**Abstract.** The representation of aerosol-cloud interaction (ACI) and its impacts in the current climate or  
20 weather model remains a challenge, especially for the severely polluted region with high aerosol  
concentration, which is even more important and worthy of study. Here, ACI is first implemented in the  
atmospheric chemistry model GRAPES\_Meso5.1/CUACE by allowing for real-time aerosol activation  
in the Thompson cloud microphysics scheme. Two experiments are conducted focusing on a haze  
pollution case with coexisted high aerosol and stratus cloud over the Jing-Jin-Ji region in China to  
25 investigate the impact of the ACI on the mesoscale numerical weather prediction (NWP). Study results  
show that the ACI increases cloud droplets number concentration, water mixing ratio, liquid water path  
(CLWP), and optical thickness (COT), as a result, improving the underestimated CLWP and COT  
(reducing the mean bias by 21% and 37%, respectively) over a certain subarea by the model without  
ACI. Cooling in temperature at daytime below 950 hPa occurs due to ACI, which can reduce the mean  
30 bias of 2 m temperature at daytime by up to 14% ( $\sim 0.6$  °C) in the subarea with the greatest change in  
CLWP and COT. The 24 h cumulative precipitation in this subarea corresponding to moderate rainfall  
events increases with reduced the mean bias by 18%, depending on the enhanced melting of the snow  
by more cloud droplets. In other areas or periods with a slight change in CLWP and COT, the impact of  
the ACI on NWP is not significant, suggesting the inhomogeneity of the ACI. This study demonstrates  
35 the critical role of the ACI in the current NWP model over the severely polluted region and the  
complexity of the ACI effect.

## 1 Introduction

Cloud covers approximately 70% of the Earth's surface (Ding et al., 2005; Mao et al., 2019), which plays key roles in Earth's radiation budget, hydrologic cycle, and chemical reactions of gaseous and particulate materials (Ramanathan et al., 2005; Rosenfeld et al., 2014). Accurate simulation of cloud in the numerical weather prediction (NWP) model is one of the most important elements in the weather forecast (Seifert et al., 2012; Makar et al., 2015; Wang et al., 2014; Xu et al., 2022).

Aerosol is a key factor for cloud formation—no aerosol, no cloud (Andreae and Rosenfeld, 2008; Pruppacher and Klett, 1980; McFiggans et al., 2006). The influence of aerosol on cloud is mainly reflected in two aspects: under the conditions of holding liquid water content constant, more cloud condensation nuclei (CCN) produce smaller but more cloud droplets, causing the albedo of the cloud to be larger (Twomey, 1977); the smaller cloud droplets reduce the collision rate, changing the liquid water content and thickness of the cloud and prolonging of the cloud lifetime (Albrecht, 1989). Aerosol-cloud interaction (ACI) has been the largest uncertainty factor in the climate prediction and weather forecast (Quaas, 2015; Myhre et al., 2013; Makar et al., 2015). One of the key potential challenges is to define the ability of aerosol to act as cloud droplets (Chang et al., 2021; Rosenfeld et al., 2019; Che et al., 2017; Sun and Ariya, 2006).

In the current NWP model, the cloud microphysics scheme determines the evolution of hydrometeors (Listowski and Lachlan-Cope, 2017). However, the number concentration of cloud droplets in most cloud microphysics schemes is usually set to be constant (i.e., space-time invariant) (Thompson et al., 2008; Thompson et al., 2004; Hong and Lim, 2006; Morrison et al., 2009), which ignores the impact of aerosol on the cloud. Even in schemes that can predict the number concentration of cloud droplets, such as the WDM6 scheme (the initial CCN is a constant) (Lim and Hong, 2010) and Thompson scheme (a preset aerosol emission) (Thompson and Eidhammer, 2014), the impact of aerosol is still not fully considered. According to previous studies, there are huge differences in the anthropogenic aerosol emission globally (e.g., higher aerosol loading over northern India and eastern China) (Che et al., 2015), and the response of cloud physical properties to aerosol is obvious (Miltenberger et al., 2018; Lawand et al., 2022; McCoy et al., 2018; Zheng et al., 2018b). The lack of anthropogenic aerosol emission, bringing large simulation errors, cannot meet the requirements of weather forecast by the NWP model, especially in precipitation and temperature predictions (Su and Fung, 2018; Zhang et al., 2015; Huang and Ding, 2021). For example, in the Global Forecast System (GFS) model without aerosol feedback, the simulation of 2 m temperature showed larger errors when heavy aerosol pollution or thick cloud cover occurs (Huang and Ding, 2021).

Recognizing the importance of aerosol changes to the cloud, weather, chemistry, etc., many studies have incorporated ACI effects into the NWP models to evaluate the impact of the ACI (Zhao et al., 2017; Zhou et al., 2016; Miltenberger et al., 2018; Wong, 2012; Makar et al., 2015). The study results show that the ACI significantly increases the number concentration of cloud droplets and liquid water content during the selected study period and further leads to a decrease in surface downward short-wave radiation (SDSR), boundary layer height, and surface temperature (Makar et al., 2015; Zhang et al., 2015; Zhang et al., 2010). As a result, the simulated errors in precipitation and temperature are reduced (Zhou et al., 2016). In addition, a recent study using the two-way coupled

Weather Research and Forecasting and Community Multi-scale Air Quality (WRF-CMAQ) model to conduct long-term (2008-2012) simulations in the contiguous US indicates that the main simulated meteorological factors (e.g., temperature, precipitation, wind speed) and air pollutants (e.g., ozone, sulfate, nitrate) show improved performance compared to the original model (Wang et al., 2021). These studies further prove the critical role of the ACI in the NWP model, yet the ability to consider the ACI effect in weather forecast is still poor. Meanwhile, due to the predominantly extremely inhomogeneous ACI in time and space, especially under haze pollution conditions, the significance of the ACI effect may not be fully realized in long-term or large-scale studies, thus putting its focus on the weather scale NWP in severe aerosol polluted Jing-Jin-Ji in China is essential and meaningful.

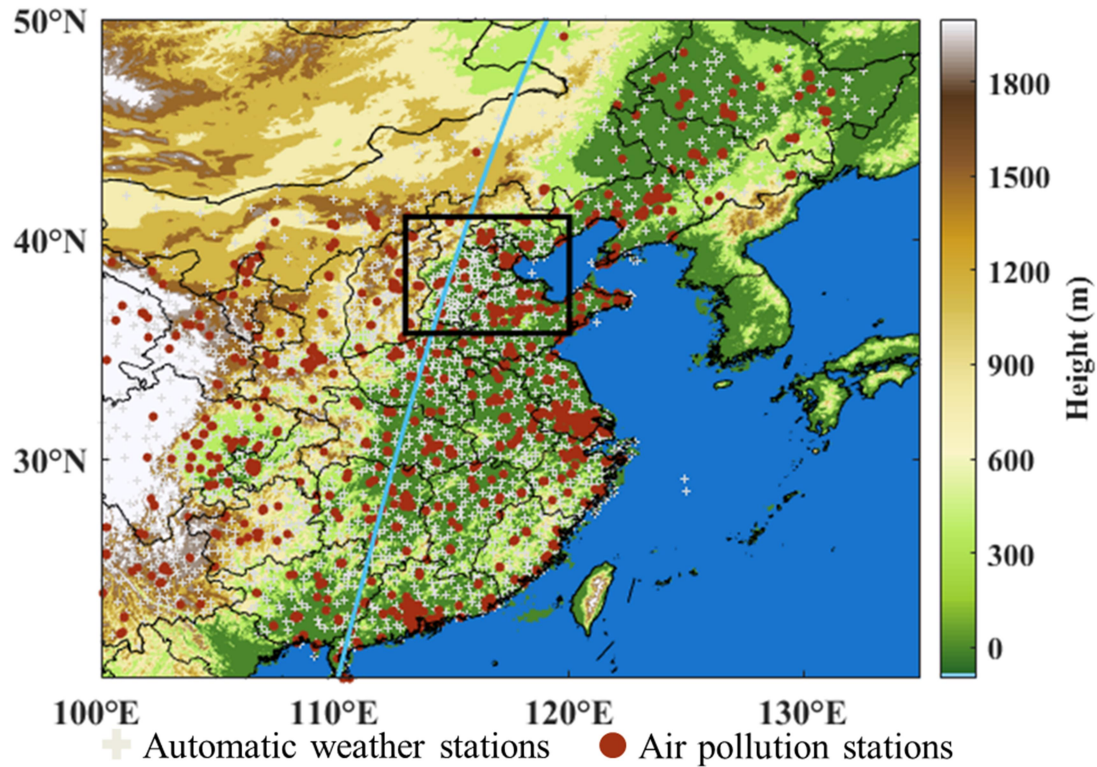

In this paper, the real-time ACI is first coupled into the atmospheric chemistry model GRAPES\_Meso5.1/CUACE for the study of the impact of ACI on the cloud, temperature, and precipitation predictions under haze pollution conditions in Jing-Jin-Ji in China. A representative case, the haze pollution episode from 4 to 8 January 2017 with coexisted severe aerosol pollution and stratus cloud, is selected to be as the research object. Through this short-term case study, the operating mechanism of ACI in the current model and the spatiotemporal inhomogeneous ACI effect under haze pollution conditions can be clearly understood.

