the reaction mechanism unless otherwise

175 stated. All electronic structure calculations are carried out by using Gaussian 09

176 program (Frisch et al., 2009). The Multiwfn program and Visual molecular dynamics

177 (VMD) are utilized to analysis and visualize the molecular orbitals of the relevant

178 species (Lu and Chen, 2012; Humphrey et al., 1996).

2.2 Kinetics calculations

180 The rate coefficients for the barrierless 1,4 O-H insertion reactions are computed

181 by employing the variable-reaction-coordinate variational transition-state theory

182 (VRC-VTST) (Bao and Truhlar, 2017), in which the potential energies are calculated

183 by direct dynamics using the M06-2X/6-311+G(2df,2p) method. Rate coefficients for

184 the SCIs + HCOOH reactions are calculated using the E,J-resolved microcanonical

185 variational theory (E,J-μVT) using a single-faceted dividing surface. In the

186 VRC-VTST calculations, the reaction coordinate s is defined by pivot points, which

187 are used to orientate the reactants 1 and 2. s is defined as the minimal value of r_{ij},

188 where r_{ij} is the distance between pivot points i and j, i is a pivot point on reactant 1

189 and j is a pivot point on reactant 2. Two of the pivot points are located at a distance $\pm d$

190 from the center of mass (COM) of SCIs, and the other two pivot points are located at

191 a distance $\pm d$ from the COM of HCOOH with a fixed length of 0.05, 0.10, 0.15, 0.2

192 and 0.25 Å. Then, for a given choice of pivot points, the variationally lowest rate

193 coefficients are minimized with respect to s at each of the temperatures. We observed

194 that d=0.05 produces the best variation results and only its value is reported in the

195 present study.

196 The rate coefficients for the bimolecular reactions with the tight transition states

are calculated by using the canonical transition state theory (CTST) along with one-dimensional asymmetric Eckart tunneling correction (Truhlar et al., 1996; and Eckart, 1930). As shown in Fig. 1, the entrance pathway Entry2 of R_1R_2COO reaction with HCOOH consists of two steps: (i) an intermediate IMent2 is formed via a barrierless process; (ii) then, it rearranges to the product Pent2 through a tight transition state TSent2. The whole reaction process can be described as Eq. (1):

$$R_1R_2COO + HCOOH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} IMent2 \overset{k_2}{\longrightarrow} Pent2 \qquad (1)$$

Assuming the rapid equilibrium is established between the IMent2 and reactants. According to the steady-state approximation (SSA), the total rate coefficient is approximately expressed as Eq. (2) (Zhang et al., 2012):

$$k_{tot} = \frac{k_1}{k_{-1} + k_2} k_2 \approx \frac{k_1}{k_{-1}} k_2 = K_{eq} k_2 \qquad (2)$$

The equilibrium constant K_{eq} is written as Eq. (3):

$$K_{eq} = \sigma \frac{Q_{IM}(T)}{Q_{R1}(T)Q_{R2}(T)} \exp\left(\frac{G_R - G_{IM}}{RT}\right) \qquad (3)$$

where σ refers to reaction symmetry number, $Q_{IM}(T)$, $Q_{R1}(T)$ and $Q_{R2}(T)$ denote the partition functions of intermediate, reactants R1 and R2, which are equal to the multiplication of translational, rotational, vibrational and electronic partition functions ($Q = Q_{rot}Q_{vib}Q_{trans}Q_{elec}$) (Mendes et al., 2014), T is the temperature in Kelvin, R is the ideal gas constant, G_R and G_{IM} are the total Gibbs free energies of reactant and intermediate, respectively. The rate coefficient calculations are performed with the Polyrate 2017-C and KiSThelP 2019 programs (Canneaux et al., 2013; Zheng et al., 2018).

3. Results and discussion

3.1 Initiation reactions of distinct SCIs with HCOOH

The reaction with HCOOH is one of the dominant loss processes for SCIs and is expected to trigger the formation of SOA in the atmosphere (Chhantyal-Pun et al., 2018; Cabezas and Endo, 2020; Zhao et al., 2018; Zhou et al., 2019). The potential

223   energy surface (PES) of distinct SCIs (CH_2OO, *syn*-, *anti*-CH_3CHOO and $(CH_3)_2COO$)

224   reactions with HCOOH is drawn in Fig. 1. The geometries of all stationary points are

225   displayed in Fig. S1. The relative free energy of each stationary point and free energy

226   barrier ($\Delta G^{\neq}$) of each elementary reaction are summarized in Table 1. As shown in Fig.

227   1, the bimolecular reaction of distinct SCIs with HCOOH proceeds via four possible

228   pathways, namely (1) 1,4 O-H insertion (Entry 1), (2) 1,2 O-H insertion (Entry 2), (3)

229   C-H insertion (Entry 3), and (4) C=O cycloaddition (Entry 4). For Entry 1, the

230   addition reaction of CH_2OO with HCOOH proceeds through the 1,4 O-H insertion of

231   CH_2OO into HCOOH to form a hydroperoxide ester $HC(O)O\text{-}CH_2OO\text{-}H$ with a

232   exoergicity of 37.6 kcal·mol^{-1}. The formation of $HC(O)O\text{-}CH_2OO\text{-}H$ is obtained

233   through a concerted process of $O_2\text{-}H_2$ bond breaking in the HCOOH and $O_4\text{-}H_2$ and

234   $C_2\text{-}O_1$ bonds forming. Despite an attempt by various methods, the corresponding

235   transition state is still not located in the effort of optimization. To further validate the

236   barrierless process of 1,4 O-H insertion reaction, a relaxed scan over the O-H and C-O

237   bonds is performed at the M06-2X/6-311+G(2df,2p) level of theory. The scans start

238   from the optimized structure of the adduct products, and the O-H and C-O bond

239   lengths are then increased in steps of 0.10 Å, while other geometric parameters are

240   fully optimized. The zero of energy is set to be the energy of the adduct products. The

241   electronic potential energy profiles along the O-H and C-O dissociation coordinate are

242   presented in Fig. S2. As seen in Fig. S2a, the electronic potential energy of the

243   minimum potential-energy path (MEP) decreases monotonically when the bond

244   length of the O-H and C-O bonds decreases, suggesting that the 1,4 O-H insertion

