23 **Abstract.** Here we present a field measurement of ClNO<sub>2</sub> (nitryl chloride) and N<sub>2</sub>O<sub>5</sub> (dinitrogen  
24 pentoxide) by a Time-of-Flight Chemical Ionization Mass Spectrometer (ToF-CIMS) with the Filter  
25 Inlet for Gas and AEROSols (FIGAERO) at a regional site in Pearl River Delta during a  
26 photochemical pollution season from Sept. 26<sup>th</sup> to Nov. 17<sup>th</sup>, 2019. Three patterns of air masses are  
27 sampled during this campaign, including the dominating air masses from the north and northeast  
28 urban regions (Type A), the southeast coast (Type B), and the South China Sea (Type C). The  
29 concentration of ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> were observed to be much higher in Type A and B than in Type C,  
30 indicating that the urban nighttime chemistry is more active than the background marine regions.  
31 N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> production yield were estimated based on the field measurement,  
32 and the performance of the previously derived parameterizations was assessed. The nighttime ClNO<sub>2</sub>  
33 correlated with particulate chloride and the mass concentration of fine particles (most likely due to  
34 aerosol surface area), suggested that the ClNO<sub>2</sub> formation was limited by the N<sub>2</sub>O<sub>5</sub> uptake at this site.  
35 By examining the relationship between particulate chloride and other species, we implied that  
36 anthropogenic emissions (e.g., biomass burning) rather than sea salt particles dominate the origin of  
37 particulate chloride, although the site beings only about 100 km away from the ocean. A box model  
38 with detailed chlorine chemistry is used to investigate the impacts of ClNO<sub>2</sub> chemistry on  
39 atmospheric oxidation. Model simulations showed the chlorine radical liberated by ClNO<sub>2</sub> photolysis  
40 during the next day had a slight increase in concentrations of OH, HO<sub>2</sub> and RO<sub>2</sub> radicals, as well as  
41 minor contributions to RO<sub>2</sub> radical and O<sub>3</sub> formation (<5%, on daytime average) in all the three types  
42 of air masses. Relative higher contributions were observed in Type A and B. The overall low  
43 contributions of ClNO<sub>2</sub> to atmospheric oxidation are consistent with those reported recently from  
44 wintertime observations in China (including Shanghai, Beijing, Wangdu and Mt. Tai). This may be  
45 attributed to: (1) Relative low particle mass concentration limited ClNO<sub>2</sub> formation; (2) Other  
46 reactions channels, like nitrous acid (HONO), oxygenated volatile organic compounds (OVOCs,  
47 including formaldehyde), and ozone photolysis, had more significant radical formation rate during  
48 the ozone pollution episodes and weakened the ClNO<sub>2</sub> contribution indirectly. The results provided  
49 scientific insights into the role of nighttime chemistry in photochemical pollution under various  
50 scenarios in coastal areas.

51

## 52 1. Introduction

53 Chlorine radical is an important oxidant in the tropospheric besides OH radicals, NO<sub>3</sub> radicals and  
54 ozone (Saiz-Lopez and von Glasow, 2012; Simpson et al., 2015; Wang et al., 2019b), which alters the  
55 fate of many atmospheric compositions, including oxidants, reactive nitrogen compounds, volatile  
56 organic compounds (VOCs), and other halogens. Cl radical is much more reactive than OH  
57 concerning certain VOCs (e.g., alkanes) by a few orders of magnitude for reaction rate constant  
58 (Atkinson and Arey, 2003; Atkinson et al., 2006). therefore, it contributes to atmospheric oxidation  
59 capacity considerably in the troposphere despite low concentrations. For example, the global model  
60 showed about 20 % of ethane, 14 % of propane oxidation are attributed to chlorine chemistry at the  
61 global scale (Wang et al., 2019c). Modeling simulations also demonstrated that chlorine chemistry  
62 enhanced oxidative degradation of VOCs by >20% at some locations (Sarwar et al., 2014).

63 Photolysis of ClNO<sub>2</sub> (R1) is a major source of the tropospheric chlorine radical (Thornton et al.,  
64 2010b; Simpson et al., 2015), other chlorine radical sources include the reaction of HCl with OH  
65 (Riedel et al., 2012; Eger et al., 2019), photolysis of Cl<sub>2</sub> and other halogen compounds like ICl and  
66 BrCl (Peng et al., 2021). Tropospheric ClNO<sub>2</sub> is not only a critical chlorine activation precursor but  
67 also a nocturnal reservoir of reactive nitrogen, which is mainly formed by N<sub>2</sub>O<sub>5</sub> heterogeneous  
68 reaction on chlorine-containing particles with a branching ratio at nighttime (R2).

