11 **Abstract.**

12 Dust aerosols affect the radiative and energy balance at local and global scales by  
13 scattering and absorbing sunlight and infrared light. Previous study suggests dust size  
14 distribution is one of the major sources of uncertainty in modelling the dust global  
15 distribution. Climate models overestimates the fine dust ( $\leq 5 \mu\text{m}$ ) by an order of  
16 magnitude, while underestimates the coarse dust ( $\geq 5\mu\text{m}$ ) ranges between half to one-  
17 and-a-half orders of magnitude compared with the global observations. Here we  
18 improved the simulated size distribution of dust aerosol using a sectional aerosol  
19 model coupled with the Community Earth System Model (CESM1/CARMA).  
20 Simulated dust mass size distributions peak at around 2-3 micrometers in diameter  
21 and increase by 4 orders of magnitude from  $0.1 \mu\text{m}$  to  $2 \mu\text{m}$ . Our model demonstrates  
22 that North African, Middle Eastern, and Asian dust accounts for  $\sim 59.7\%$ ,  $12.5\%$ , and  
23  $13.3\%$  to the global annual mean dust emissions, with the remaining  $14.5\%$   
24 originating from scattered smaller dust sources. The model dust vertical distributions  
25 are validated against the NASA Atmospheric Tomography (ATom) field campaign  
26 datasets. Both simulations and ATom in-situ measurements during ATom field  
27 campaign suggest that dust mass concentrations over the remote ocean drop by two to  
28 three orders of magnitude from the surface to the upper troposphere ( $200 \text{ hPa}$ ). Our  
29 model suggests that Asian dust contributes to more than  $40\%$  of annual mean dust  
30 mass abundances in the global upper troposphere and lower stratosphere (UTLS).  
31 Model suggests that the Asian dust dominates the dust mass budget in the UTLS of  
32 the Asian summer monsoon (ASM) region, with a relative contribution 1-2 orders of  
33 magnitude higher than the dust originated from North African and Middle Eastern  
34 deserts.

## 35 **1 Introduction**

36 Mineral dust, from both natural and anthropogenic sources, accounting for more than 50% of the  
37 total global aerosol mass burden (Textor et al., 2006; Andreae, 1995; Andreae et al., 1986; Zender et  
38 al., 2004). Mineral dust impacts the radiation balance of the planet by scattering and absorbing  
39 sunlight, and unlike most other types of aerosols, dust has significant effects on thermal radiation due  
40 to its relatively large particle sizes (i.e., Satheesh and Moorthy, 2005; Sokolik and Toon, 1996;  
41 Balkanski et al., 2007; Tegen and Lacis, 1996). Dust optical properties vary between different sources  
42 (Sokolik and Toon, 1999), making it complex to construct global models of dust radiative effects. Dust  
43 also indirectly impacts climate by serving as a prominent nuclei for heterogenous ice formation (e.g.,  
44 Maloney et al., 2022; Cziczo et al., 2013). Despite being insoluble, dust can also serve as cloud  
45 condensation nuclei due to the large particle sizes of dust, influencing cloud microphysical and rainfall  
46 processes (Rosenfeld et al., 2001; Levin et al., 1996).

47 Tegen and Schepanski (2009) suggest that the Sahara and Asia are the largest source regions of  
48 mineral dust on Earth, accounting for more than 60-95% of the global dust load. Saharan dust is lifted  
49 all year, primarily due to subtropical weather systems. Saharan dust can travel across the Atlantic  
50 Ocean, driven by the trade wind circulation (Karyampudi, 1979; Karyampudi et al., 1999). Asian dust  
51 is mostly lifted in the spring by mid-latitude frontal systems, and is likely to be removed near its source  
52 due to rainfall though it can be carried at upper levels across the Pacific (Su and Toon, 2011). The  
53 North African and Asian dust can be transported to the upper troposphere (UT) and even farther around  
54 the Earth by subtropical westerly jets (Yang et al., 2022).

55 The accurate representation of the dust emissions from individual source regions is important to  
56 understand the climate impact of dust on the Earth system (Kok et al., 2021). The contributions of dust  
57 from the different source regions to the global dust load are still uncertain. Global model simulations  
58 show that the dust emission from different sources regions differ by an order of magnitude among  
59 different models (Huneus et al., 2011).

60 One source of uncertainty in quantify the emission of dust aerosols that can be attributed to the  
61 size distribution of dust aerosol (Tegen, 2003). The emitted dust size distribution is a basic parameter  
62 to simulate (Huneus et al., 2011) and the lifetime and radiative of dust with different particle sizes  
63 differ substantially that impact the simulation of dust on global scale (Kok, 2011). Kok (2011) showed

64 that most Global Climate Models (GCM) overestimate the dust emitted fraction with particle size less  
65 than  $2\ \mu\text{m}$  by a factor of  $\sim 2\text{-}8$  and underestimate the fraction of emitted with greater than  $5\ \mu\text{m}$  which  
66 causes the underestimation of dust global emission rate.

67 The vertical distribution of dust are crucial for understanding the vertical and long-distance  
68 transport of dust aerosols. Bourgeois et al. (2015) showed that the residence time of dust is  
69 significantly affected by its vertical location during long-range transport. However, in-situ  
70 measurements of dust's vertical distribution from the surface to the upper troposphere are extremely  
71 limited compared with surface measurements. Yu et al. (2015a) calculated the vertical mass flux of  
72 dust by converting the dust extinction coefficient of CALIOP to dust mass concentration, yielding  
73 estimated dust mass fluxes with an uncertainty of  $\pm (45\text{-}70\%)$ . Yu et al. (2010) showed that the  
74 modeled dust extinction of GOCART exceeded CALIOP's measurements by more than a factor of two  
75 from the middle to the upper troposphere over the northwestern Pacific. Based on CloudSat satellite  
76 data from 2007 to 2009 combined with CALIOP/CPR nighttime measurements, Yang et al. (2022)  
77 suggested that the dust mass loading at 4-10 km in the Northern Hemisphere (NH) reaches a maximum  
78 in March-April-May. The dust concentrations in 4-6 km have an opposite phase with the wind speed  
79 over Africa and West Asia. Despite the great coverage of satellite data, remote sensing techniques have  
80 considerable uncertainty in retrieving the dust vertical distribution. From 2016-2018, a pole-to-pole  
81 airborne in-situ measurement from NASA Atmospheric Tomography Mission (ATom) field campaign  
82 (Froyd et al., 2022; Wofsy et al., 2018) in-situ measured dust vertical distributions from pole to pole  
83 and from surface to the upper troposphere over the remote ocean.

84 Dust aerosol can be transported to the upper troposphere (UT) via the deep convections. Dust  
85 transported to the upper troposphere can affect cirrus formation through heterogeneous nucleation (???;  
86 Froyd et al., 2022). Ma et al. (2019) simulated the chemical composition of Asian tropopause aerosol  
87 layer and found a dust maximum inside the anticyclone of Asian Summer Monsoon (ASM). However,  
88 the abundance, source attributions, and spatial-temporal distribution of dust in the UT of ASM are still  
89 of large uncertainties.

90 We use a sectional aerosol model coupled with a climate model to study the global distribution of  
91 dust, with a focus on the size distribution and vertical distribution. We compare the simulated dust  
92 abundance from the surface to the upper troposphere with in-situ measurements from ATom field  
93 campaign (Froyd et al., 2022). Then we use the constrained model to simulate the spatiotemporal

94 distribution of dust coming from the Sahara, Middle East, and East Asia. Finally, we estimate dust  
95 source attributions during the Asian summer monsoon from the three source regions.

## 96 **2 Methods**

### 97 **2.1 CESM1/CARMA model**

98 We use a sectional aerosol microphysics model, the Community Aerosol and Radiation Model for  
99 Atmospheres (CARMA) (Yu et al., 2015b; Yu et al., 2019; Bardeen et al., 2008; Toon et al., 1988)  
100 coupled with the NSF/DOE Community Earth System Model (CESM) to simulate the global  
101 distribution of dust between 2014 and 2019. The model simulations are conducted at a horizontal  
102 resolution of  $1.9^{\circ} \times 2.5^{\circ}$  and with a time step of 30 min. The model has 56 hybrid levels from the surface  
103 up to about 45 km, with a vertical resolution of about 1 km near the tropopause. The meteorological  
104 fields were nudged to Goddard Earth Observing System (GEOS5) reanalysis data.

105 CESM1/CARMA includes two groups of particles. The first group is liquid sulfuric acid droplets  
106 that form from gas phase nucleation and span a diameter range from 0.2 nm to 2.6  $\mu\text{m}$ . The second  
107 group is an internal mixture of primary emitted organics, secondary organics, dust, sea salt, black  
108 carbon, and condensed sulfate (Yu et al., 2015b). The mixed particles are resolved with 20 discrete size  
109 bins with diameters ranging from 100 nm to 17  $\mu\text{m}$  in the model. The aerosol optical properties in  
110 CESM1/CARMA are estimated using a Mie scattering code, with inputs based on particle size, relative  
111 humidity, and aerosol composition (Yu et al., 2015b). We assume that dust has a density of 2.65  $\text{g}/\text{cm}^3$   
112 and use wavelength dependent refractive indices (RI) (Yu et al., 2015b). The RI at 532 nm is 1.53-  
113 0.006i in the mode, which is independent of the dust source region, even though these properties vary  
114 with dust source in reality. Note that the reported imaginary part of the refractive index of dust aerosol  
115 ranges from 0.0006 to 0.0048 according to previous studies (Sinyuk et al., 2003; Di Biagio et al., 2019;  
116 Balkanski et al., 2007), which suggests that our model may overestimates the absorption aerosol optical  
117 depth from dust aerosol.