245   reaction of CH_2OO with HCOOH is indeed barrierless. Similar conclusion is also

246   obtained from the electronic potential energy profiles for the *anti*-CH_3CHOO +

247   HCOOH, *syn*-CH_3CHOO + HCOOH and $(CH_3)_2COO$ + HCOOH (Fig. S2b-d)

248   reactions that 1,4 O-H insertion reactions are barrierless. This conclusion is further

249   supported by the analogous reaction systems that 1,4 O-H insertion reactions of

250   carbonyl oxides with carboxylic acids are a barrierless process including concerted

251   hydrogen atom transfer and new C-O bond formation (Chhantyal-Pun et al., 2017;

252   Long et al., 2009; Vereecken, 2017; Cabezas and Endo, 2019; Lin et al., 2019).

253  The exothermicities of 1,4 O-H insertion reactions of distinct SCIs with HCOOH

254 are assessed by the reaction enthalpies ($\Delta_r H_{298}^{\circ}$), which are defined as the difference

255 between the enthalpies of formation ($\Delta_f H_{298}^{\circ}$) of the products and reactants

256 ($\Delta_r H_{298}^{\circ} = \sum\limits_{products} \Delta_f H_{298}^{\circ} - \sum\limits_{reactants} \Delta_f H_{298}^{\circ}$). To the best of our knowledge, there are no literature

257 values available on the enthalpies of formation of carbonyl oxides and hydroperoxide

258 esters except the simplest carbonyl oxide CH_2OO. Therefore, the isodesmic reaction

259 method is adopted to obtain the enthalpies of formation, and the results are listed in

260 Table S2. An isodesmic reaction is a hypothetical reaction, in which the type of

261 chemical bonds in the reactants is the similar as that of chemical bonds in the products.

262 The following isodesmic reaction is constructed because the experimental values of

263 H_2, CH_4 and H_2O are available ($\Delta_f H_{298}^{\circ}(H_2) = 0.00$ kcal·mol^{-1}; $\Delta_f H_{298}^{\circ}(CH_4) = -17.82$

264 kcal·mol^{-1}; $\Delta_f H_{298}^{\circ}(H_2O) = -57.79$ kcal·mol^{-1}).

$$SCIs + nH_2 \rightarrow CH_4 + mH_2O \tag{4}$$
266  As seen in Table S2, the enthalpy of formation of CH_2OO is calculated to be

267 23.23 kcal·mol^{-1}, which is in good agreement with the available literature values

268 (Chen et al., 2016; Karton et al., 2013). This result implies that the theoretical method

269 employed herein is reasonable to predict the thermochemical parameters. The

270 enthalpies of formation of carbonyl oxides and hydroperoxide esters significantly

271 decrease with increasing the number of methyl groups. Notably, the decreased values

272 in the enthalpies of formation of carbonyl oxides are greater than those of

273 hydroperoxide esters under the condition of the same number of methyl groups. For

274 example, the enthalpy of formation of *anti*-CH_3CHOO decreases by 12.95 kcal·mol^{-1}

275 compared to the enthalpy of formation of CH_2OO (23.23 kcal·mol^{-1}), and the enthalpy

276 of formation of Pent1b decreases by 12.12 kcal·mol^{-1} compared to the enthalpy of

277 formation of Pent1a (-112.08 kcal·mol^{-1}). The reaction enthalpies of the reactions of

278 distinct SCIs with HCOOH decrease in the order of -44.69 ($CH_2OO + HCOOH \rightarrow$

279 Pent1a) < -43.86 (*anti*-$CH_3CHOO + HCOOH \rightarrow$ Pent1b) < -38.13 (*syn*-$CH_3CHOO +$

280 $HCOOH \rightarrow$ Pent1c) < -37.12 kcal·mol^{-1} ((CH_3)$_2COO + HCOOH \rightarrow$ Pent1d),

281 indicating that the reaction enthalpies are highly dependent on the number and

282 location of methyl groups. The trend in reaction enthalpies is consistent with the trend

283 in the enthalpies of formation of carbonyl oxides.

284   For Entry 2, each addition reaction starts with the formation of a pre-reactive

285 hydrogen bonded complex IMent2 in the entrance channel. Then it immediately

286 converts into product Pent2 through the 1,2 O-H insertion transition state. The

287 formation of Pent2 is obtained via a concerted process of O_2-H_2 bond rupture in the

288 HCOOH and O_4-H_2 and C_2-O_2 bonds forming. The reaction barrier $\Delta G^{\neq}$ increases in

289 the order of 10.0 (CH_2OO) < 13.0 (*anti*-CH_3CHOO) < 14.6 (*syn*-CH_3CHOO) $\approx$ 14.4

290 (($CH_3)_2COO$) kcal·mol^{-1}, suggesting that the parent CH_2OO + HCOOH reaction is

291 favored kinetically. Compared with the barrier of the parent system, the barrier

292 increases by 3.0 kcal·mol^{-1} when a methyl substitution occurs at the R_1 position, and

293 the barrier increases by $\sim$ 5 kcal·mol^{-1} when a methyl group is introduced at the R_2

294 position and dimethyl substituent. The aforementioned result implies that the

295 methyl-substituted CH_2OO hinders the 1,2 O-H insertion of carbonyl oxides into

296 formic acid. Notably, the exothermicity decreases significantly as the number of

297 methyl group is increased. The products Pent1 and Pent2 formed from Entry 1 and 2

298 are two conformations that differ in the orientation of the –C(O)H moiety over the –

299 OOH group. The calculated result shows that Pent1 is more stable than Pent2 in

300 energy due to the existence of intramolecular hydrogen bond between hydrogen atom

301 of –OOH group and carbonyl oxygen atom.

302   For Entry 3, the addition reaction begins with the formation of a pre-reactive

303 complex IMent3 in the entrance channel, and then it surmounts a barrier to reaction.