## 2 Materials and Methods

### 2.1 Data used

Hourly PM<sub>2.5</sub> observation data ( $\mu\text{g m}^{-3}$ ) are provided by more than 1300 air pollution stations (Figure 1) from the Chinese Ministry of Ecology and Environment. Hourly surface meteorological observation data come from the automatic weather stations (Figure 1) of the China Meteorological Administration (CMA), including temperature ( $^{\circ}\text{C}$ ) and precipitation (mm). Daily aerosol optical depth (AOD), cloud top pressure (CTP, hPa), cloud optical thickness (COT), cloud liquid water path (CLWP,  $\text{g m}^{-2}$ ), and cloud fraction (CF, %) data are from the Suomi National Polar-orbiting Partnership (SNPP) Visible Infrared Imaging Radiometer Suite (VIIRS) NASA Level-3 (L3) aerosol and cloud properties continuity product with a spatial resolution  $1^{\circ}$  ([https://ladsweb.modaps.eosdis.nasa.gov/search/order/1/CLDPROP\\_D3\\_VIIRS\\_SNPP--5111/](https://ladsweb.modaps.eosdis.nasa.gov/search/order/1/CLDPROP_D3_VIIRS_SNPP--5111/)). The number concentration of cloud droplets ( $/\text{cm}^3$ ) can be derived based on CLWP, COT, and CF from previous studies (Bennartz, 2007; Pawlowska and Brenguier, 2000). SDSR data ( $\text{W m}^{-2}$ ) are derived from the Clouds and the Earth's Radiant Energy System (CERES) project L3 product, which provides satellite-based observations of Earth's radiation budget (ERB) and cloud with a spatial resolution  $1^{\circ}$  ([https://asdc.larc.nasa.gov/data/CERES/SYN1deg-1Hour/Terra-NPP\\_Edition1A/2017/01/](https://asdc.larc.nasa.gov/data/CERES/SYN1deg-1Hour/Terra-NPP_Edition1A/2017/01/)). The vertical profiles of aerosol and cloud data are provided by the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) Level 2 (L2) vertical feature mask (VFM) data product ([https://asdc.larc.nasa.gov/data/CALIPSO/LID\\_L2\\_VFM-Standard-V4-20/2017/01/](https://asdc.larc.nasa.gov/data/CALIPSO/LID_L2_VFM-Standard-V4-20/2017/01/)). All data ranges are from 4 to 8 January 2017. National Centers for Environmental Prediction (NCEP) Final analysis (FNLs) data with  $0.25^{\circ}$  horizontal resolution and 6 h interval (<https://rda.ucar.edu/datasets/ds083.3/>) are used as meteorological boundary conditions and initial fields in the model. The anthropogenic emission

data entered into the model are the Multi-resolution Emission Inventory for China (MEIC) of Tsinghua University in December 2016, which covers more than 700 anthropogenic emission sources on China's mainland (Li et al., 2014; Zheng et al., 2018a; Li et al., 2017).

**Figure 1: The map and topographic height of the simulated domain. The turquoise line represents a part of the CALIPSO satellite orbit tracks at 18:12 on 7 January 2017, the black rectangle represents the location of Jing-Jin-Ji, the gray cross signs are the automatic weather stations, and the dark red dots are the air pollution stations.**

## 2.2 Model introduction

The updated operational atmospheric chemistry model GRAPES\_Meso5.1/CUACE developed by CMA mainly includes four modules: Pre-processing and Quality control, Standard initialization, assimilating forecasting, and Post-processing (Chen, 2006; Chen et al., 2008; Zhang and Shen, 2008; Wang et al., 2010). The dynamic frame includes an Arakawa C staggered grid, a semi-implicit and semi-Lagrangian scheme for temporal and advection discretion, and a height-based terrain-following coordinate. The selected physical-chemistry options include RRTM long-wave radiation (Mlawer et al., 1997), Thompson cloud microphysics (Thompson et al., 2008), Goddard short-wave radiation (Chou et al., 1998), Noah land-surface (Chen and Dudhia, 2001), MRF planetary boundary layer (Hong and Pan, 1996), KFeta cumulus cloud (Kain and Fritsch, 1993), SFCLAY surface-layer (Pleim, 2007), RADM II gas-phase chemistry (Stockwell et al., 1990), and CUACE aerosol (Gong and Zhang, 2008; Zhou et al., 2012) schemes. In the RADM II gas-phase chemistry scheme, 63 gas species through 21 photochemical reactions and 136 gas-phase reactions participate in the calculations. In the CUACE aerosol scheme (Wang et al., 2010; Gong and Zhang, 2008), 7 types of aerosol (sea salt (SS), sand/dust, black carbon, organic carbon (OC), sulfate (SF), nitrate (NT), and ammonium salt (AM)) are calculated by

hygroscopic growth, dry and wet depositions, condensation, etc. These aerosols (except for AM) are divided into 12 bins with diameter ranges of 0.01-40.96  $\mu\text{m}$ .

The simulated domain of the model covers eastern China (100°E-135°E, 20°N-50°N) (Figure 1) with a horizontal resolution of  $0.1^\circ \times 0.1^\circ$  and the 49 vertical layers from the ground (about 52 m) to ~31 km. The whole simulation period is from 30 December 2016 to 10 January 2017 with 72 h as a looping experiment. The results of the first 72 h (30 December 2016 to 1 January 2017) are regarded as the spin-up time to keep the model stable and to avoid the effects of the chemical initial fields. The study period is from 4 to 8 January 2017 (from cloud formation to dissipation in Jing-Jin-Ji) in this paper.

### 2.3 Implementation of ACI in the model

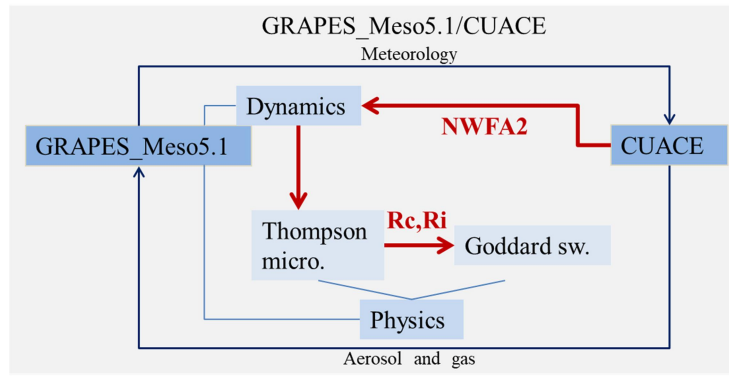

To account for the indirect effect of aerosol, we first update the Thompson cloud microphysics scheme from the original version in the model to the “aerosol-aware” version based on previous studies (Thompson and Eidhammer, 2014; Thompson et al., 2008). The calculation of supersaturation degree is detailed in Text S1.1 in the Supplement. The new Thompson cloud microphysics scheme includes the activation of water-friendly aerosol to cloud droplets (Text S1.2 in the Supplement) and the ice nucleation (Text S1.3 in the Supplement). The source of water-friendly aerosol derives from the preset aerosol emission based on the climatological mean state. Second, the assumed aerosol concentration is replaced by real-time simulated aerosol concentration by CUACE. Water-friendly aerosol number concentration (/kg) required by the activation in the cloud microphysics scheme are calculated by aerosol mass concentration at each grid point according to equations (1), (2), and (3):

$$m_{\text{num}} = \frac{4}{3} * \pi * r_{\text{num}}^3 * (\rho_{\text{num}}) \quad (1),$$

$$N(i, k, j, \text{num}) = \text{tracer}(i, k, j, \text{num}) / m_{\text{num}} \quad (2),$$

$$\text{NWFA2}(i, k, j) = \sum_{\text{num}=1}^{49} N(i, k, j, \text{num}) \quad (3).$$