### 118 **2.2 Dust emission parameterization**

119 Mineral dust emission is simulated as a saltation-sandblasting process, which can be explained by the  
120 wind erosion theory. The process is driven by surface stress, which is usually expressed as friction wind  
121 velocity (Ginoux et al., 2001). When the frictional wind speed exceeds a certain threshold, the force of

122 the wind will overcome the gravitational force of the sand grains and the cohesive forces between  
123 particles, and sand-sized particles will saltate. When they impact the surface dust particles will be  
124 lofted into the air (Marticorena and Bergametti, 1995). The wind-driven emission of dust aerosols in  
125 CESM1/CARMA is provided by Su and Toon (2009) and Yu et al. (2015b). The total emission flux is  
126 parameterized as:

$$127 \quad F_{total} = C \times S_e \times (u - u_t) \times u^2,$$

128 where  $F_{total}$  is the particle size dependent flux of dust;  $C$  is an arbitrary constant that depends on  
129 the spatial resolution of the climate model among other factors and is set to  $0.6 \mu g s^2 m^{-5}$ ;  $u$  is the 10-  
130 m wind speed, which is parameterized by the surface friction velocity ( $u^*$ ) and the 10-m drag  
131 coefficient ( $C_d$ ) so that under neutral conditions  $u = \frac{u^*}{\sqrt{C_d}}$ ; and  $u_t$  is the threshold wind speed, which  
132 depends on the particle size (Su and Toon, 2009; Marticorena and Bergametti, 1995). Details on  $u^*$ ,  $u_t$ ,  
133 and  $C_d$  can be found in Yu et al. (2015b).  $S_e$  is the dust erodibility factor, which denotes the efficiency  
134 of dust lifting and derived from the TOMS aerosol index reported by Ginoux et al. (2001).

135 Following Prospero and Bonatti (1969), the model assumes that 90% of the dust emission mass  
136 flux is distributed in silt bins with diameter ranges from 2.6 to 17.4  $\mu m$ , and the remaining 10% is in  
137 clay bins with diameter ranges from 0.1 to 2  $\mu m$  (Yu et al., 2015b). In the present study, we adjust the  
138 relative mass fractions in clay and silt bins to match the data reported by Adebisi and Kok (2020) and  
139 discussed in section 3.1 below.

### 140 **2.3 Convective transport parameterization**

141 Particles are primarily activated at the cloud base. CESM1/CARMA considers the activation of  
142 particles, including dust, from the entrained air above the cloud bases (secondary activation, Froyd et  
143 al., 2022; Yu et al., 2019). Previous studies have found that climate models that fail to consider  
144 secondary activation above the cloud base overestimate the abundance of primary particles like sea salt  
145 and black carbon in the upper troposphere by orders of magnitude (Yu et al., 2019; Murphy et al.,  
146 2021). A comparison with global airborne measurements of dust suggests that dust is also subject to  
147 secondary activation above the cloud base and subsequent in-cloud removal (Froyd et al., 2022). For  
148 below-cloud scavenging, the tuning parameter for aerosol's solubility in CESM1/CARMA is 0.2 for  
149 dust and 1.0 for sea salt (Yu et al., 2015b). For convective removal, we treat dust's removal efficiency  
150 the same as other aerosol types. Details of the parameterizations can be found in Wang et al. (2013),

151 Grell and Freitas (2014), and the supplement of Yu et al. (2019).

## 152 **2.4 ATom airborne field campaign**

153 The Atmospheric Tomography Mission (ATom) was an airborne field campaign with in-situ  
154 measurements of atmospheric composition in the remote troposphere from about 0.18 to 12 km in  
155 altitude in the Pacific and Atlantic basins, spanning from  $\sim 82^{\circ}\text{N}$  to  $\sim 86^{\circ}\text{S}$  latitude (Spanu et al., 2020;  
156 Wofsy et al., 2018). It consisted of 48 science flights by the NASA DC-8 aircraft with 548 vertical  
157 profiles during four flight series covering roughly the same loop (Bourgeois et al., 2020). A  
158 comprehensive set of aerosol measurement data including mineral dust was collected from July 2016 to  
159 May 2018.

160 In this study we compare the simulations with measured dust concentrations during the ATom  
161 mission from 2016 to 2018. Dust concentration data are based on data from the National Oceanic and  
162 Atmospheric Administration (NOAA) Particle Analysis by Laser Mass Spectrometry (PALMS)  
163 instrument (Froyd et al., 2019; Brock et al., 2019; Murphy et al., 2003). The PALMS instrument measures  
164 the chemical composition of individual ambient particles from about 0.1 to 4.8  $\mu\text{m}$  in diameter by  
165 evaporating individual particles and then using a time of flight mass spectrometer to analyze ions  
166 (Murphy et al., 2006). Dust and other particle types are classified using spectral signatures. Dust mass  
167 concentrations are then determined by combining the PALMS classifications with absolute particle  
168 concentrations from independent optical particle counters (Froyd et al., 2019; Froyd et al., 2022). The  
169 measured aerodynamic particle size are converted to the geometric diameter using a constant density and  
170 shape factor as described Froyd et al. (2022). To directly compare with ATom dust vertical profiles  
171 measured by PALMS, we sample the simulated dust concentration with diameter between 0.1  $\mu\text{m}$  and  
172 4.5  $\mu\text{m}$  along the ATom flight track.

## 173 **2.5 Surface measurement networks**

174 Huneeus et al. (2011) summarize dust measurements at the surface around the globe including  
175 compiled by Mahowald et al. (2009) and the University of Miami network (Prospero, 1989; Arimoto et  
176 al., 1996). Data compiled by Mahowald et al., (2009) contain the data set of short-term measurements  
177 from cruises and monitoring stations with daily averaged surface dust concentrations. Cruises measured  
178 iron (Fe) and converted to dust by assuming a 3.5% Fe in dust. The iron content in dust varies

179 according to the source regions and this value is the average iron content of the Earth's crust  
180 (Mahowald et al., 2005). Long-term observations by the University of Miami include Pacific, Atlantic,  
181 and Antarctic Ocean sites globally and measure the mass concentration of dust with diameter less than  
182 40  $\mu\text{m}$  (Prospero, 1989, 1996; Arimoto et al., 1996).

### 183 **3 Model validation**

#### 184 **3.1 Dust size distribution and emission**

185 Based on global measurements of atmospheric dust size distributions, Adebisi and Kok (2020) found  
186 that the global models in AeroCom (Aerosol Comparison between Observations and Models project)  
187 underestimate the coarse dust mass load in the atmosphere by a factor of four and overestimate the fine  
188 dust mass load by 1-3 orders of magnitude. Figure 1 shows that CESM1/CARMA Yu et al. (2015b)  
189 generally reproduces the measured dust size distribution with diameter less than 1  $\mu\text{m}$  or greater than 3  
190  $\mu\text{m}$  within the variabilities of the data. However, the CESM1/CARMA Yu et al. (2015b)  
191 underestimates the dust in the size range between 1 and 3  $\mu\text{m}$  by one order of magnitude (red dashed  
192 line). In this study, we simply adjust the mass fraction of the emitted dust in the silt bins with geometric  
193 diameter greater than 2  $\mu\text{m}$  from 90% to 94%. The global dust size distribution simulated in the  
194 modified model (CESM-CARMA solid red line in Fig.1) agrees better with measurements from  
195 Adebisi and Kok (2020) (Figure 1). The simulation show that the model underestimates the coarse-  
196 mode dust with diameter larger than 10  $\mu\text{m}$  by ~48%. The modeled total dust concentration at surface  
197 can be biased low, while modeled dust in the upper troposphere is not significantly affected as giant  
198 dust particles sediments quickly.