304 However, the barriers of C-H insertion reactions are significantly high (21.8-27.6

305 kcal·mol^{-1}), such that they are of less importance in the atmosphere. The high reaction

306 barriers might be attributed to the large bond dissociation energy (BDE) of C-H bond

307 in the formic acid. For Entry 4, the addition reaction proceeds through a cyclization

308 process of C_2-O_1 and O_4-C_1 bond forming to produce a five-membered ring compound

309 Pent4. The barrier of C=O cycloaddition reaction in the CH_2OO + HCOOH reaction is

310 5.8 kcal·mol^{-1}, which is lower than that of the corresponding channels in Entry 2 and

Entry 3 by 4.2 and 16.0 kcal·mol^{-1}, respectively. The result reveals that the C=O cycloaddition reaction is feasible kinetically. A similar conclusion is also obtained from the reactions of HCOOH with *syn*-, *anti*-CH$_3$CHOO and (CH$_3$)$_2$COO that the C=O cycloaddition reactions are favored over 1,2 O-H and C-H insertion reactions.

The rate coefficients of each elementary pathway included in the initiation reactions of distinct SCIs with HCOOH are tabulated in Table S3-S6. The total rate coefficient is equal to the sum of the rate coefficient of each elementary pathway. As shown in Table S3, the total rate coefficients $k_{\text{tot-CH2OO}}$ of CH$_2$OO reaction with HCOOH are in excess of 1.0×10^{-10} cm^3 molecule^{-1} s^{-1}, and they exhibit a slightly negative temperature dependence in the temperature range of 273-400 K. At room temperature, $k_{\text{tot-CH2OO}}$ is estimated to be 1.29×10^{-10} cm^3 molecule^{-1} s^{-1}, which is in good agreement with the experimental values reported by Welz et al. (2014) ([1.1 $\pm$ 0.1] $\times 10^{-10}$), Chung et al. (2019) ([1.4 $\pm$ 0.3] $\times 10^{-10}$), and Peltola et al. (2020) ([1.0 $\pm$ 0.03] $\times 10^{-10}$). $k(\text{TS}_{\text{ent1}})$ is approximately equal to $k_{\text{tot-CH2OO}}$ in the whole temperature range, and it decreases in the range of 1.34×10^{-10} (273 K) to 1.05×10^{-10} (400 K) cm^3 molecule^{-1} s^{-1} with increasing temperature. $k(\text{TS}_{\text{ent1}})$ is several orders of magnitude greater than $k(\text{TS}_{\text{ent2}})$, $k(\text{TS}_{\text{ent3}})$ and $k(\text{TS}_{\text{ent4}})$ over the temperature range from 273 to 400 K. The result again shows that the barrierless 1,4 O-H insertion reaction is predominant. It should be noted that although the barrier of Entry 2 is 4.2 kcal·mol^{-1} higher than that of Entry 4, $k(\text{TS}_{\text{ent2}})$ is merely about 1-2 fold smaller than $k(\text{TS}_{\text{ent4}})$. The reason is ascribed to the fact that the C=O cycloaddition reaction is entropically unfavorable (Vereecken, 2017).

Equivalent to the case of the reaction of CH$_2$OO with HCOOH, the total rate coefficient $k_{\text{tot-}anti}$ of *anti*-CH$_3$CHOO reaction with HCOOH also decreases slightly with the temperature increasing (Table S4). This table shows that Entry 1 is kinetically favored over Entry 2, 3 and 4, and Entry 2 is competitive with Entry 4 in the temperature range of 273-400 K. Similar conclusion is also obtained from the results of the rate coefficients for the reactions of *syn*-CH$_3$CHOO and (CH$_3$)$_2$COO with HCOOH that Entry 1 is the dominant pathway (Table S5-S6). It deserves mentioning that the competition of Entry 2 is significantly greater than that of Entry 4

341 in the *syn*-CH$_3$CHOO + HCOOH and (CH$_3$)$_2$COO + HCOOH systems. Based on the

342 above discussions, it can be concluded that the relative importance of different

343 pathways is highly dependent on the number and location of methyl substituents in

344 the carbonyl oxides. Notably, the rate coefficient of each elementary pathway

345 included in the *anti*-CH$_3$CHOO + HCOOH reaction is several orders of magnitude

346 greater than that of the corresponding channel involved in the other SCIs + HCOOH

347 systems. It is because that *anti*-CH$_3$CHOO is substantially more reactive toward

348 HCOOH than other SCIs. Similar phenomenon has also observed from the reactivity

349 of *anti*-CH$_3$CHOO toward water and SO$_2$ (Taatjes et al., 2013; Long et al., 2016;

350 Huang et al., 2015; Cabezas and Endo, 2018). At ambient temperature, the total rate

351 coefficients of HCOOH reactions with *anti*-CH$_3$CHOO, *syn*-CH$_3$CHOO and

352 (CH$_3$)$_2$COO are estimated to be 5.22, 2.18 and 3.97 $\times$ 10^{-10} cm^3 molecule^{-1} s^{-1},

353 respectively, which are consistent with the prior experimental measurements of 5 $\pm$ 3,

354 2.5 $\pm$ 0.3 and 4.5 $\pm$ 0.9 $\times$ 10^{-10} cm^3 molecule^{-1} s^{-1} (Welz et al., 2014; Sipilä et al.,

355 2014).

356   In summary, the barrierless 1,4 O-H insertion reaction is the dominant pathway

357 in the initiation reactions of distinct SCIs with HCOOH. This conclusion is consistent

358 with the recent experimental results derived from the reactions of formic acid with

359 methacrolein oxide (MACR-OO) and methyl vinyl ketone oxide (MVK-OO) that the

360 1,4-addition mechanism is energetically favorable (Vansco et al., 2021; Caravan et al.,

361 2020). Therefore, in the present study, the adduct products Pent1 formed form the

362 barrierless 1,4 O-H insertion of carbonyl oxides into HCOOH are selected as the

363 model compounds to investigate the oligomerization reaction mechanisms of carbonyl

364 oxides reactions with hydroperoxide esters.

3.2. The reactions of distinct SCIs with their respective hydroperoxide esters

The formed hydroperoxide ester has two possible unimolecular decay pathways. The first is the direct O-O bond rupture resulting in the formation of oxylmethylformate and OH radicals (Vereecken, 2017). The second is the –OH fragment binding to adjacent hydrogen atom leading to the formation of anhydride and H_2O (Aplincourt and Ruiz-López, 2000; Neeb et al., 1998). However, the barriers of these two unimolecular reactions are extremely high, such that they are of less importance in the atmosphere. The formed hydroperoxide ester possess –OOH and –OC(O)H groups, both of them can serve as the reactive moieties to react with carbonyl oxides giving rise to the formation of oligomers. In the present study, we mainly consider two types of pathways: (a) –OOH insertion and (b) –CH insertion, while the C=O cycloaddition reaction is not taken into account because it is entropically unfavorable (Vereecken, et al., 2017; Lin et al., 2009). The aforementioned reactions are discussed in detail in the following subsections.