Here, the  $m$  is the aerosol mass (kg), the  $\text{num}$  is the tracer number from 1 to 49, the  $r$  is the mean radius ( $\mu\text{m}$ ), the  $\rho$  is the aerosol density ( $\text{g cm}^{-3}$ ), the  $\text{tracer}$  is the aerosol mass concentration (kg/kg), the  $N$  is the aerosol number concentration (/kg), and the NWFA2 is the total water-friendly aerosol number concentration (/kg).  $i$ ,  $j$ , and  $k$  represent the grid point. The  $\text{tracer}$  is the prognostic variable. The  $\text{num}$ ,  $r$ , and  $\rho$  are specified in Table S1. The controversial black carbon and sand/dust in the activation are ignored in this study. The calculated NWFA2 is input into the cloud microphysics scheme instead of the original assumed aerosol number concentration (Figure 2). The wet scavenging of aerosol and evaporation of cloud droplets are described in Text S1.4 in the Supplement. Finally, the cloud physical parameters (cloud water and cloud ice effective radius ( $R_c$  and  $R_i$ )) from the Thompson scheme are input into the Goddard short-wave radiation scheme for radiation calculation and ACI is then completed in the current GRAPES\_Meso5.1/CUACE model (Figure 2).

**Figure 2: Diagram of Aerosol cloud interaction in GRAPES\_Meso5.1/CUACE model.**

## 2.4 The Case Description

175 This case is a haze pollution episode (from 4 to 8 January 2017) over Jing-Jin-Ji accompanied by the appearance of stratus cloud, which demonstrates the rationality and pertinence of this simulated study. During this episode, the peak mass concentration of  $\text{PM}_{2.5}$  exceeds  $200 \mu\text{g m}^{-3}$  (i.e., heavy aerosol pollution occurs in Jing-Jin-Ji) (Figure S1(a)). Figure S2(b) shows the vertical distribution of aerosol and cloud layers in Jing-Jin-Ji at 18:12 on 7 January 2017. The aerosol layer is partly overlapped with  
180 the cloud layer, suggesting the potentiality of aerosol as CCN and ACI in this region. Different types of cloud can be identified by CTP and COT from satellite data, including stratus, cumulus, cirrus, etc., according to the International Satellite Cloud Climatology Project (ISCCP) (Rossow and Schiffer, 1991; Hahn et al., 2001). Figure S2(a) shows the daily mean CTP and COT in Jing-Jin-Ji from 4 to 8 January 2017. It can be confirmed that the types of cloud over Jing-Jin-Ji are basically stratus cloud (except for  
185 4 January 2017) with lower cloud base height.

## 2.5 Experimental Design

To investigate the ACI and its feedback on the simulated cloud, temperature, and precipitation in the current model, we conduct two experiments (E1 and E2) as shown in Table 1. The E1 experiment is the control experiment with the constant  $100 \text{ cm}^{-3}$  number concentration of cloud droplets, which is the  
190 default setting in the Thompson cloud microphysics scheme. The E2 experiment includes the ACI combined with real-time aerosol activation. The difference of simulations between the E2 and E1 experiment can be attributed to the impact of ACI on current NWP predictions.