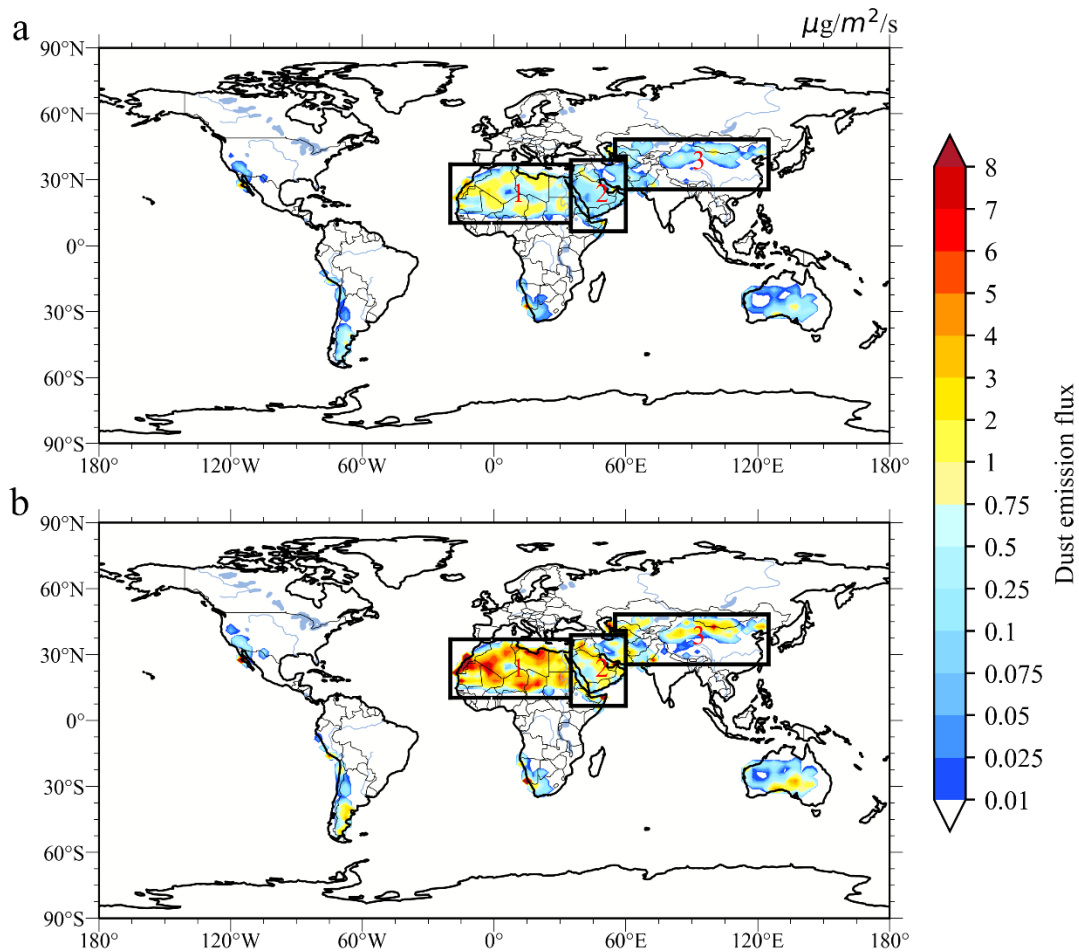

199

200 **Figure 1.** Comparison of the simulated and measured normalized global mean dust size distributions.  
 201 The dust mass size distributions are divided by the total dust mass integrated over the size range (i.e.  
 202 the area under each  $dM/d\ln D$  curve). The global and annual mean dust size distribution simulated by  
 203 CESM1/CARMA with the dust emission parameterization described in Yu et al. (2015b) is shown by  
 204 the dashed red line; the simulation by CESM1/CARMA with the modified emission parameterization is  
 205 shown by the solid red line; temporal variabilities (1 standard deviation) from Yu et al., (2015b) and  
 206 CESM1/CARMA are denoted by green and cyan lines; the simulated size distribution by the AeroCom  
 207 models reported in Adebisi and Kok (2020) is denoted by the gray lines; the measured dust size  
 208 distribution derived from the global measurements reported in Adebisi and Kok (2020) is denoted by  
 209 the solid black line; the shading represent the 95% confidence interval.

210

211 Figure 2 shows the global annual mean emission of fine (with diameter less than  $4.5 \mu\text{m}$ ) and  
 212 coarse (with diameter greater than  $4.5 \mu\text{m}$ ) dust simulated by CESM1/CARMA. The simulated global  
 213 and annual mean mass emission of coarse dust is higher than that of fine dust by a factor of 2.8. The  
 214 three largest dust source regions in the world, i.e., the Sahara, Middle East, and Asia contribute  $\sim 85\%$   
 215 of total global dust emissions, and about 97% of Northern Hemisphere (NH) dust. Dust emissions from  
 216 the Sahara in North Africa account for  $\sim 59.7\%$  of global emissions by mass. Middle Eastern and Asian  
 dust emissions account for  $\sim 12.5\%$  and  $13.3\%$  of global emissions, respectively.

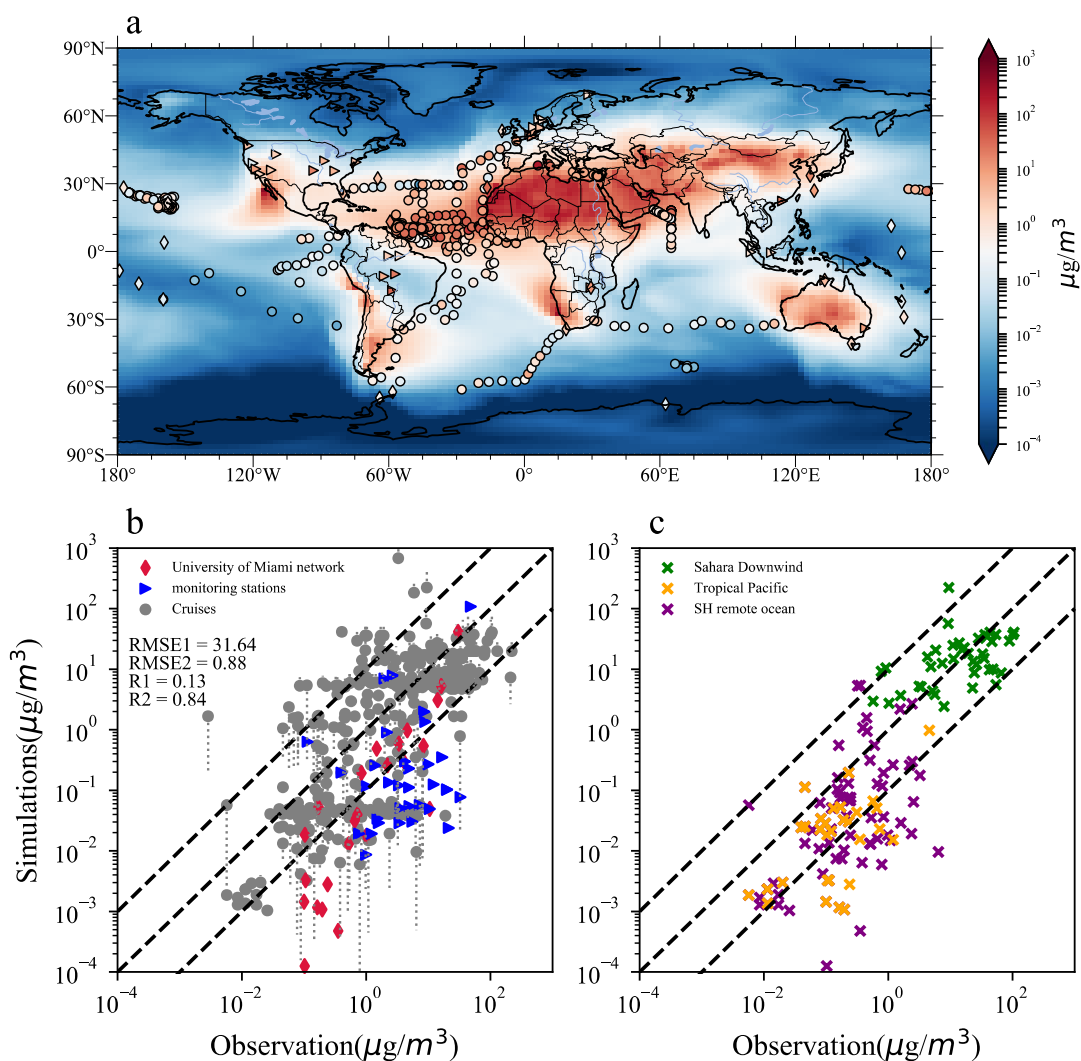

217

218 **Figure 2.** (a) Simulated annual emission flux ( $\mu\text{g}/\text{m}^2/\text{s}$ ) of dust with geometric diameter less than  $4.5$   
 219  $\mu\text{m}$  in CESM1/CARMA averaged from Feb 2014 to Jan 2018. (b) same as (a) but for dust with  
 220 geometric diameter larger than  $4.5 \mu\text{m}$ . The regions of interest are denoted by the black boxes. The  
 221 coordinates of the three regions are (1) North African source ( $20^\circ\text{W}$ - $35^\circ\text{E}$ ;  $10.4^\circ$ - $36.9^\circ\text{N}$ ), (2) Middle  
 222 Eastern source ( $35^\circ$ - $60^\circ\text{E}$ ;  $6.6^\circ$ - $38.8^\circ\text{N}$ ), and (3) Asian source ( $55^\circ$ - $60^\circ\text{E}$  for  $40.7^\circ$ - $48.3^\circ\text{N}$ , and  $60^\circ$ -  
 223  $125^\circ\text{E}$  for  $25.5^\circ$ - $48.3^\circ\text{N}$ ).