3.2.1 The reactions of 2CH₂OO with Pent1a

The simplest carbonyl oxide, CH_2OO, originates from the reaction of all terminal alkenes with ozone (ozonolysis) in the atmosphere (Lin and Chao, 2017). The reaction with HCOOH is expected to be one of the dominant loss processes for CH_2OO, and the main product is Pent1a (also called HPMF) (Welz et al., 2014; Cabezas and Endo, 2019). A schematic PES for the addition reaction $2CH_2OO$ + Pent1a is drawn in Fig. 2, and the optimized geometries of all stationary points are displayed in Fig. S3. As seen in Fig. 2, the successive insertion of CH_2OO into Pent1a eventually leads to the formation of oligomers P2a and P2b composed of CH_2OO as the repeat unit. These oligomerization reactions are strongly exothermic and spontaneous (> 83 kcal·mol^{-1}), implying that they are feasible thermodynamically.

The addition reaction $2CH_2OO$ + Pent1a initially proceeds through two possible pathways, namely (1) –OOH insertion reaction R1a, and (2) –CH insertion reaction R1b. For the –OOH insertion reaction R1a, the pre-reactive intermediate IM1a with a seven-membered ring structure is formed in the entrance channel, which is stabilized by the hydrogen bond interactions between the H_4 atom of Pent1a and the O_6 atom of

CH$_2$OO (D$_{(O6-H4)}$ = 1.706 Å), and between the H$_6$ atom of CH$_2$OO and the O$_3$ atom of Pent1a (D$_{(O3-H6)}$ = 2.115 Å). Then IM1a converts into P1a (C$_3$H$_6$O$_6$, HC(O)O–(CH$_2$OO)$_2$–H) via a concerted process of O$_4$-H$_4$ bond breaking in the Pent1a and O$_4$-C$_3$ and H$_4$-O$_6$ bonds forming with a barrier of 8.1 kcal·mol^{-1}. For the –CH insertion reaction R1b, the pre-reactive intermediate IM1b with a seven-membered ring structure is formed in the entrance channel, which is stabilized by the van der Waals (vdW) interactions between the O$_3$ atom of Pent1a and the C$_3$ atom of CH$_2$OO (D$_{(O3-C3)}$ = 2.602 Å), and between the O$_6$ atom of CH$_2$OO and the C$_1$ atom of Pent1a (D$_{(O6-C1)}$ = 2.608 Å). Due to the absence of hydrogen bond in IM1b, the energy of IM1b is lower than that of IM1a by 3.0 kcal·mol^{-1}. IM1b transforms into P1b (C$_3$H$_6$O$_6$, HO$_2$CH$_2$OC(O)CH$_2$OOH) via a concerted process of C$_1$-H$_1$ bond breaking in the Pent1a and C$_1$-C$_3$ and H$_1$-O$_6$ bonds forming with a barrier of 21.5 kcal·mol^{-1}. By comparing the barriers of R1a and R1b, it can be concluded that the –OOH insertion reaction is favored over the –CH insertion reaction. The high reaction barrier of R1b is attributed to the large bond dissociation energy (BDE) of C-H bond in the Pent1a. To further insight into the reaction mechanism of R1a, the natural bond orbital (NBO) analysis of the donor-acceptor orbitals involved in the TS1a is performed using the M06-2X wave function. The possible donor-acceptor interactions are estimated by using the second order perturbation theory. As illustrated in Fig. S4, the strong interactions are identified as the interaction of the lone pair orbital of O$_6$ atom and the antibonding orbital of O$_4$-H$_4$ bond, and the interaction of the lone pair orbital of O$_4$ atom and the antibonding orbital of C$_3$-O$_5$ bond.

Similarly, the addition reaction CH$_2$OO + P1a proceeds through the formation of the pre-reactive intermediates IM2a and IM2b in the entrance channel, which are stabilized by a hydrogen bond between the terminal oxygen atom of CH$_2$OO and the reacting hydrogen atom of P1a, and a van der Waals (vdW) interaction between the central carbon atom of CH$_2$OO and the carbonyl oxygen atom of P1a. The relative energies of IM2a and IM2b with respect to the separate reactants P1a and CH$_2$OO are -1.2 and 3.2 kcal·mol^{-1}, respectively, below the energies of the initial reactants 2CH$_2$OO and Pent1a are 41.6 and 37.2 kcal·mol^{-1}, respectively. Then they

immediately transform into the respective products P2a and P2b through the –OOH
and –CH insertion transition states TS2a and TS2b with the barriers of 10.1 and 21.6
kcal·mol^{-1}. This result again shows that the –OOH insertion reaction is favored
kinetically. It deserves mentioning that the barrier of –OOH insertion reaction
increases as the number of CH$_2$OO is increased. From the viewpoint of the
geometrical parameters of TS2a and TS2b, the breaking O-H and C-H bonds are
elongated by 14.8% and 20.6%, respectively, with respect to the equilibrium
structures of IM2a and IM2b, while the forming C-O and C-C bond length are 2.013
and 2.264 Å, respectively. The result reveals that TS2a and TS2b are structurally
reactant-like, which are consistent with the Hammond's hypothesis that the earlier
transition states are generally exothermic (Hammond, 1955).
Figure 2. PES (ΔG and ΔE, in italics) for the 2CH$_2$OO + Pent1a reaction at the
M06-2X/ma-TZVP//M06-2X/6-311+G(2df,2p) level of theory

3.2.2 The reactions of *anti*-CH$_3$CHOO with Pent1b

The methyl-substituted CH$_2$OO has two conformers, *syn-* and *anti*-CH$_3$CHOO
that distinguish by the orientation of methyl group relative to the terminal oxygen
(Taatjes et al., 2013). *syn*-CH$_3$CHOO is more stable than *anti*-CH$_3$CHOO in energy
due to the existence of intramolecular hydrogen bond (Long et al., 2016). The
activation enthalpy of the interconversion between *syn*-CH$_3$CHOO and
anti-CH$_3$CHOO is up to 38.5 kcal·mol^{-1}, implying that they can treat as independent