**Table 1: The setup of two experiments in the model.**

Experiment	Description
E1	Model run without ACI
E2	Model run with ACI

195

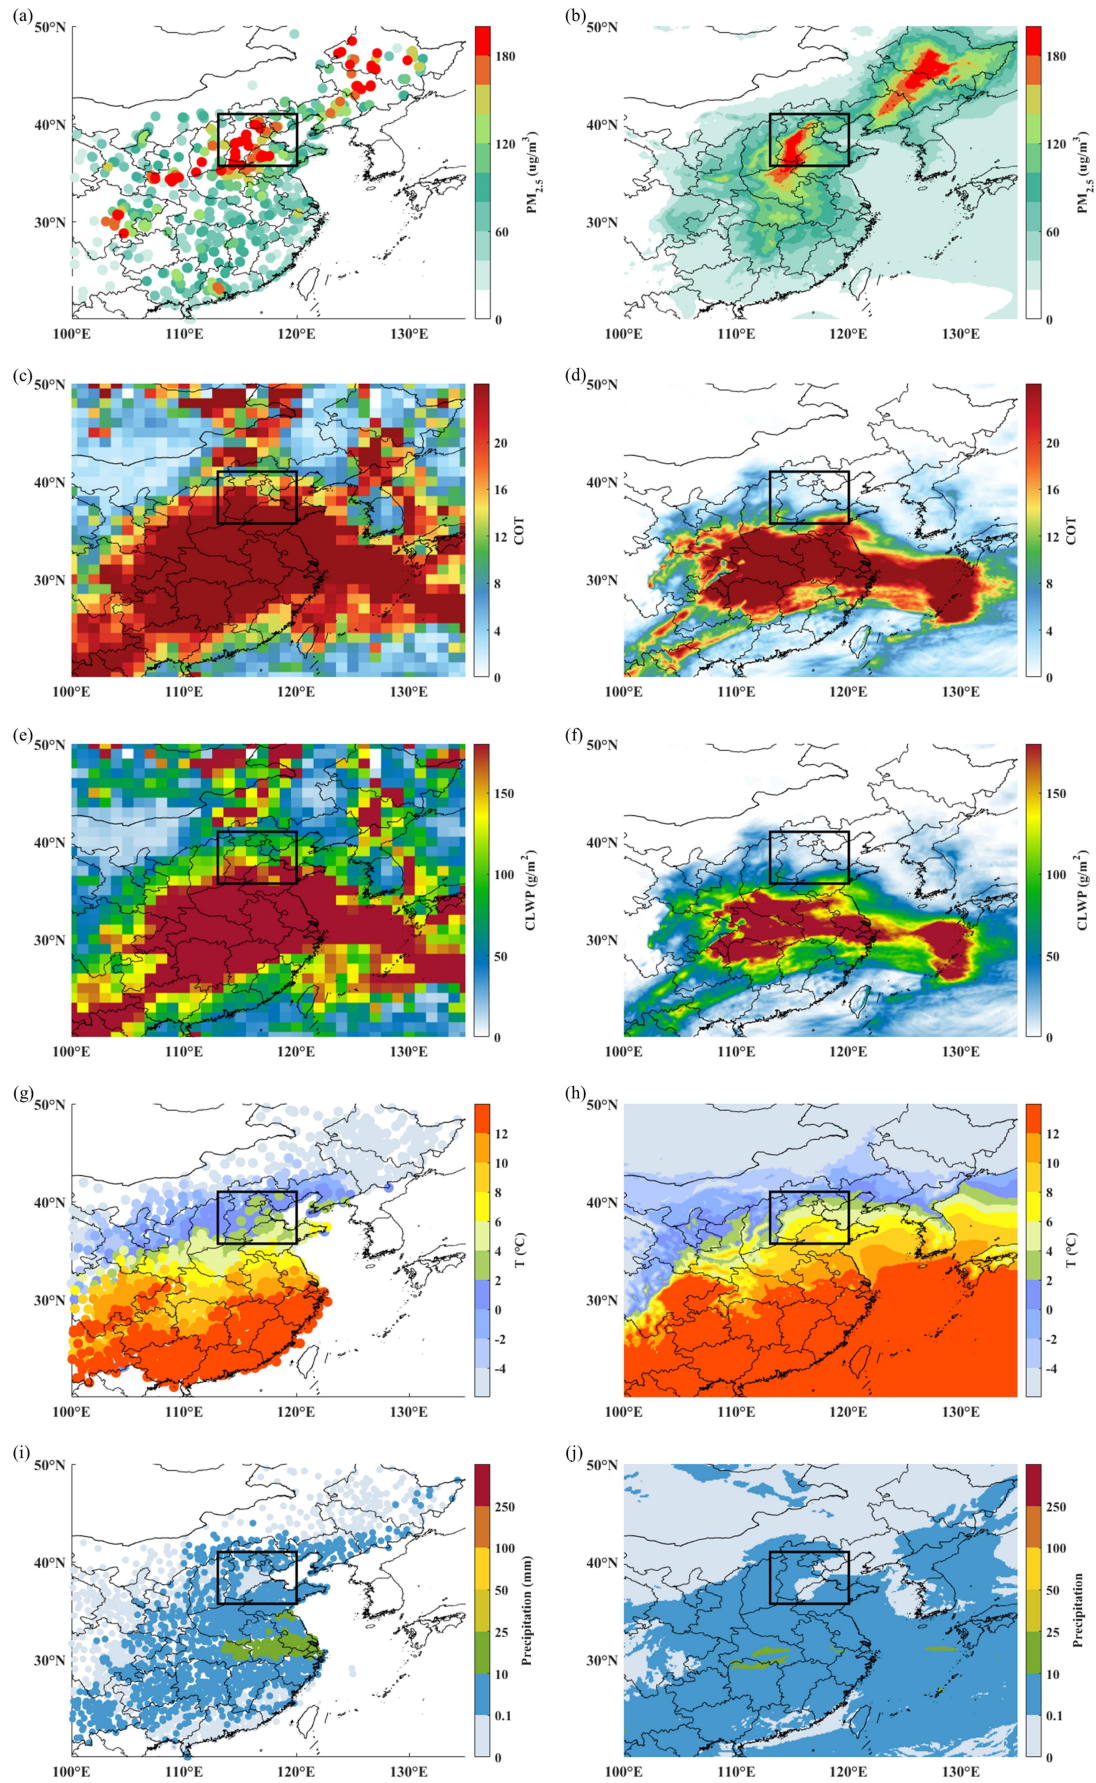

## 3 Results

### 3.1 Model Evaluation

Figure 3(a) and (b) show the spatial distributions of observed and simulated (E1 experiment) mean  $PM_{2.5}$  mass concentration during the whole study period, both of which indicate that there is a high-value center of  $PM_{2.5}$  mass concentration in the southwest of Jing-Jin-Ji. However, the simulations in the southeast of Jing-Jin-Ji are lower than the observations. The model also captures the observed temporal variation of  $PM_{2.5}$  mass concentration, including the rising and falling period, and the correlation coefficient (R) is 0.75 (Figure. S1(a)). To further evaluate the aerosol information at the boundary layer height, Figure S1(b) and (c) show the spatial distributions of the time-average AOD from the E1 experiment and VIIRS. The simulated AOD is consistent with the VIIRS, both exhibiting a high-value center of AOD similar to  $PM_{2.5}$  mass concentration. All these results indicate that the model can accurately reproduce the aerosol pollution level reasonably in Jing-Jin-Ji.

In addition to ensuring reasonable aerosol simulations, it is necessary to have a brief understanding of simulated performance in meteorological factors from the current model without the ACI (the E1 experiment). As shown in Figure 3(c-j), the model basically reproduces the location of the large-scale stratus cloud and accurately simulates the distributions and magnitudes of mean 2 m temperature at daytime (i.e., from 08:00 to 16:00 local time) and 24 h cumulative precipitation in China. However, compared with VIIRS, the simulated mean COT and CLWP in Jing-Jin-Ji for 5 days (JJJ-5d) show obvious negative bias (i.e.,  $\text{bias} = X_{\text{sim}} - X_{\text{obs}}$  where  $X_{\text{sim}}$  and  $X_{\text{obs}}$  represent the simulations and observations) (-18.4 and -104.2  $g\ m^{-2}$ ). Besides, the mean bias of the 2 m temperature at daytime and 24 h cumulative precipitation for JJJ-5d are 3.2 °C and -0.11 mm against observations. It can be seen that 2 m temperature at daytime is overestimated and 24 h cumulative precipitation is underestimated by the E1 experiment without ACI, especially in the southern part of Jing-Jin-Ji with more cloud cover.

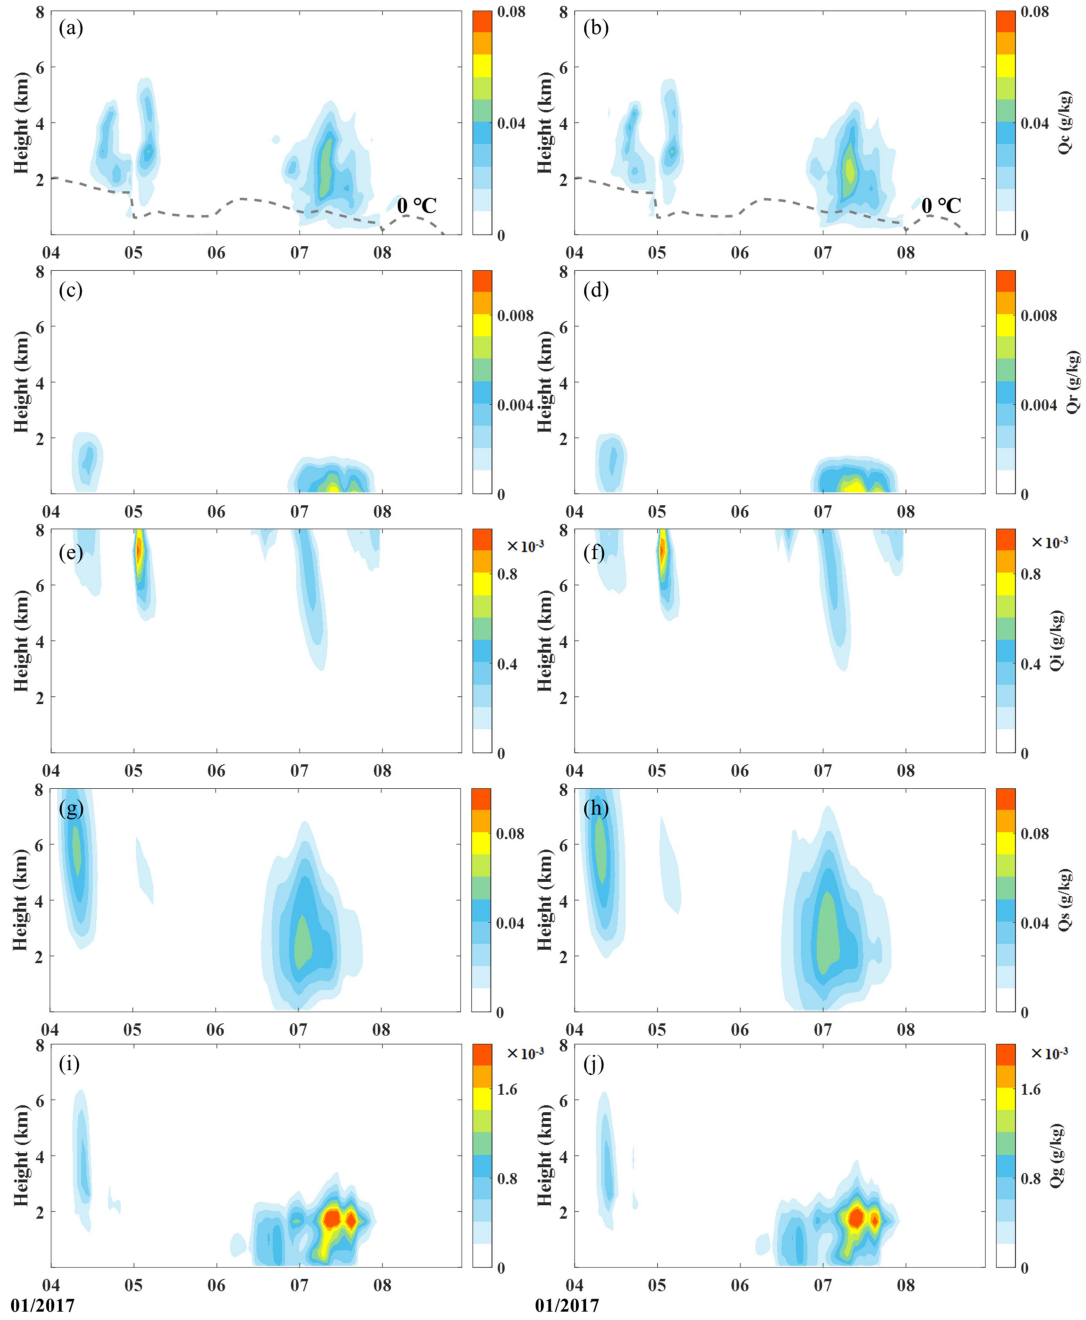

220 **Figure 3: Comparisons of observed (the left column) and simulated by the E1 experiment (the right column)**