### 224 3.2 Comparison with dust surface measurements

225 In Figure 3, we compare the simulated annual mean dust concentrations at the surface from 2014 to  
 226 2018 with the observational datasets summarized in Huneus et al. (2011). In general, the simulated  
 227 dust concentrations are within one order of magnitude of observations (Figure 3b). The simulated dust  
 228 underestimated the measured dust concentration from University of Miami network by 70%, while  
 229 overestimated the dust concentration from the compiled dataset (Mahowald et al., 2009) by a factor of  
 230 3.75. Both the model and observations show that the dust concentration in the Northern Hemisphere  
 231 (NH) is about one order of magnitude higher than that in the Southern Hemisphere (SH) due to higher  
 232 NH dust emissions because of the greater area of Northern Hemisphere (NH) deserts. Because a lack of

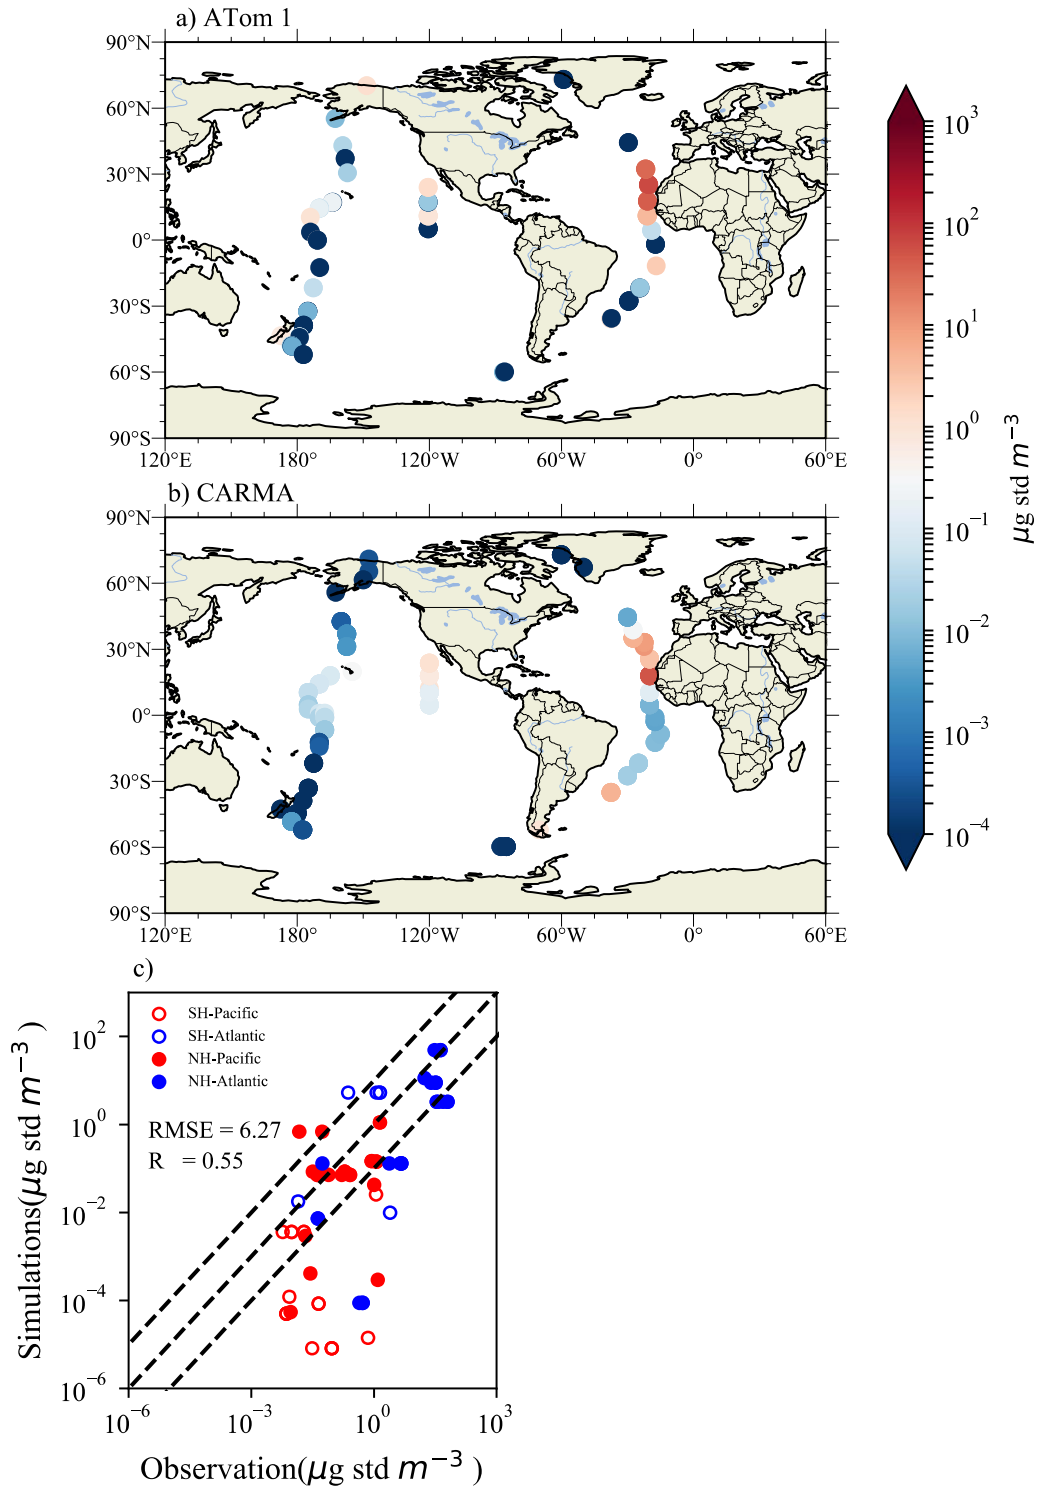

233 detailed date information in measurements compiled by Mahowald et al. (2009), the comparison of  
 234 annual mean model concentration and short-term observations possible result in a large bias but still  
 235 provide valuable information (Wang et al., 2015). In order to explain the bias, we show the error bars  
 236 by the median 66 % of the modeled daily averaged model concentration (denoted by the vertical  
 237 dashed line) for each cruise data following the method suggested by Mahowald et al. (2008) and  
 238 Huneus et al. (2011). Near the dust source region (e.g., downwind of the Sahara), the model  
 239 underestimates the measured median dust surface concentrations by 5.4%. The dust simulation  
 240 underestimates the averaged ship cruise measurements by 11% over remote ocean basins in the SH.  
 241 Higher model low biases of 72% are found in the tropical Pacific, which indicates that dust is removed  
 242 too efficiently amid transport from the source regions.

243  
 244 **Figure 3.** (a) Simulated global dust surface concentrations ( $\mu\text{g}/\text{m}^3$ ) averaged from 2014 to 2019 from  
 245 CESM1/CARMA shown in the filled contour. The summarized dust surface concentration data sets

246 from Huneus et al. (2011) are denoted by markers of different shapes. Compiled observations  
247 including those from long-term observational sites and cruise data reported in Mahowald et al. (2009)  
248 are denoted by triangles and circles, respectively; measurements from the University of Miami network  
249 (Prospero 1989; Arimoto et al., 1996) from 1981 to 1998 are denoted by diamonds. (b) Comparison of  
250 the simulated dust concentrations by CESM1/CARMA with the compiled observational dataset from  
251 Mahowald et al. (2009) and University of Miami network. Gray circles and blue triangles represent  
252 selected data from Mahowald et al. (2009) short-term cruises and long-term observations, respectively;  
253 red diamonds represent the University of Miami network measurements. “R1” and “RMSE1”  
254 represents correlation coefficient (R) and the Root mean square error (RMSE) between simulations and  
255 measurements from Mahowald et al., (2009), respectively. In the meantime, “R2” and “RMSE2”  
256 denoted the University of Miami dust data. The gray dotted line donated the simulated error bar  
257 extracted from the simulated daily concentration following the method in Mahowald et al. (2008). (c)  
258 Same as (b), but the North African downwind area as well as the tropical Pacific basin and Southern  
259 Hemisphere (SH) remote ocean are represented as green, orange, and purple stars, respectively. The  
260 1:1, 1:10, and 10:1 relationships between the simulated and observed dust concentrations are denoted  
261 by the black dashed lines.

262 Figure 4 compares the simulated concentrations of dust below 1 kilometer above the sea level with  
263 diameter less than  $4.5 \mu\text{m}$  near the surface (0-1 km above sea level) over remote ocean basins with the  
264 NASA Atmospheric Tomography (ATom1) airborne field campaign (Froyd et al., 2022; Wofsy et al.,  
265 2018). Both observations and the model suggest that higher dust concentrations are found in the  
266 Atlantic basin downwind of the North African and near the west coast of North America. As shown in  
267 Figure 4c, the model underestimates the average dust surface concentrations observed during ATom1  
268 by 62%, with a correlation coefficient of 0.55. Except for the Southern Ocean, the modeled dust  
269 concentration is within an order of magnitude of the observations in general. The model strongly  
270 underestimates the observed dust concentration in the remote Southern Ocean by over one order of  
271 magnitude. The underestimation of southern Pacific Ocean dust could be partly due to underestimation  
272 of the emissions in SH. In addition to a possible lack of emissions, the model may generate too much  
273 convection and thereby have a too efficient wet scavenging of dust aerosols.