454 species in the atmosphere (Long et al., 2016; Yin and Takahashi, 2017). A schematic

455 PES for the addition reaction 2*anti*-CH$_3$CHOO + Pent1b is presented in Fig. 3, and

456 the optimized geometries of all stationary points are shown in Fig. S5. As shown in

457 Fig. 3, the addition reaction 2*anti*-CH$_3$CHOO + Pent1b proceeds through successive

458 insertion of *anti*-CH$_3$CHOO into Pent1b leading to the formation of oligomers P4a

459 and P4b that contain *anti*-CH$_3$CHOO as chain unit. The first *anti*-CH$_3$CHOO addition

460 reaction begins with the formation of IM3a and IM3b in the entrance channel, which

461 lie -2.2 and 2.4 kcal·mol^{-1} respectively, with respect to the separate reactants. Then the

462 IM3a and IM3b transform into P3a and P3b via –OOH and –CH insertion transition

463 states TS3a and TS3b with the barriers of 5.6 and 20.3 kcal·mol^{-1}. This result shows

464 that the –OOH insertion reaction is more favorable than the –CH insertion pathway.

465 Compared with the barriers of R1a and R1b in the 2CH$_2$OO + Pent1a reaction, the

466 barriers of R3a and R3b decrease by 2.5 and 1.2 kcal·mol^{-1} when a methyl group is

467 introduced at the *anti*-position. The result reveals that the reactivity of

468 *anti*-CH$_3$CHOO is substantially higher than that of CH$_2$OO. This conclusion is further

469 supported by the findings of other studies, which have reported that *anti*-CH$_3$CHOO

470 is more reactive toward H$_2$O, SO$_2$, and H$_2$O$_2$ than CH$_2$OO (Chen et al., 2017; Taatjes

471 et al., 2013; Huang et al., 2015). Similarly, the secondary *anti*-CH$_3$CHOO addition

472 reaction starts with the formation of IM4a and IM4b in the entrance channel with the

473 0.1 and 3.7 kcal·mol^{-1} stability, followed by conversion to the final products P4a and

474 P4b through the –OOH and –CH insertion reactions R4a and R4b. The transition

475 states TS4a and TS4b lie 7.0 and 21.0 kcal·mol^{-1}, respectively, above the energies of

476 the respective intermediates IM4a and IM4b. This result again shows that the –OOH

477 insertion reaction is the most favorable channel, and the barrier increases as the

478 number of *anti*-CH$_3$CHOO is increased.

479
Figure 3. PES (ΔG and ΔE, in italics) for the 2*anti*-CH$_3$CHOO + Pent1b reaction at the M06-2X/ma-TZVP//M06-2X/6-311+G(2df,2p) level of theory

3.2.3 The reactions of *syn*-CH$_3$CHOO with Pent1c

Equivalent to the 2*anti*-CH$_3$CHOO + Pent1b reaction, the addition reaction 2*syn*-CH$_3$CHOO + Pent1c has similar transformation pathways, and is thus briefly discussed in the present study. From Fig. 4, it can be seen that the addition reaction 2*syn*-CH$_3$CHOO + Pent1c undergoes via successive insertion of *syn*-CH$_3$CHOO into Pent1c to form P6a and P6b that involve *syn*-CH$_3$CHOO as the repeating unit. The most favorable pathway is that the breakage of O$_4$-H$_6$ bond in the –OOH group of Pent1c occurs simultaneously with the insertion of first *syn*-CH$_3$CHOO into Pent1c to form P5a, followed by the insertion of secondary *syn*-CH$_3$CHOO into P5a to produce P6a. The barriers of these two –OOH insertion reactions R5a and R6a are 13.8 and 11.8 kcal·mol^{-1}, respectively, which are higher than those of R3a and R4a in the 2*anti*-CH$_3$CHOO + Pent1b system by 8.2 and 4.8 kcal·mol^{-1}, respectively. The result reveals that the reactivity of *syn*-CH$_3$CHOO is substantially lower than that of *anti*-CH$_3$CHOO. Notably, the barrier of the favorable –OOH insertion pathway decreases with increasing the number of *syn*-CH$_3$CHOO in the 2*syn*-CH$_3$CHOO + Pent1c reaction, which is contrary to the case of the 2CH$_2$OO + Pent1a and 2*anti*-CH$_3$CHOO + Pent1b reactions.
Figure 4. PES (ΔG and ΔE, in italics) for the $2syn$-CH$_3$CHOO + Pent1c reaction at the M06-2X/ma-TZVP//M06-2X/6-311+G(2df,2p) level of theory

3.2.4 The reactions of 2(CH$_3$)$_2$COO with Pent1d

The dimethyl-substituted Criegee intermediate, (CH$_3$)$_2$COO, is generated from the ozonolysis of 2,3-dimethyl-2-butene in the atmosphere (Lester and Klippenstein, 2018; Drozd et al., 2017; Long 2018). The bimolecular reaction of (CH$_3$)$_2$COO with water is not fast enough ($k < 1.5 \times 10^{-16}$ cm^3 molecule^{-1} s^{-1}), while the reaction of (CH$_3$)$_2$COO with HCOOH has a near gas kinetic limit rate ($k = 5.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) (Huang et al., 2015). The result implies that a fraction of (CH$_3$)$_2$COO may survive under high humidity environments and react with HCOOH leading to the formation of hydroperoxide ester Pent1d. A schematic PES for the addition reaction 2(CH$_3$)$_2$COO + Pent1d is plotted in Fig. 5, and the optimized geometries of all stationary points are shown in Fig. S7.