mean (a) and (b) PM<sub>2.5</sub> mass concentration, (c) and (d) COT, (e) and (f) CLWP, (g) and (h) 2 m temperature at daytime, and (i) and (j) 24 h cumulative precipitation from 4 to 8 January 2017. The black rectangle represents the location of Jing-Jin-Ji.

### 3.2 The impact of ACI on cloud

When the ACI is activated in the model (i.e. the E2 experiment), there are more generated cloud droplets and more reasonable distributions of cloud droplets (Figure S3) compared with the constant number concentration of cloud droplets ( $100 \text{ cm}^{-3}$ ) in the E1 experiment. Furthermore, the  $R_c$  decreases (Figure omitted) due to competitive growth. Such changes have impacts on hydrometeors in the cloud (Lohmann and Feichter, 2005). Figure 4 shows the temporal variation of the regional mean hydrometeors mixing ratio in Jing-Jin-Ji from the E1 and E2 experiments. On the whole, the cloud top height is above the  $0^\circ\text{C}$  isotherm and the magnitude of snow mixing ratio ( $Q_s$ ) is relatively larger, indicating that this cloud system is the mixed-phase cloud with more significant cold cloud processes. Taking a day (7 January 2017) as an example (Figure 4 and S4), compared with the E1 experiment, we find that the cloud water mixing ratio ( $Q_c$ ) increases significantly (the maximum increase in the vertical direction is more than  $4 \times 10^{-3} \text{ g kg}^{-1}$ ) in the E2 experiment. This is mainly due to the smaller  $R_c$  and lower auto-conversion of cloud water to form rain. Typically, during the warm cloud process, inhibited auto-conversion of cloud water may reduce the rainwater mixing ratio ( $Q_r$ ). However,  $Q_r$  increases in the E2 experiment, which is mainly related to the increased rain water from enhanced snow melting. This phenomenon also reflects the characteristics of the cold cloud processes. To further confirm the changes in snow, we find a significant increase of  $Q_s$  in the mid-troposphere, which promotes the melting of the snow to form rain. The increase of  $Q_s$  in the E2 experiment is mainly because the ACI increases the supercooled cloud water in the mid-troposphere and may promote the riming growth process. The  $Q_s$ , in addition, decreases in the lower troposphere, which may be related to the melting of snow to form rain. The changes in ice mixing ratio ( $Q_i$ ) and graupel mixing ratio ( $Q_g$ ) are relatively small. It should be noted that, in the E2 experiment, additional cloud fields do not generate in the original area without cloud (the E1 experiment), even though the ACI is activated. For example, on 5 January 2017 (Figure 4), the original model do not reproduce the fact that VIIRS indicated the presence of cloud in Jing-Jin-Ji and the ACI effect also do not improve this phenomenon, indicating the limitations of the ACI. More detailed studies are needed in the future.

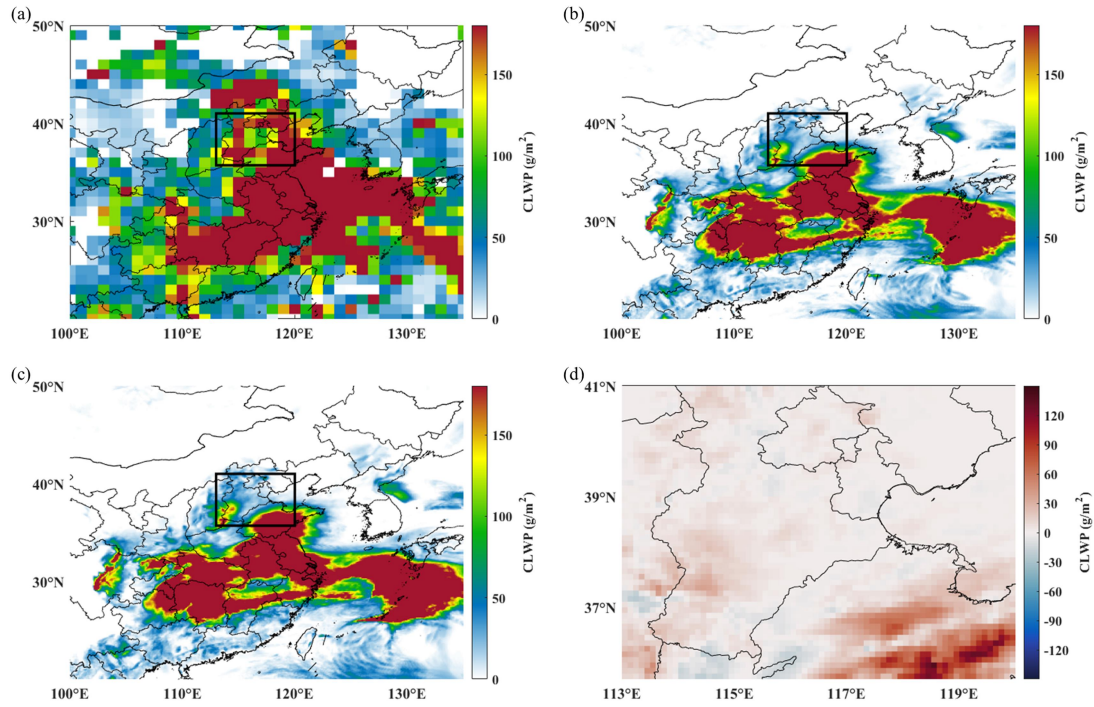

**Figure 4: The vertical distribution of regional mean hydrometeors mixing ratio ( $Q_c$ ,  $Q_r$ ,  $Q_i$ ,  $Q_s$ , and  $Q_g$ ) in Jing-Jin-Ji from the (the left column) E1 and (the right column) E2 experiment.**