274

275 **Figure 4.** Comparison of the dust concentration below 900 mb with particle diameter less than  $4.5 \mu\text{m}$   
 276 simulated by CESM1/CARMA with the NASA ATom 1 airborne campaign. Both model and  
 277 observations are sampled along the NASA Atom-1 flight track. (a) Observed dust surface concentration  
 278 according to ATom 1; (b) same as (a), but simulations from CESM1/CARMA. (c) Scatterplot of  
 279 CARMA simulation compared with ATom 1 for dust surface concentration. Southern Pacific and  
 280 Atlantic basin sites are denoted by red and blue circles, respectively, while northern Pacific and  
 281 Atlantic basin sites are denoted by red and blue points, respectively. The black dashed lines in each

282 panel denote 1:10, 1:1, and 10:1 relationships between observations and simulations, respectively.

### 283 **3.3 Comparison with dust vertical distribution**

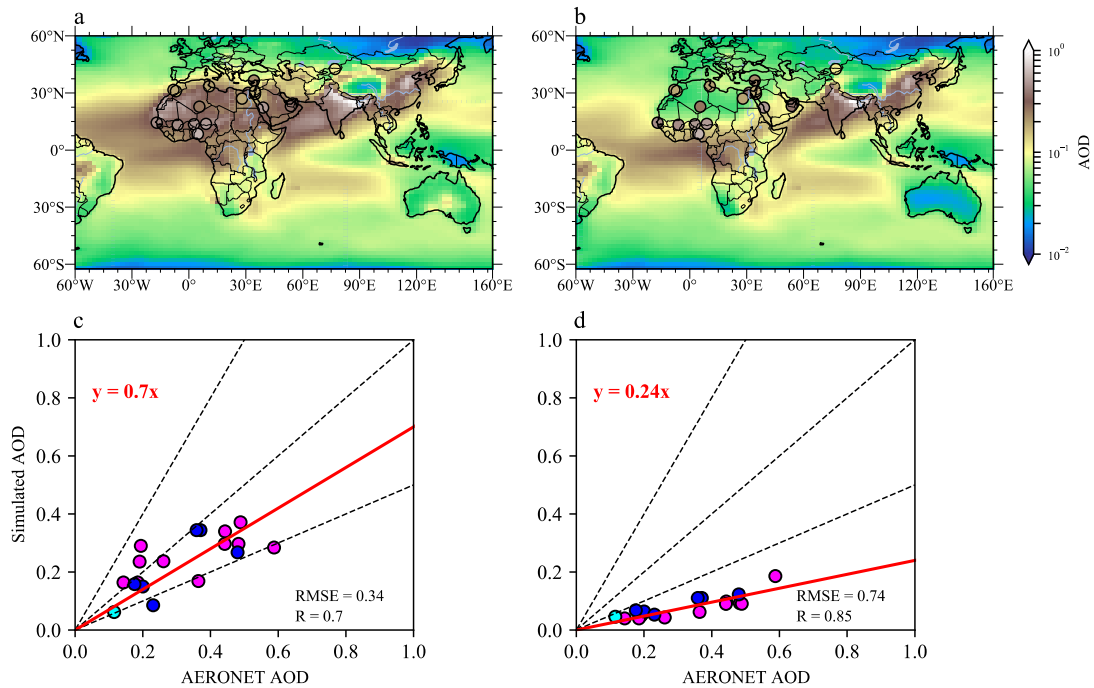

284 Figure 5 compares the dust vertical distribution between CESM1/CARMA and measurements by  
285 PALMS during ATom1 in August 2016. The observed dust concentrations in the lower tropospheric NH  
286 midlatitudes (27°N-60°N) and tropics (27°S-27°N) are about an order of magnitude higher than those in  
287 the SH midlatitudes (27°S-60°S) due to higher surface emissions in NH (Figure 2). The tropical lower  
288 tropospheric dust loading in the Atlantic basin, which is downwind of the North African, is over one  
289 order of magnitude higher than that in the Pacific Ocean. Both observations and the model show that  
290 the dust concentration decreases by two to three orders of magnitude from the surface to about 12 km.  
291 The strong vertical gradient is consistent with the findings reported in Yu et al. (2019) and Froyd et al.  
292 (2022), that deep convection activates the entrained dust aerosols above the cloud base and  
293 subsequently removes the particles in-cloud. Maloney et al. (2022) suggests that there is a strong  
294 removal of dust by ice formation through heterogeneous nucleation. The model overestimates the  
295 observed dust concentration in the mid and upper troposphere possibly because our model does not  
296 include the interaction. A layer of dust between 2 and 8 km, which the model fails to reproduce over the  
297 southern Atlantic, is observed during ATom1 but not in ATom2-4 (Figure S1-S3). Figure S1 shows that  
298 about 35% of the simulated dust near the surface are coarse mode dust (4.5 $\mu$ m – 17  $\mu$ m) and the coarse  
299 dust mass fraction drops rapidly with altitude. Simulations show that 95% of the total dust  
300 concentration above 5 km is fine dust (with diameter less than 4.5  $\mu$ m) because coarse dust is subject to  
301 more efficient wet and dry deposition during long-range transport vertically or horizontally.

302  
 303 **Figure 5.** Simulated (long dash line) and measured (solid line) vertical profiles of the dust  
 304 concentrations during the ATom1 field campaign. Both model and observations are sampled along the  
 305 flight track. The profiles are averaged over the Pacific Ocean (pink) or Atlantic Ocean (blue) in the  
 306 Northern Hemisphere (NH) midlatitudes (27°N-60°N, panel a) and tropics (27°S-27°N, panel b), and in  
 307 the Southern Hemisphere (SH) midlatitudes (27°S-60°S, panel c).

### 308 **3.4 Comparison with AERONET in Asia and North Africa**

309 The simulated aerosol optical depth (AOD) at 532 nm wavelength from CESM1/CARMA is compared  
 310 to the measurements near dust source regions from 2014 to 2018 for most of the Aerosol Robotic  
 311 Network (AERONET) sites (Figure 6a). We use 18 AERONET sites inside of the major dust emission  
 312 region shown in Figure 2. On average, the model underestimated the annual mean AOD of the selected  
 313 18 AERONET sites by 19%. The model underestimates the averaged AOD by ~14% in North Africa  
 314 and ~25% in Middle East. Figure 6b shows the simulated AOD without dust emitted in the model  
 315 underestimated the AERONET AOD by 74% on average. The simulations with and without dust  
 316 emission suggest that dust contribute to over 50% of simulated AOD in the selected AERONET sites.  
 317 Consistent with the dust emission distribution shown in Figure 2, the simulated and observed AOD  
 318 near the dust source regions in the tropics and NH (e.g., Sahara, Middle East, and Asia) is significantly  
 319 higher than that near SH deserts (e.g., central Australia). Dust from the source regions in NH and  
 320 tropical deserts is transported downwind into the Pacific and Atlantic Ocean basins.

321  
 322 **Figure 6.** (a) Annual mean AOD at 532 nm wavelength from 2014 to 2018 simulated by  
 323 CESM1/CARMA, denoted by the color-filled contours; (b) same as (a) for simulation without dust.  
 324 The measured AOD from 18 AERONET ground sites located inside the major dust emission regions  
 325 (Figure 2) are denoted by the color-coded circles. (c) Comparison of the simulated annual mean AOD  
 326 at 532 nm wavelength with measurements from 2014 to 2018 for the most of the AERONET sites.  
 327 North Africa, the Middle East and Asia are represented as pink, cyan and blue number, respectively. (d)  
 328 same as (c) but for without dust. The solid red line denotes the best fit. The dashed black lines represent  
 329 1:2, 1:1, and 2:1 relationships between the observations and simulations.