As seen in Fig. 5, the addition reaction 2(CH$_3$)$_2$COO + Pent1d starts with the formation of complexes IM7a and IM7b, which lie 1.9 and 2.4 kcal·mol^{-1}, respectively, above the energies of the separate reactants. Then they subsequently transform into products P7a and P7b through the –OOH and –CH insertion transition states TS7a and TS7b with the barriers of 12.2 and 26.4 kcal·mol^{-1}. This result again shows that the –OOH insertion reaction is favored over the –CH insertion pathway. A similar conclusion is also obtained from the secondary (CH$_3$)$_2$COO addition reaction

520   that the –OOH insertion reaction is the dominant pathway. It is of interest to compare

521   the barriers of –OOH insertion reactions in the $(CH_3)_2COO$ + Pent1d system with

522   those of the analogous reactions in other SCIs + Pent1 reactions. It can be found that

523   the barriers decrease in the order of *syn*-CH_3CHOO > $(CH_3)_2COO$ > CH_2OO >

524   *anti*-CH_3CHOO in the first-step SCIs addition reaction, while they become

525     $(CH_3)_2COO$ > *syn*-CH_3CHOO > CH_2OO > *anti*-CH_3CHOO in the second-step SCI

526   addition pathway. The result shows that the reactivity of SCIs is significantly affected

527   by the number and location of methyl substituents. A similar conclusion is also

528   obtained from the thermodynamic parameters that the exothermicity of –OOH

529   insertion reactions significantly decreases with increasing the number of methyl

530   substituents, and the exothermicity of *anti*-methyl substituted carbonyl oxide is

531   obviously higher than that of *syn*-methyl substituted carbonyl oxide.
532
533 **Figure 5.** PES (ΔG and ΔE, in italics) for the $2(CH_3)_2COO$ + Pent1d reaction at the
534 M06-2X/ma-TZVP//M06-2X/6-311+G(2df,2p) level of theory.

535 ## 3.3 The reactions of distinct SCIs with Pent1a and implications in

536 ## atmospheric chemistry

537   To further elucidate the effect of the number and location of methyl substituents

538 on the reactivity of carbonyl oxides toward hydroperoxide esters, Pent1a (also called

539 HPMF) is selected as the model compound since it is the simplest hydroperoxide ester

540 formed from the barrierless reaction of 1,4 O-H insertion of CH_2OO into HCOOH. As

mentioned above, –OOH insertion reaction in the oligomerization reactions is the most favorable pathway. Therefore, this type of reaction is merely considered in the reactions of distinct SCIs with Pent1a. The corresponding PES and the optimized geometries of all stationary points are displayed in Figs. 6 and S8, respectively. As seen in Fig. 6, each pathway starts with the formation of a pre-reactive intermediate, and then it overcomes a modest barrier to reaction. The barrier of the reaction of CH_2OO with Pent1a is calculated to be 8.1 kcal·mol^{-1}, which is higher than that of the *anti*-CH_3CHOO + Pent1a reaction by 2.5 kcal·mol^{-1}. The reason of low barrier can be explained by the NPA atomic charges, as presented in Fig. S9. As seen in Fig. S9, the charges of the central carbon atom C_1 and the terminal oxygen atom O_1 of CH_2OO are 0.186e and -0.459e, respectively, indicating that CH_2OO is indeed a zwitterion. The C_1 atom charge becomes more positive (0.393e), while the O_1 atom charge becomes more negative (-0.497e) when a methyl substituent occurs at the *anti*-position. This result suggests that the *anti*-methyl substituent enhances the characteristic of carbonyl oxides zwitterion and reduces the reaction barriers. Compared with the barrier of the CH_2OO + Pent1a reaction, the barriers increase by about 3.0 kcal·mol^{-1} when a methyl group is introduced at the *syn*-position and dimethyl substituent. Although *syn*-methyl and dimethyl substituent promote the raise of carbonyl oxides zwitterion, the steric hindrance effect and intramolecular hydrogen bond are obviously dominant for *syn*-CH_3CHOO and $(CH_3)_2COO$, that are not thus conducive to the nucleophilic attack of hydroperoxide esters. It is worth noting that the exothermicity of distinct SCIs reactions with Pent1a obviously decreases as the number of methyl group is increased, and the exothermicity of *anti*-methyl substituent is higher than that of *syn*-methyl substituent.

The rate coefficients of distinct SCIs reactions with Pent1a are calculated in the temperature range of 273-400 K as summarized in Table S7. This table shows that the rate coefficients k_{R1a} of the CH_2OO + Pent1a reaction (R1a) decrease in the range of 5.0×10^{-11} (273 K) to 5.0×10^{-12} cm^3 molecule^{-1} s^{-1} (400 K) with increasing temperature. A similar phenomenon is also observed from the rate coefficients of Pent1a reactions with *anti*-CH_3CHOO (R9), *syn*-CH_3CHOO (R10), and $(CH_3)_2COO$

571 (R11) that they exhibit a slightly negative temperature dependence. k_{R9} is several

572 orders of magnitude greater than k_{R1a}, k_{R10} and k_{R11} in the whole temperature range,

573 suggesting that the bimolecular reaction *anti*-CH$_3$CHOO + Pent1a (R9) is favored

574 kinetically. Compared with the rate coefficients of R1a, the rate coefficients increase

575 by about one order of magnitude when a methyl substituent occurs at the *anti*-position,

576 whereas the rate coefficients decrease by 1 to 2 orders of magnitude when a methyl

577 group is introduced at the *syn*-position. It should be noted that although the barrier of

578 R10 is nearly identical to that of R11, k_{R10} is 1 to 2 orders of magnitude lower than

579 k_{R11} in the entire temperature range. This is probably because the rate coefficients are

580 mediated by pre-reactive intermediates that IM11 is more stable than IM10 in energy.

581   It is of interest to assess whether the reactions of distinct SCIs with HPMF can

582 compete well with the losses to reactions with trace species (e.g., H$_2$O, HCOOH and

583 SO$_2$), because it is well known that the reactions with trace species are expected to be

584 the dominant chemical sinks for SCIs in the atmosphere (Taatjes et al., 2013; Long et

585 al., 2016). The reported concentrations of coreactant, the rate coefficients k, and the

586 effective pseudo-first-order rate constants (k_{eff} = k[coreactant]) for the reactions of

587 distinct SCIs with H$_2$O, HCOOH, SO$_2$, and HPMF are summarized in Table 2. As

588 seen in Table 2, the rate coefficient of a particular SCI reaction with trace species is

589 strongly dependent on its structure. The methyl group substitution may alter the rate

590 coefficient by several to tens of times. The atmospheric concentrations of H$_2$O,