255

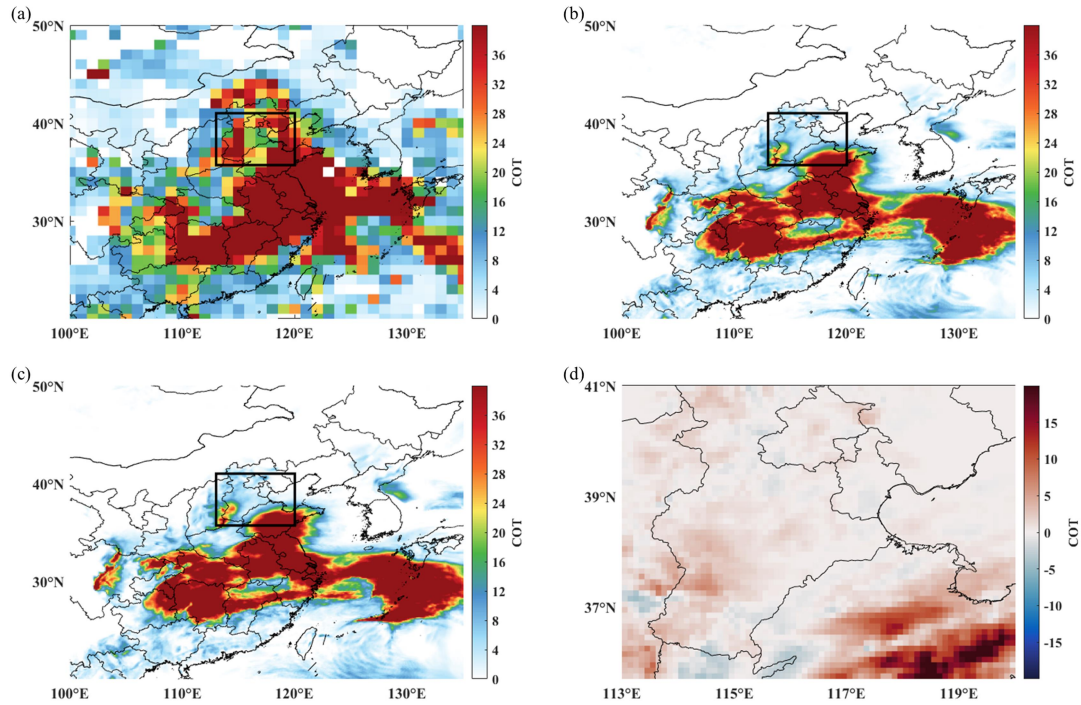

The cloud macroscopic characteristics can be affected accordingly. The ACI increases simulated CLWP and COT, both of which are more consistent with satellite observations with slightly reduced the mean bias for JJJ-5d by 2% and 2%, respectively (Figure 10(a) and (b)). In particular, on 7 January 2017, the daily mean CLWP and COT increase significantly in most areas of Jing-Jin-Ji due to the ACI (Figure 5 and 6). The maximum values of increase are  $137.7 \text{ g m}^{-2}$  and 25.1, respectively. This increase reduces the regional mean bias of the E1 experiment by 7% (from  $-163.4$  to  $-151.8 \text{ g m}^{-2}$ ) for CLWP and 7% (from  $-22.3$  to  $-20.7$ ) for COT against the VIIRS. In addition, it can be seen that the impact of the ACI

260

on CLWP and COT are significantly different in various regions of Jing-Jin-Ji. We explain this phenomenon in Section 3.4.

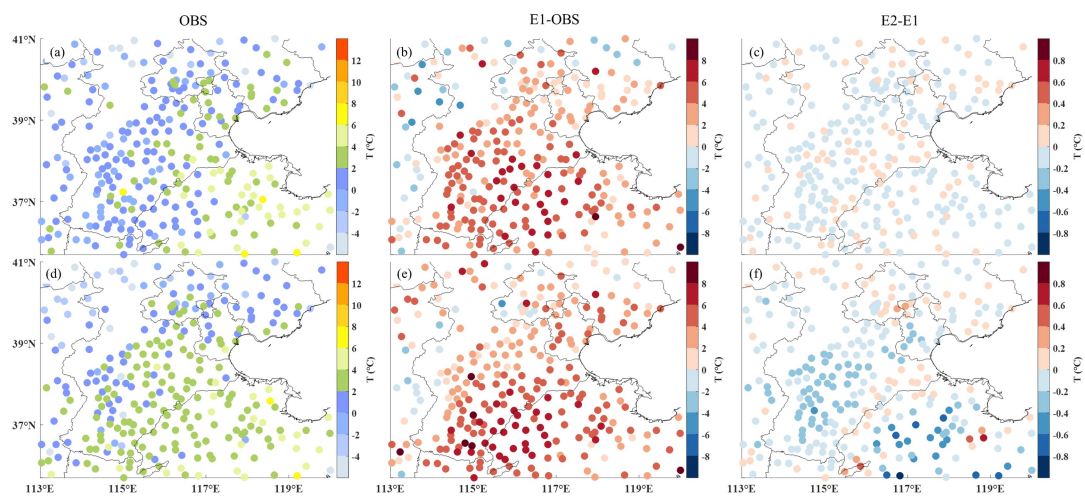

**Figure 5: The spatial distribution of mean CLWP on 7 January 2017. (a) The VIIRS. (b) The E1 experiment. (c) The E2 experiment. (d) The difference between the E2 and E1 experiment in Jing-Jin-Ji.**