#### 330 **4 Global distributions of North African, Middle Eastern, and Asian dust**

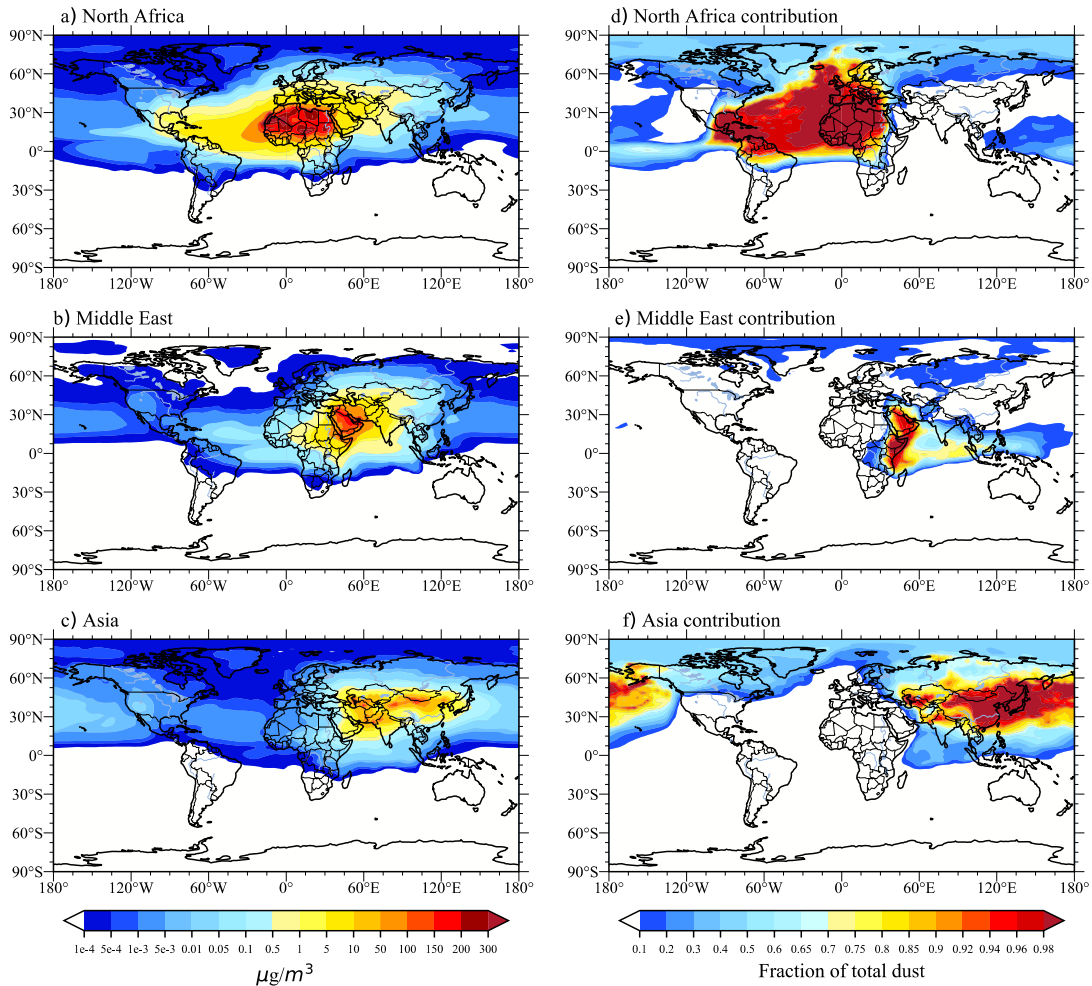

331 In this section, we show the global distributions and source attributions of dust from the surface to the  
 332 lower stratosphere. Consistent with previous studies (Tanaka et al., 2006, Chin et al., 2007 and Kok et  
 333 al., 2021), modeled North African dust accounts for about 50-60% total global dust loading (mostly in  
 334 the lower troposphere). Validated by the recent global NASA ATom measurements, our study  
 335 calculated the dust source attributions in each altitude and the dust source attribution in the anticyclone  
 336 of the Asian summer monsoon region. We show that the Asian dust with less annual emission than the  
 337 North African dust is transported higher and become dominant in the upper troposphere and lower  
 338 stratosphere (UTLS).

#### 339 **4.1 Surface distribution of dust**

340 Figure 7 shows the simulated annual mean surface concentrations of North African, Middle Eastern,

341 and Asian dust and their relative contributions to the simulated total dust from 2014 to 2018. In general,  
 342 the simulated maximum concentrations are located near the source regions. The dust concentrations  
 343 decrease dramatically by about two to three orders of magnitude from the source to remote regions due  
 344 to efficient dry and wet scavenging. Limited dust is transported across the equator from NH to SH  
 345 midlatitudes at the surface level. The simulated NH dust can travel to SH once convection lifts the dust  
 346 into the upper troposphere and lower stratosphere (Section 4.2).

347  
 348 **Figure 7.** Simulated global spatial distribution of annual mean surface dust mass concentrations and  
 349 the fractional contribution of each source. Simulations are averaged from 2014 to 2018. Left panels  
 350 represent each source's concentration of dust. Right panels represent each source's contribution to total  
 351 dust.

352 North African dust dominates the surface dust concentrations in the Western Hemisphere  
 353 including the North Atlantic basin, Europe, Caribbean, and eastern North America. The model suggests  
 354 that simulated North African dust concentrations drop by three orders of magnitude during transport  
 355 from North Africa to 60 °N and peaks in the Caribbean. The modeled shape and direction of the

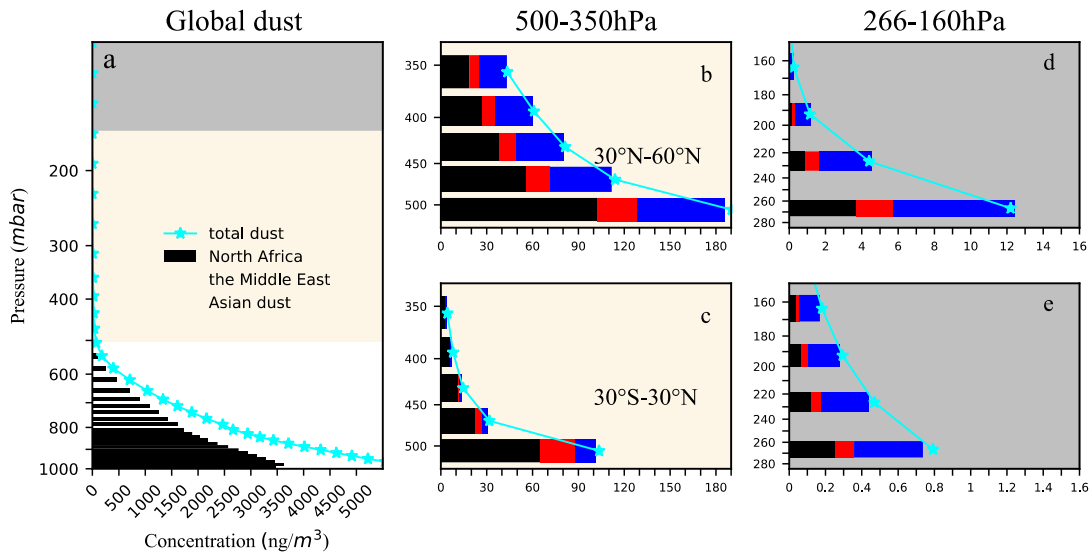

356 transported dust plume is similar to the simulations of Colarco et al. (2003). The trans-Atlantic  
357 transport of the African dust to Amazon Basin in the northeasterly trade winds are observed (Yu et al.,  
358 2015c; Swap et al., 1992; Prospero et al., 2014). Based on satellite and in-situ deposition data, Yu et al.  
359 (2015c) quantified the deposition of African dust in the Amazon basin. Consistently, our simulated dust  
360 over Amazon Basin is primarily transported from the North Africa.

361 The simulated annual mean dust concentration in Asia is about 24% of that in the North African,  
362 which Su and Toon (2011) attribute to Asia having a much smaller area of dust sources than the Sahara.  
363 Asian dust dominates in the Eastern Hemisphere including the North Pacific basin, Russia, and some  
364 can be transported to Alaska and Canada. Previous studies have indicated that dust from the Gobi  
365 Desert region entrained in a surface cyclone arrives in the western U.S. boundary layer via cross-  
366 Pacific transport (Arimoto et al., 1996). With CARMA we show that although some Asian dust can be  
367 transported to the western U.S. across the Pacific basin (Figure 7), its relative mass contribution to the  
368 total dust concentration in the Western U.S. is about 1% on the annual basis (Figure 3). Simulated dust  
369 in the boundary layer is mostly removed by wet and dry deposition during the cross-Pacific transport,  
370 while lifted Asian dust can be transported more efficiently across the Pacific basin and accounts for  
371 about 50% of the dust loading in the middle troposphere above the western U.S. (Figure S5). The  
372 Pacific Dust Experiment (PACDEX) shows that the coarse mode Asian dust is rapidly removed amid  
373 the remote transport, while the fine mode dust less than 2.5  $\mu\text{m}$  in diameter is entrained into the upper  
374 air and transported across the Pacific Basin by the upper tropospheric westerly jets (Stith et al., 2009).  
375 Consistent with PACDEX, our model shows that 92% of Asian dust mass that transported 10 km above  
376 U.S. are less than 2.5  $\mu\text{m}$  in diameter (not shown). Middle Eastern dust contributes significantly to  
377 surface dust loading over the Indian Ocean, eastern edge of Africa, southern India, and Southeast Asia.  
378 The simulated latitudinal transport of Middle Eastern dust is limited (Figure S5). Our model suggests  
379 that the contribution of North African and Asian dust to the surface dust in the Arctic is similar.  
380 Significant contributions of Asian dust are confirmed through ice core isotopic analysis of the dust  
381 deposited at the ice camp in Greenland (Bory et al., 2002; 2003). Note that the current model fails to  
382 consider high-latitude dust sources in Siberia and Alaska, which are believed to be the major  
383 contributors to Arctic dust (Lambert et al., 2015; Zwaafink et al., 2016).