591 HCOOH and SO$_2$ in the tropical forest environments are measured to be 3.9-6.1 $\times$

592 10^{17}, 5.0-10 $\times$ 10^{10}, and 1.7-9.0 $\times$ 10^{10} molecules cm^{-3}, respectively (Vereecken et al.,

593 2012). For the reactions of CH$_2$OO with H$_2$O, HCOOH, and SO$_2$, the experimental

594 rate coefficients are determined to be < 1.5 $\times$ 10^{-15}, [1.1 $\pm$ 0.1] $\times$ 10^{-10}, and [3.9 $\pm$ 0.7]

595 $\times$ 10^{-11} cm^3 molecule^{-1} s^{-1}, respectively (Welz et al., 2012 and 2014; Chao et al., 2015),

596 which translate into $k_{eff(CH2OO+H2O)}$, $k_{eff(CH2OO+HCOOH)}$ and $k_{eff(CH2OO+SO2)}$ of 5.9-9.2 $\times$

597 10^2, 5.5-11, and 0.7-3.5 s^{-1}, respectively. The result reveals that the reaction of

598 CH$_2$OO with H$_2$O is the most important bimolecular reaction. $k_{eff(CH2OO+HCOOH)}$ is

599 greater by a factor of 3-8 than $k_{eff(CH2OO+SO2)}$, indicating that CH$_2$OO reaction with

600 HCOOH is favored over reaction with SO$_2$. Similar conclusion is also obtained from

the results of k_{eff} for the reactions of *anti*-CH_3CHOO, *syn*-CH_3CHOO and $(CH_3)_2COO$ with H_2O, HCOOH and SO_2 that SCIs reactions with H_2O are faster than with HCOOH, which, in turn, are faster than with SO_2.

According to the results shown in the Table 2, the room temperature rate coefficient for the reaction of CH_2OO with HPMF is calculated to be 2.7×10^{-11} cm^3 molecule^{-1} s^{-1}. However, to the best of our knowledge, the atmospheric concentration of HPMF has not been reported up to now. We assume that the concentration of HPMF is approximately equal to the atmospheric concentration of SCIs, since the SCIs is the deficient reactant in the bimolecular reaction of SCIs with HCOOH. Previous model-measurement studies have estimated the surface-level SCIs concentrations in the range of 1.0×10^4 to 1.0×10^5 molecules cm^{-3} (Khan et al., 2018; Novelli et al., 2017). $k_{eff(CH2OO+HPMF)}$ is calculated to be $2.7\text{-}27 \times 10^{-7}$ s^{-1}, which is several orders of magnitude lower than $k_{eff(CH2OO+H2O)}$, $k_{eff(CH2OO+HCOOH)}$ and $k_{eff(CH2OO+SO2)}$. Similar conclusion is also obtained from the reactions of *anti*-CH_3CHOO, *syn*-CH_3CHOO and $(CH_3)_2COO$ with HPMF.

To further evaluate the relative importance of the complex SCIs reactions with coreactant, the bimolecular reactions of methyl vinyl ketone oxide (MVK-OO) with H_2O, HCOOH, SO_2, and HPMF are taken into account. MVK-OO, formed with 21 to 23% yield from the ozonolysis of isoprene, is a four carbon, asymmetric, resonance-stabilized Criegee intermediate (Barber et al., 2018). MVK-OO has four conformers, *syn-trans*-, *syn-cis*-, *anti-trans*-, and *anti-cis*- as shown in Fig. S10. Herein, *syn* and *anti* refer to the orientation of the –CH_3 group relative to the terminal oxygen of MVK-OO, whereas *cis* and *trans* refer to the orientation of the $C_8=C_9$ bond relative to the $C_1=O_2$ bond. According to the results shown in the Fig. S10, the lowest-energy conformer is *syn-trans*-MVK-OO, which is lower than *syn-cis*-, *anti-trans*-, and *anti-cis*-MVK-OO by 1.42, 2.43 and 2.69 kcal·mol^{-1}, respectively. Therefore, the lowest-energy conformer *syn-trans*-MVK-OO is selected as the model compound to study its bimolecular reactions. As shown in Table 2, the rate coefficient of H_2O reaction with *syn-trans*-MVK-OO is lower than with other SCIs by 2 to 3 orders of magnitude. The reason is likely to be that the existence of methyl and vinyl

631 groups hinders the occurrence of bimolecular reaction with water vapour.

632 Consequently, a fraction of *syn-trans*-MVK-OO may survive in the presence of water

633 vapour and react with other species. $k_{\text{eff(MVK-OO+H2O)}}$ is nearly identical to

634 $k_{\text{eff(MVK-OO+HCOOH)}}$, which is greater than $k_{\text{eff(MVK-OO+SO2)}}$, which, in turn, is greater than

635 $k_{\text{eff(MVK-OO+HPMF)}}$ when the concentration of HPMF is equal to the atmospheric

636 concentration of SCIs. Based on the above discussions, it can be concluded that the

637 reactions of SCIs with HPMF is of minor importance in the atmosphere. These

638 reactions may play a certain role in the formation and growth of organic new particle

639 in some regions where low concentration of water vapour and high concentration of

640 hydroperoxide esters occur.

3.4 Vapour pressure and volatility of the adduct products

The saturated vapour pressure (P^0) of the adduct products formed from the successive reactions of SCIs with HCOOH is estimated by using the EVAPORATION method proposed by Compernolle et al. (2011), and the room temperature results are

summarized in Table S8. This table shows that the P^0 of the adduct products decreases significantly as the number of SCIs is increased. Notably, the P^0 of the adduct products decreases when the size of SCIs increases. For example, the P^0 of the adduct product $HC(O)O(CH_2OO)_3H$ in the $nCH_2OO + HCOOH$ reaction is estimated to be 3.41×10^{-5} atm, which is greater than those of the corresponding adduct products in the n$anti$-$CH_3CHOO + HCOOH$ (4.73×10^{-6} atm), nsyn-$CH_3CHOO + HCOOH$ (4.73×10^{-6} atm), and $n(CH_3)_2COO + HCOOH$ (1.03×10^{-6} atm) reactions by 7.21, 7.21 and 33.11 times, respectively.