**Figure 6: As in Figure 5, but for mean COT on 7 January 2017.**

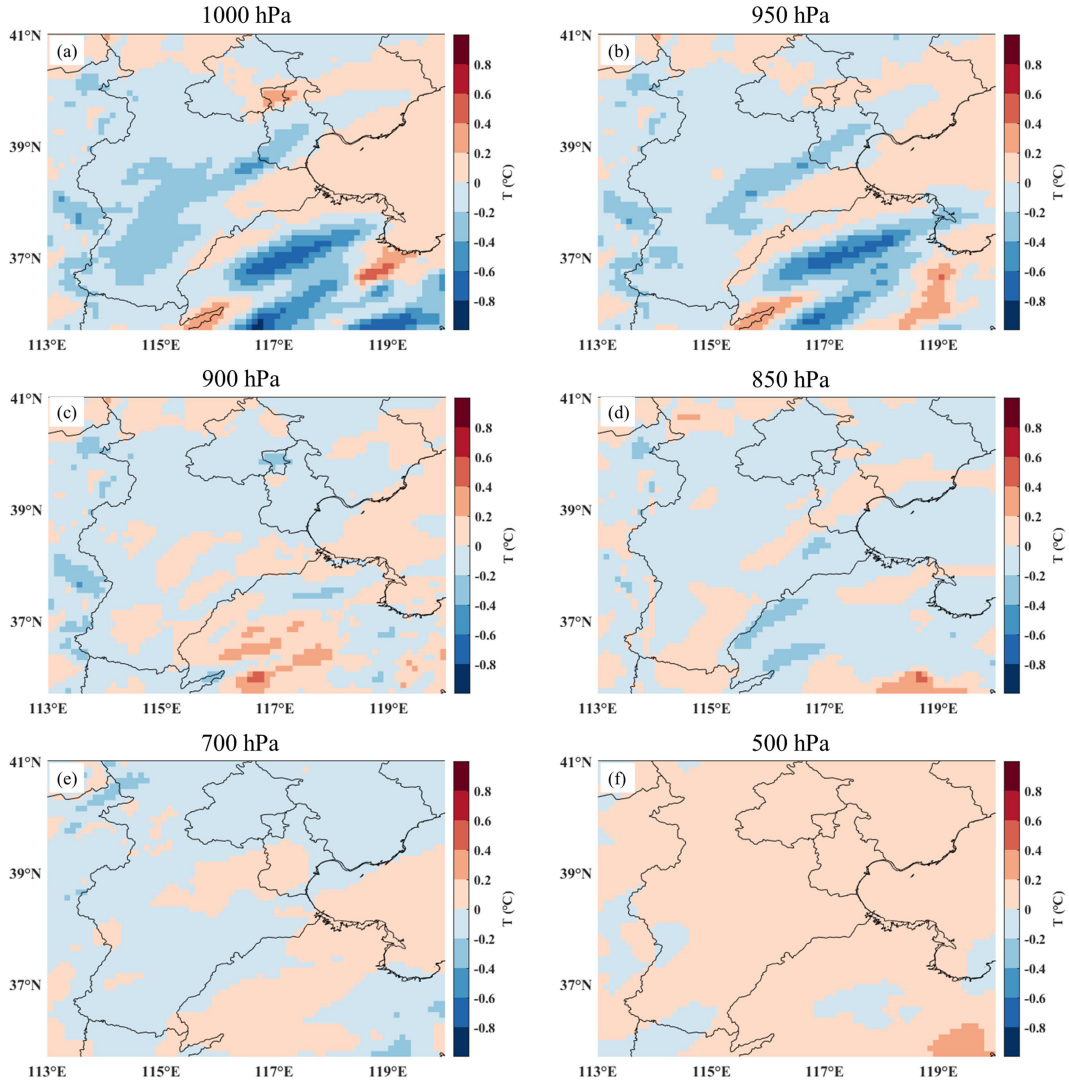

### 3.3 The impact of ACI on NWP

Changes in simulated cloud inevitably affect NWP such as radiation, temperature, precipitation, etc. (Liu et al., 2019; Borys et al., 2000). The above section shows that the ACI effect significantly influences the cloud's micro and macro physical properties. Furthermore, the spatial distribution of daily mean SDSR on 7 January 2017 is shown in Figure S5. Compared with the E1 experiment, the decreased SDSR from the E2 experiment has better performance against the data from CERES, with the regional mean bias of 44.6 vs. 42.9 W m<sup>-2</sup> in Jing-Jin-Ji. Evaluations in Section 3.1 have pointed out that the simulated 2 m temperature at daytime from the E1 experiment has a significantly positive bias in Jing-Jin-Ji, further supported by simulations on 5 and 7 January 2017 (Figure 7(b) and (e)). The simulated mean 2 m temperature at daytime by the E2 experiment with ACI has significantly decreased in cloudy fields of Jing-Jin-Ji with the maximum decrease value of 1 °C on 7 January 2017 (Figure 7(f)). However, other days during the study period are not significantly affected. For example, on 5 January 2017, the highest absolute difference of 2 m temperature at daytime between the E2 and E1 experiment is less than 0.2 °C (Figure 7(c)). In summary, the regional mean bias of 2 m temperature at daytime has been slightly improved (2%) for JJJ-5d (3.2 °C for the E1 experiment vs. 3.1 °C for the E2 experiment) (Figure 10(c)); while this improvement on 7 January 2017 increases to 4% with the bias of 2.7 vs. 2.6 °C. Figure 8 shows the difference in temperature at daytime in the vertical direction between the E2 and E1 experiment on 7 January 2017. The decrease in temperature at 1000 and 950 hPa (Figure 8(a) and (b)) is more significant than those at 900 and 850 hPa (Figure 8(c) and (d)). The maximum value of decrease at 1000 hPa is more than 0.8 °C. As for the temperature above 700 hPa, the changes in temperature are not significant with the maximum absolute difference being less than 0.2 °C (Figure 8(e) and (f)). This phenomenon suggests that real-time ice nucleation is expected in the following study. Similar to the ACI effect on cloud characteristics, the impact on temperature is inhomogeneous in Jing-Jin-Ji, especially in the lower atmosphere. It is worth noting that the changes in CLWP, COT, and temperature at daytime are all more significant in the same areas or periods, which is emerging evidence for explaining the inhomogeneous ACI effect.

**Figure 7: The spatial distribution of mean 2 m temperature at daytime. (a) and (d) The mean observations. (b) and (e) The bias of the E1 experiment. (c) and (f) The difference between the E2 and E1 experiment. The**

above row and following row are data on 5 and 7 January 2017, respectively.

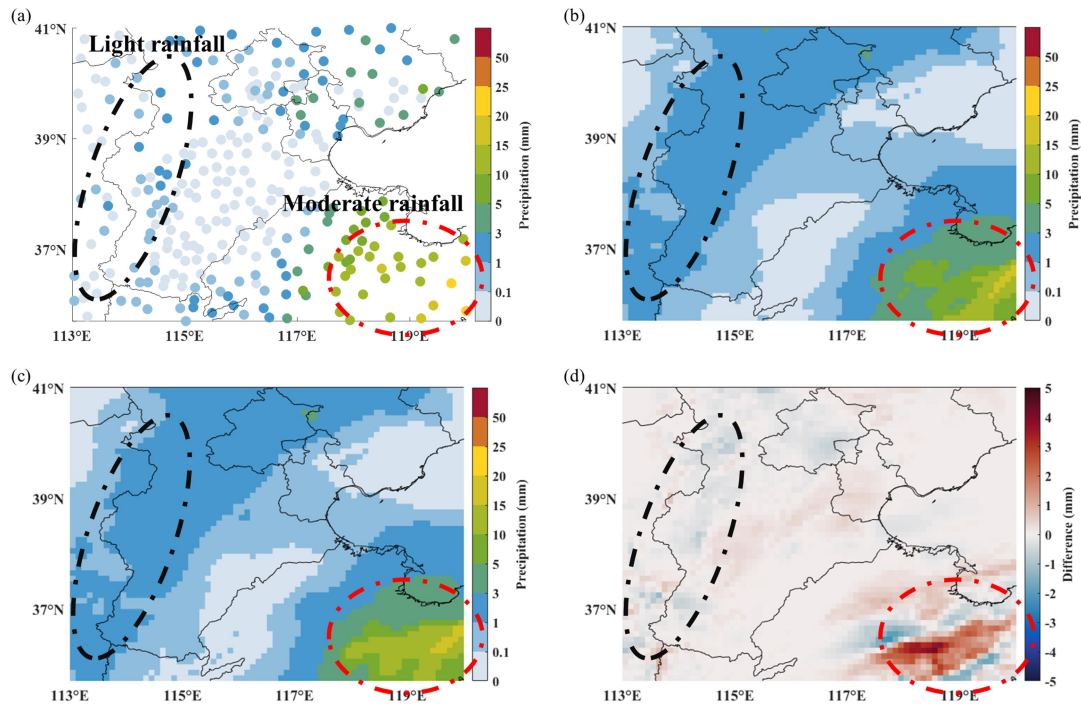

**Figure 8: The difference of mean temperature at daytime on 7 January 2017 between the E2 and E1 experiment in vertical direction. (a) 1000 hPa. (b) 950 hPa. (c) 900 hPa. (d) 850 hPa. (e) 700 hPa. (f) 500 hPa.**

The simulated precipitation is another meteorological factor that requires special attention. Unlike temperature, the impact of ACI on precipitation is more complex. In this paper, a rainfall event is selected from an automatic weather station within 24 h cumulative precipitation > 0 mm. We define a moderate (light) rainfall event as  $10 \text{ mm} < 24 \text{ h cumulative precipitation} < 25 \text{ mm}$  ( $0.1 \text{ mm} < 24 \text{ h cumulative precipitation} < 10 \text{ mm}$ ). If all rainfall events from contiguous stations in a certain region are moderate rainfall, this region is defined as the moderate rainfall area. Similar procedures are applied to the light rainfall area. The only moderate rainfall area is shown in Figure 9(a). Apart from this, other areas in Jing-Jin-Ji are light rainfall areas during the study period. In the moderate rainfall area associated with significant changes in CLWP and COT, the ACI increases 24 h cumulative precipitation with the maximum value exceeding 4.2 mm (Figure 9(d)), which improves underestimated mean

precipitation by 26% (Figure 9(c)). Besides, the ACI decreases 24 h cumulative precipitation in light rainfall areas. For example, in a light rainfall area (the black oval in Figure 9), this decrease due to ACI is observed with the maximum value exceeding -1 mm (Figure 9(d)). In terms of the study period average, the ACI reduces the mean bias of 24 h cumulative precipitation by 7% in these light rainfall areas. The combined effect of ACI on moderate rainfall and light rainfall improves the simulated mean 24 h cumulative precipitation for JJJ-5d with the mean bias of -0.11 vs. -0.07 mm (Figure 10(d)). The regionality of the ACI effect on precipitation is reflected. In Section 3.4, we continue to quantify the improvement in the selected areas and explore the possible reasons for discrepancies. More detailed evaluations about precipitation will be carried out in future works.