## 384 4.2 Vertical distribution of dust

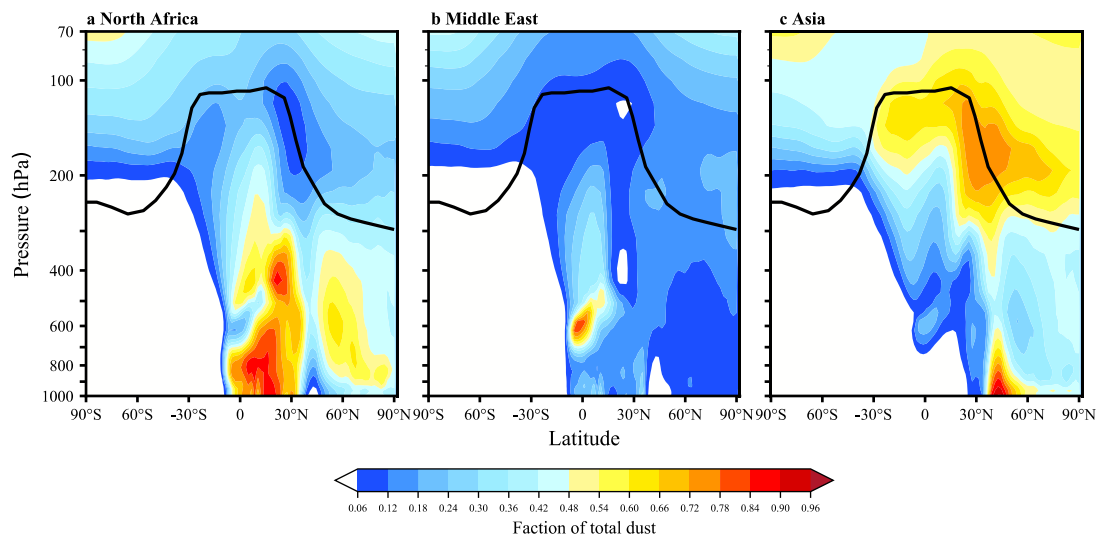

385 Figure 8 compares the simulated vertical distributions of North African, Middle Eastern, and Asian dust  
386 in the lower, middle, and upper troposphere averaged from 2014 to 2018. Simulated global dust  
387 concentrations drop by one order of magnitude from the surface to about 600 hPa and by four orders of  
388 magnitude from the surface to 160 hPa. The rapid decline of dust mass concentration is due mostly to  
389 deposition and subgrid-scale convective removal above the cloud base (Yu et al., 2019; Froyd et al.,  
390 2022). However, Maloney et al. (2022) show that heterogenous nucleation of ice on dust, followed by  
391 sedimentation also contributes to loss of dust from the mid and upper troposphere. Model results show  
392 that the dust from the Sahara, Middle East, and Asia accounts for ~61.7%, 12.9%, and 13.9% of global  
393 annual mean surface dust concentration, respectively. In the NH midlatitudes, the relative contribution  
394 of Asian dust increases with altitude and becomes dominant in the upper troposphere. Asian dust  
395 contributes ~60.9% of the dust at pressures from 266 hPa to 160 hPa. Asian dust is mostly lifted in the  
396 spring by mid-latitude frontal systems (Caffrey et al., 2018). This higher relative contribution of Asian  
397 dust in the upper troposphere of the NH midlatitudes and tropics suggests that Asian dust is lifted more  
398 efficiently than North African dust. Asian dust is mostly lifted in mid-latitude springtime weather  
399 systems that are efficient at transporting dust aloft. North African dust is lifted in tropical systems that  
400 are less efficient at transporting dust to high altitudes since there is widespread descending air at the  
401 latitudes of the North African, which is in the descending branch of the Hadley circulation (Su and  
402 Toon, 2011). The upward transport of North African dust is restricted due to infrequent deep convection  
403 over the North African (Froyd et al., 2022). Frequent convective activity and cold frontal systems  
404 (Kawai et al., 2018, 2015; Hara et al., 2009) transport Asian dust upward to higher altitudes. Figures  
405 8d-8e show that the upper tropospheric dust concentration in the NH midlatitudes is about one order of  
406 magnitude higher than that in the tropics. Note that the tropical dust in the middle and upper  
407 troposphere over the Pacific basin is overestimated by one order of magnitude compared with the  
408 Atom1 observation (Figure 5). However, model's performance on the tropical dust varies with seasons.  
409 For example, model underestimated the Atom3 observation by one-order of magnitude, while better  
410 agreements are made compared with Atom2 and Atom4 observations (Supplement figures S2-S4). In  
411 general, modeled annual mean distribution of tropical dust is subject to large uncertainties (in Figure  
412 8). Especially the convective transport parameterization for a climate model with coarse resolution is

413 still highly uncertain.

414  
415 **Figure 8.** (a) Simulated vertical profiles of average dust concentration for 2014 to 2018 from each  
416 desert emission zone; green bars denote North African dust, red bars denote Middle Eastern dust, and  
417 blue bars denote Asian dust. (b-d) Same as Figure 8a but averaged for Northern Hemisphere (NH)  
418 midlatitudes (30°N-60°N) and tropics (30°S-30°N) from 500 to 350 hPa. (d-e) Same as Figure 8b-8c  
419 but for pressure levels from 266 to 160 hPa.

420 Figure 9 shows the vertical distribution of the zonal and annual mean dust fractional contributions  
421 from the three dust source regions. The Sahara dominates the tropical dust budget from the surface to  
422 the upper troposphere and accounts about 50% of dust in the troposphere of the NH mid-high latitudes.  
423 The model shows that limited North African dust is transported into the stratosphere. In contrast, Asian  
424 dust contributes less than North African dust in the troposphere except for the midlatitudes where the  
425 sources are located. Asian dust contributes more than 40% of the dust in the global UTLS, with the  
426 peak in the NH midlatitude UTLS having a mass fraction of more than 60%. Once the Asian dust is  
427 lifted high enough into the stratosphere, some can be transported to the SH UTLS. Our model suggests  
428 that Asian dust might be the dominant source of ice nucleating particles in the global UTLS. The  
429 simulations show that the fractional contribution of North African and Asian dust is comparable in the  
430 lower and middle troposphere of the Arctic.

431

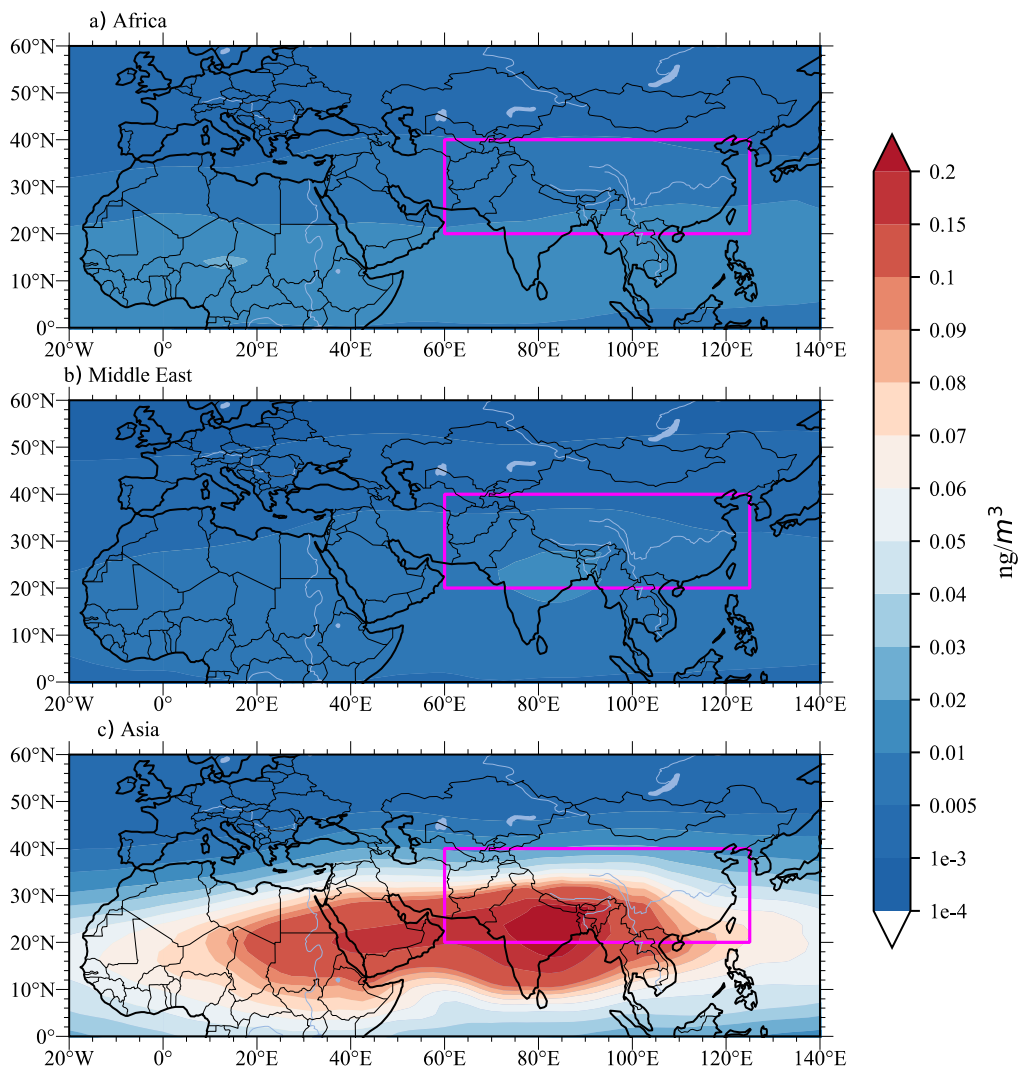

432 **Figure 9.** Simulation of each dust source’s fractional contribution to zonal and annual average total  
 433 dust as a function of altitude (left axis) and latitude (bottom axis). Shading indicates dust  
 434 concentrations, and the black line in each figure denotes the annually averaged simulated tropopause  
 435 height.