A classify scheme of various organic compounds is based on their volatility, as presented by Donahue et al. (2012) The volatility of organic compounds is described by their effective saturation concentrations. The saturated concentrations (c^0) of the adduct products formed from the successive reactions of SCIs with HCOOH are listed in Table S8. As shown in Table S8, the c^0 of the adduct products decrease significantly as the number of SCIs is increased. It deserves mentioning that the c^0 of the adduct products decrease with increasing the size of SCIs. For the $nCH_2OO + HCOOH$ reaction, the c^0 of the adduct products are estimated to be 1.03×10^8 (n=1), 5.42×10^6 (n=2), 2.53×10^5 (n=3), 1.11×10^4 (n=4) and 4.67×10^2 (n=5) ug/m^3, respectively. According to the Volatility Basis Set (VBS) of organic compounds (Donahue et al., 2012), the adduct products belong to volatile organic compounds (VOC, $c^0 > 3 \times 10^6$ ug/m^3) when the number of SCIs is less than or equal to two, while they belong to intermediate volatility organic compounds (IVOC, $300 < c^0 < 3 \times 10^6$ ug/m^3) when the number of SCIs is greater than or equal to three. Similarly, the adduct products in the n$anti$-$CH_3CHOO + HCOOH$, nsyn-$CH_3CHOO + HCOOH$, and $n(CH_3)_2COO + HCOOH$ reactions belong to IVOC when the number of SCIs ranges from 2 to 4, whereas they belong to semivolatile organic compounds (SVOC, $0.3 < c^0 < 300$ ug/m^3) when the number of SCIs is equal to 5. Based on the above discussions, it can be concluded that the volatility of the adduct products is significantly affected by the number and size of SCIs in the successive reaction of SCIs with HCOOH. The formed adduct products may participate in the formation and growth processes of organic new particle in the atmosphere.

4. Conclusions

The oligomerization reaction mechanism and kinetics of Criegee intermediates reactions with their respective hydroperoxide esters as well as HPMF are investigated using quantum chemical calculations and kinetics modeling methods. The main conclusion is summarized as follows.

(a) For the initiation reactions of distinct SCIs with HCOOH, the barrierless 1,4 O-H insertion reaction leading to the formation of hydroperoxide esters is the most favorable pathway. The exothermicity of distinct SCIs reactions with HCOOH decreases when the number of methyl groups increases, and the exothermicity of the $anti$-CH$_3$CHOO + HCOOH reaction is higher than that of the syn-CH$_3$CHOO + HCOOH system.

(b) The addition reactions of SCIs with hydroperoxide esters proceed through successive insertion of SCIs into hydroperoxide ester to form oligomers that involve SCIs as the repeating unit. These oligomerization reactions are strongly exthermoic and spontaneous. The exothermicity of oligomerization reactions significantly decreases when the number of methyl substituents increases, and the exothermicity of $anti$-methyl substituted carbonyl oxides is higher than that of syn-methyl substituted carbonyl oxides.

(c) The –OOH insertion reaction is favored over the –CH insertion pathway in the SCIs oligomerization reactions, and the barrier heights increase with increasing the number of SCIs added to the oligomer except syn-CH$_3$CHOO. The barrier of -OOH insertion pathway shows a dramatic decrease when a methyl substituent occurs at the $anti$-position, while it reveals a significant increase when a methyl group is introduced at the syn-position and dimethyl substituent.

(d) Compared with the barrier of CH$_2$OO reaction with HPMF (8.1 kcal·mol^{-1}), the barrier decreases by 2.5 kcal·mol^{-1} when a methyl substituent occurs at the $anti$-position, while the barrier increases by about 3.0 kcal·mol^{-1} when a methyl group is introduced at the syn-position and dimethyl substituent. The rate coefficients increase by about one order of magnitude when a methyl substituent occurs at the

anti-position, whereas the rate coefficients decrease by 1 to 2 orders of magnitude when a methyl group is introduced at the syn-position compared to the rate coefficients of the CH_2OO + HPMF reaction.

(e) In the tropical forest environments, the effective pseudo-first-order rate constants for the reactions of distinct SCIs with HPMF ($k_{eff(SCIs+HPMF)}$) are several orders of magnitude lower than those for the reactions of distinct SCIs with H_2O ($k_{eff(SCIs+H2O)}$), HCOOH ($k_{eff(SCIs+HCOOH)}$) and SO_2 ($k_{eff(SCIs+SO2)}$). $k_{eff(SCIs+H2O)}$ is greater than $k_{eff(SCIs+HCOOH)}$, which, in turn, is greater than $k_{eff(SCIs+SO2)}$.

(f) The saturated vapour pressure and saturated concentration of the adduct products formed from the successive reactions of SCIs with HCOOH decrease significantly as the number of SCIs is increased. The adduct products in the nCH_2OO + HCOOH reactions belong to IVOC when the number of SCIs is greater than or equal to 3. The adduct products in the n$anti$-CH_3CHOO + HCOOH, nsyn-CH_3CHOO + HCOOH, and n$(CH_3)_2COO$ + HCOOH reactions belong to IVOC when the number of SCIs ranges from 2 to 4, whereas they belong to SVOC when the number of SCIs is equal to 5.

Data availability

The data are accessible by contacting the corresponding author (huangyu@ieecas.cn).

Supplement

The following information is provided in the Supplement: The electronic energy ($\Delta E^{\neq}$) and Gibbs free energy ($\Delta G^{\neq}$) barriers for the initiation reactions of distinct SCIs with HCOOH predicted at different levels; Enthalpies of formation for the various carbonyl oxides and hydroperoxide esters; Rate coefficients of initiation reactions of distinct SCIs with HCOOH; Rate coefficients of distinct SCIs reactions with HPMF; Predicted saturated vapour pressure (P^0) and saturated concentrations (c^0) for the adduct products; Electronic potential energy along the O-H and C-O distance

calculated by the M06-2X/6-311+G(2df,2p) method for the barrierless 1,4-insertion reactions; Natural bond orbital (NBO) analysis of the donor-acceptor orbitals involved in the TS1a; The NPA charges of different atoms in the distinct SCIs; Optimized geometries of all the stationary points.

Author contribution

LC designed the study. LC and YH wrote the paper. LC performed theoretical calculation. YX, ZJ, and WW analyzed the data. All authors reviewed and commented on the paper.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgments

We thank Dr. Makroni Lily for valuable discussions on the barrierless 1,4 O-H insertion reactions.