**Figure 9: The spatial distribution of 24 h cumulative precipitation on 7 January 2017. (a) The observations. (b) The E1 experiment. (c) The E2 experiment. (d) The difference between the E2 and E1 experiment. The red and black ovals represent the moderate and light rainfall areas, respectively.**

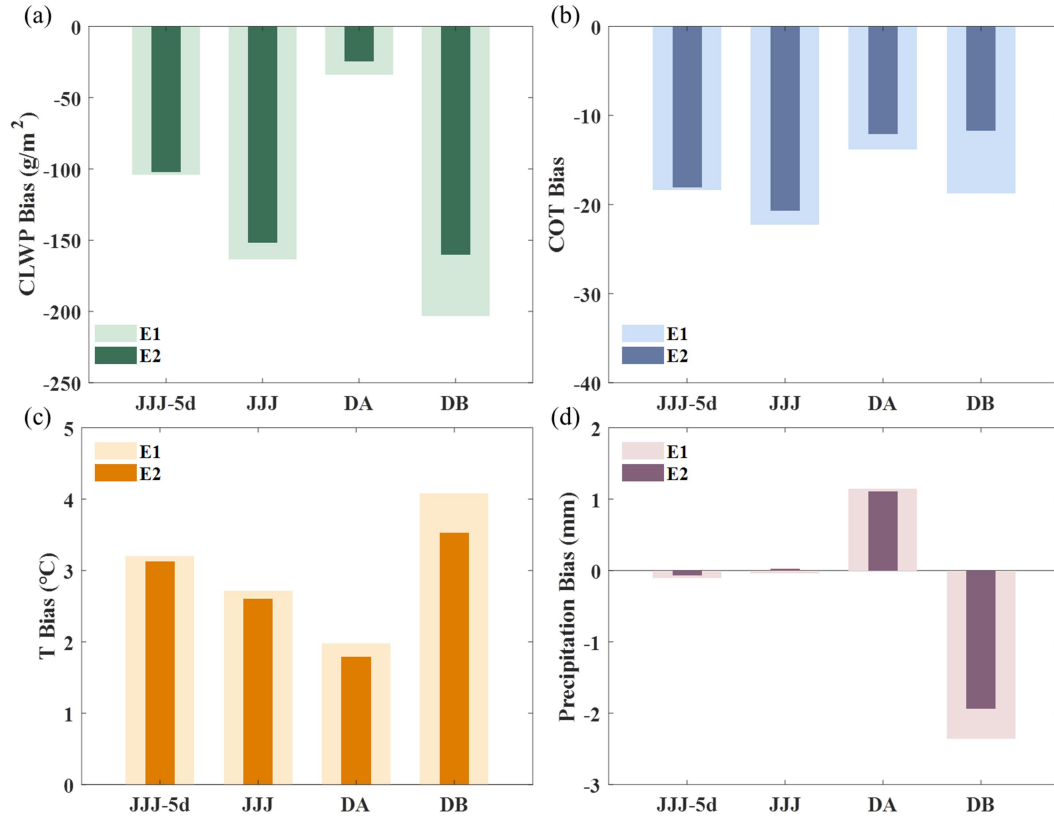

### 3.4 The possible attributions of significant variations of ACI effect in time and space

Based on previous studies (Pawlowska and Brenguier, 2000; Lohmann and Feichter, 2005; Zhou et al., 2020; Lu et al., 2012), the factors affecting the ACI include aerosol concentration, local meteorological conditions, cloud types, overlap degree of cloud and aerosol layers, etc. To avoid averaging out the distinct patterns of ACI effect that could possibly exist for different regions within the whole Jing-Jin-Ji, domain-A (i.e., DA (113°E-115°E, 36.4°N-38.5°N)) and domain-B (i.e., DB (116.2°E-120°E, 35.7°N-37.5°N)) are selected according to the aerosol concentration and the magnitude of CLWP on 7 January 2017 (Figure S6(a) and (b)).

Clear from the above sections and Figure 10 is that the impact of the ACI on simulations varies significantly in time and space even in this localized area (Jing-Jin-Ji) for a few reasons. First, the possible attributions of this phenomenon are mainly derived by comparing the results in the DA and

DB, where the observed cloud fields are reproduced. In the DA, the ACI increases CLWP and COT with the mean bias decreased by 27% (from -33.8 to -24.5 g m<sup>-2</sup>) and 12% (from -13.8 to -12.1); while in the DB, the changed CLWP and COT helps to reduce the mean bias by 21% (from -203.2 to -160.1 g m<sup>-2</sup>) and 37% (from -18.7 to -11.7) (Figure 10(a) and (b)). The changes in absolute values due to the ACI are more significant in the DB. Then we find that the regional mean PM<sub>2.5</sub> mass concentration in the DA (164.3 g m<sup>-3</sup>) is much greater than that in the DB (74.5 g m<sup>-3</sup>) (Figure S6(a)); while the positive supersaturation (900 hPa) and ascent speed (900 hPa), two typical meteorological factors, control more areas in the DB (Figure S6(c) and (d)). This suggests that the ACI effect is probably dominated more by supersaturation degree and ascent speed, rather than aerosol concentration, in these subareas of Jing-Jin-Ji. As pointed out by Hudson and Noble (2014), the ACI depends more on ascent speed than aerosol concentration when CCN is larger than 400 cm<sup>-3</sup> in stratus cloud. In addition, the mean bias of 2 m temperature at daytime decreases by 10% (from 1.9 to 1.7 °C) in the DA and 14% (from 4.1 to 3.5 °C) in the DB (Figure 10(c)), indicating the more significant ACI effect in 2 m temperature at daytime occurs in the subarea with a greater increase in CLWP and COT. This can also be further proved by comparing the improved 2 m temperature at daytime in four cases (JJJ-5d, JJJ, DA, and DB) with different changes in CLWP and COT (Figure 10(c)). As for the simulated precipitation, in the DB with moderate rainfall events, the ACI increases 24 h cumulative precipitation with the mean bias reduced by 18% (from -2.36 to -1.94 mm) (Figure 10(d)); while in the DA with light rainfall events, the ACI decreases 24 h cumulative precipitation with the mean bias reduced by 3% (from 1.14 to 1.11 mm). According to Figure S7 and Text S2 in the Supplement, we have enough evidence to believe that the increased/decreased precipitation in the DB/DA is mainly caused by the enhanced/inhibited melting of the snow to form rain in cold cloud processes. Second, if the original model cannot reproduce the observed cloud fields in some areas or periods, the ACI has almost no effect on simulations, which can be likely attributed to the cloud microphysical scheme, the initial fields, etc. (Thompson and Eidhammer, 2014; Fan et al., 2016; White et al., 2017). Finally, the systematic errors in the model itself may limit the improvement from the ACI effect. More detailed studies are needed.

**Figure 10: Comparisons of the mean bias of simulations from the E1 and E2 experiment for JJJ-5d and a day (7 January 2017) in Jing-Jin-Ji (JJJ), DA, and DB. (a) CLWP. (b) COT. (c) 2 m temperature at daytime. (d) 24 h cumulative precipitation.**

#### 4 Conclusions

In this work, the ACI is first completed in the GRAPES\_Meso5.1/CUACE model by linking the real-time calculated aerosol in CUACE to cloud droplets nucleation in the Thompson cloud microphysics scheme and transferring diagnostic variables ( $R_c$  and  $R_i$ ) to Goddard short-wave radiation scheme. Using this developed model, two experiments, including a control experiment without ACI and a comparative experiment with activated ACI, are conducted to investigate the impact of ACI on simulations (e.g., cloud, temperature, and precipitation) in a typical haze pollution episode (from 4 to 8 January 2017) with heavy aerosol concentration and stratus cloud over Jing-Jin-Ji in China.

The results show that the ACI increases the number concentration of cloud droplets,  $Q_c$ , CLWP, and COT; and decreases  $R_c$ . The increased CLWP and COT are more consistent with satellite observations,

especially in a certain subarea with the mean biases decreased by up to 21% (from -203.2 to -160.1 g m<sup>-2</sup>) and 37% (from -18.7 to -11.7). The cloud extinction enhanced by the ACI accompanied by the decreased SDSR further cools temperature at daytime below 950 hPa, as a result, reducing the regional mean biases of 2 m temperature at daytime by up to 14% (from 4.1 to 3.5 °C) in the subarea with the greatest change in CLWP and COT. The 24 h cumulative precipitation in this subarea, corresponding to moderate rainfall events, increases due to the ACI with reduced mean biases by 18% (from -2.36 to -1.94 mm), which is caused by the enhanced melting of the snow to form rain in cold cloud processes. However, in other areas or periods with a slight change in CLWP and COT, the improvement of ACI on NWP is not significant, suggesting the spatiotemporal inhomogeneous ACI effect.

In general, the GRAPES\_Meso5.1/CUACE model coupled with the ACI has a better performance on simulated cloud, temperature, and precipitation under haze pollution conditions in Jing-Jin-Ji. However, the inhomogeneous ACI effect in time and space still needs more detailed work in the future. In addition, there are still some shortcomings worth improving such as aerosol activation in the convective cloud (Ekman et al., 2011), real-time ice-friendly aerosol input (Demott et al., 2010; Thompson and Eidhammer, 2014), etc.

### Competing Interests

The authors declare that they have no conflict of interest.

### Author contributions