#### 436 **4.3 Dust attribution in the Asian summer monsoon region**

437 A layer of aerosols in the UTLS of the ASM is revealed by satellites (Thomason and Vernier, 2013;  
 438 Vernier et al., 2015; Vernier et al., 2011) and balloon-borne optical particle counters (Vernier et al.,  
 439 2018; Yu et al., 2017). In the meantime, a high occurrence of cirrus clouds is found by satellites (Sassen  
 440 et al., 2008; Nazaryan et al., 2008). The relative contributions of dust particles to the cirrus cloud in the  
 441 ASM region remain unquantified and worth future evaluation. Recent airborne in-situ measurements  
 442 suggest that the ASM tropopause aerosol layer is composed of mostly sulfate, organics, and nitrate  
 443 (Hopfner et al., 2019; Appel et al., 2022). The budget of dust particles near the tropopause (~100 hPa)  
 444 and at cirrus altitudes (e.g., 500-200 hPa) remains unquantified.

445 Figure 10 illustrates the simulated June-July-August (JJA) dust concentrations at 100 hPa  
 446 averaged from 2014 to 2018. A peak of dust is simulated in the ASM region associated with the  
 447 anticyclonic air flow similar to sulfate and organics. However, the dust abundance is extremely limited  
 448 compared with sulfate and organics. The simulated mass fraction of aerosol contributed by dust is ~4%  
 449 at 200 hPa and 0.08% at 100 hPa inside the ASM (Figure S6). As expected, Asian dust dominates the  
 450 dust budget in the ASM region, with a relative contribution 1-2 orders of magnitude higher than North  
 451 African and Middle Eastern dust. There is limited North African and Middle Eastern dust transport to

452 the ASM region by the strong upper tropospheric westerlies (Tanaka et al., 2005; Prasad and Singh,  
453 2007). Note that the dust concentration simulated by CESM1/CARMA at 100 hPa in the ASM region is  
454 about  $9 \times 10^{-5} \mu\text{g}/\text{m}^3$ , which is about 3 orders of magnitude smaller than the values simulated by the  
455 CESM-MAM7 model reported by Bossolasco et al. (2021). Such low values of dust concentration are  
456 due to inclusion of secondary activation of dust above the cloud base in the convective transport  
457 scheme revised by Yu et al. (2019). Failure to include this removal will lead to large overestimates of  
458 dust aloft.

459  
460 **Figure 10.** Simulated mass concentrations of North African, Middle East and Asian dust at 100 hPa  
461 (left) averaged in June-July-August (JJA) from year 2014 to 2018. Purple boxes denote the Asian  
462 Summer Monsoon region.

## 463 **5 Summary**

464 This study uses a sectional aerosol model coupled with a climate model, CESM1/CARMA, to simulate  
465 the global distribution of dust, 85% over which comes from Asian, Middle Eastern, and North African  
466 sources. Compared with measurements reported in Adebisi and Kok (2020), the model of Yu et al.  
467 (2015b) underestimates the observed dust in the size range between 1 and 3  $\mu\text{m}$  by one order of  
468 magnitude. We modified the size distribution of the dust emission, and the improved model is within  
469 the error bars of measurements summarized by Adebisi and Kok (2020). Both observations and the  
470 simulations suggest that the dust mass size distribution increases by about 4 orders of magnitude from  
471 0.1  $\mu\text{m}$  to 2  $\mu\text{m}$ , reaches its highest values around 2-3 micrometers in diameter and remains fairly  
472 constant for larger sizes up to 20  $\mu\text{m}$  diameter. We compared the simulated dust distributions with  
473 multiple observational datasets including surface and airborne in-situ measurements over remote  
474 regions and aerosol optical depth measurements near the dust source regions. CESM1/CARMA  
475 reproduces the annual mean dust surface concentrations around the globe within one order of  
476 magnitude of the observations summarized in Huneus et al. (2011). The global vertical distributions of  
477 dust measured by PALMS during the NASA ATom field campaign are used to constrain the model.  
478 Both the model and PALMS measurements suggest that dust mass concentrations over remote ocean  
479 basins drop by two to three orders of magnitude from the surface to the upper troposphere (200 hPa).  
480 Simulations show that about 52% of dust near the surface are coarse, while 95% of the total dust  
481 concentration in the upper troposphere is fine dust (with diameter less than 4.5  $\mu\text{m}$ ). The rapid decline  
482 of dust aerosols with altitude is associated with the efficient in-cloud convective removal of dust  
483 aerosols (Froyd et al., 2022; Yu et al., 2019). However, in situ cirrus formation can also lead to  
484 downward transport of dust (Maloney et al., 2022). In addition, both the model and PALMS  
485 measurements suggest that dust concentrations in the lower troposphere of the NH midlatitudes (27°N-  
486 60°N) and tropics (27°S-27°N) are about an order of magnitude higher than that in the SH midlatitudes  
487 (27°S-60°S). The model captures ~90% of the annual mean column aerosol optical depth measured by  
488 33 AERONET stations near the dust source regions.

489 Our simulations suggest that the annual mean dust emissions from the Sahara, Middle East, and  
490 Asia account for ~59.7%, 12.5%, and 13.3% of global annual mean dust emissions, respectively. Dust  
491 emitted from the Sahara is transported toward Europe, but mostly to the Western Hemisphere including

492 the North Atlantic basin, and eastern North America. Asian dust dominates the Eastern Hemisphere  
493 including the North Pacific basin, Russia, and some can be transported to Alaska and Canada. Middle  
494 Eastern dust contributes significantly to the surface dust over the Indian Ocean, the eastern edge of  
495 Africa, southern India, and Southeast Asia. Although North African dust dominates global dust mass  
496 loading at the surface, the relative contribution of Asian dust increases with altitude and becomes  
497 dominant in the upper troposphere of the northern hemisphere (NH). Once the Asian dust is lifted high  
498 enough into the stratosphere, some can be transported to the SH UTLS. Asian dust might be the  
499 dominant source of ice nucleating particles in the global UTLS. Asian dust contributes ~60.9% of the  
500 dust mass at pressure levels from 266 hPa to 160 hPa. The increasing fractional contribution of Asian  
501 dust is due to efficient vertical transport in midlatitude weather systems, while tropical weather systems  
502 are not as efficient due to subsiding motion in the descending branch of the Hadley circulation and  
503 convective activity over the Sahara is relatively infrequent (Froyd et al., 2022). Asian dust dominates  
504 the dust budget in the global upper troposphere during the summer months, with the peak fractional  
505 contribution in the ASM region, which is about 1-2 orders of magnitude higher than that of North  
506 African and Middle Eastern dust. The model suggests that the dust forms a local maximum in the ASM  
507 anticyclone as well as organics and nitrate (Yu et al., 2022). However, the simulated dust mass  
508 concentration is only ~0.08% of the total aerosols in the Asian Tropopause Aerosol Layer (ATAL).  
509 Constrained by the state-of-the-art measurements of dust at the global scale, our model highlights the  
510 significant contribution of Asian dust to the global upper troposphere where cirrus clouds may form  
511 heterogeneously.

512 *Data availability.* Dust surface measurements data are reported in Huneus et al. (2011) and can be  
513 found at [https://aerocom-classic.met.no/DATA/download/DUST\\_BENCHMARK\\_HUNEEUS2011/](https://aerocom-classic.met.no/DATA/download/DUST_BENCHMARK_HUNEEUS2011/);  
514 NASA ATom data are available at <https://espo.nasa.gov/atom/content/ATom>; AERONET data can be  
515 found <http://aeronet.gsfc.nasa.gov/>.

516

517 *Author contributions.* P.Y. designed the research and ran CESM1/CARMA model. S.L. analyzed the  
518 model output, observational datasets and wrote the paper. L.Z, D.M.M, K.D.F and O.B.T provided  
519 effective and constructive comments on the study. K.D.F and D.M.M provided the PLAMS datasets.  
520 All authors edited the paper.