71 where  $\varphi$  represents the yield of ClNO<sub>2</sub>. This mechanism was firstly proposed by Finlaysonpitts et al.  
72 (1989) through detecting the products of N<sub>2</sub>O<sub>5</sub> uptake on NaCl particles. Given this reaction, the  
73 formation of ClNO<sub>2</sub> can be influenced by the N<sub>2</sub>O<sub>5</sub> uptake (such as N<sub>2</sub>O<sub>5</sub> uptake probabilities and  
74 aerosol surface area) as well as the production yield of ClNO<sub>2</sub>.

75 N<sub>2</sub>O<sub>5</sub> uptake coefficient,  $\gamma(\text{N}_2\text{O}_5)$ , have been reported highly varied under tropospheric conditions  
76 (Brown and Stutz, 2012). Both the field and laboratory studies revealed that this process can be  
77 affected by ambient temperature, relative humidity (Mozurkewich and Calvert, 1988; Mentel et al.,  
78 1999; Hallquist et al., 2003), chemical compositions (such as the content of nitrate, liquid water,  
79 chloride, and organics) (Mentel et al., 1999; Brown et al., 2006; Bertram and Thornton, 2009; Gaston  
80 et al., 2014; McDuffie et al., 2018b; Tang et al., 2014; Anttila et al., 2006), as well as particle  
81 morphology (Mielke et al., 2013; Zong et al., 2021). Until now, the key factors that controlling N<sub>2</sub>O<sub>5</sub>

82 uptake coefficient in the different environments are still not well understood. ClNO<sub>2</sub> yield is also  
83 highly varied subject to the liquid water and chloride content in the aerosol (Behnke et al., 1997;  
84 Roberts et al., 2009; Bertram and Thornton, 2009). Several studies demonstrated that the ClNO<sub>2</sub>  
85 yield is also affected by other factors like aerosol sulfate (Staudt et al., 2019) and organics (Ryder et  
86 al., 2015; Tham et al., 2018; McDuffie et al., 2018a). However, the comprehensive quantitative  
87 relationship of these factors in controlling the yield still has large uncertainties. These gaps in  
88 parameterization of N<sub>2</sub>O<sub>5</sub> uptake coefficients and ClNO<sub>2</sub> yield result in challenging to accurately  
89 predict ClNO<sub>2</sub> and particulate nitrate production.

90 Osthoff et al. (2008) and Thornton et al. (2010a) directly observed elevated ClNO<sub>2</sub> in coastal and  
91 inland U.S. by chemical ionization mass spectrometer (CIMS), respectively. They shed light on the  
92 significance of ClNO<sub>2</sub> photolysis in launching the radical chemistry during the morning time, and  
93 also affecting halogen chemistry and reactive nitrogen cycling. Large amounts of chlorine radicals  
94 are liberated through the photolysis of nocturnal accumulated ClNO<sub>2</sub> (R1), which oxidizes VOCs and  
95 produces peroxy radicals (RO<sub>2</sub>) to initiate the daytime radical cycling in the morning, when other  
96 radical source, like ozonolysis and photolysis of O<sub>3</sub>, HONO and HCHO, are still weak (Osthoff et al.,  
97 2008). The impacts of ClNO<sub>2</sub> chemistry on primary source of radicals and ozone formation is a  
98 critical topic, the answer of which is very helpful to narrow the gap of the missing primary source of  
99 RO<sub>x</sub> and improve our knowledge of the correct ozone pollution mechanism (Tan et al., 2017; Tham  
100 et al., 2016). Model simulation highlighted ClNO<sub>2</sub> chemistry could increase mean daily maximum 8  
101 h ozone by up to 7.0 ppbv in some areas in the Northern Hemisphere (Sarwar et al., 2014). The large  
102 contribution was also confirmed in the southern California region by a box model study (Riedel et al.,  
103 2014). In addition, global model simulation showed ClNO<sub>2</sub> chemistry increases wintertime ozone by  
104 up to 8 ppb over polluted continents (Wang et al., 2019c). Particularly, previously modelling results  
105 also highlight the importance of ClNO<sub>2</sub> chemistry in enhancing O<sub>3</sub> production in China (Li et al.,  
106 2016; Yang et al., 2022b).

107 Several field studies reported the measurement of ClNO<sub>2</sub> in varied environments in the past  
108 decade (Riedel et al., 2012; Young et al., 2012; Mielke et al., 2013; Riedel et al., 2013; Bannan et al.,  
109 2015; Faxon et al., 2015; Mielke et al., 2015; Phillips et al., 2016; Bannan et al., 2017; Wang et al.,  
110 2017c; Wang et al., 2017d; Le Breton et al., 2018; McDuffie et al., 2018a; Yun et al., 2018a; Zhou et  
111 al., 2018; Bannan et al., 2019; Eger et al., 2019; Haskins et al., 2019; Jeong et al., 2019; Xia et al.,  
112 2020; Xia et al., 2021; Tham et al., 2016; Tham et al., 2014; Wang et al., 2016; Phillips et al., 2012;  
113 Lou et al., 2022; Sommariva et al., 2018), in which the maximum ClNO<sub>2</sub> up to sub-ppbv to several  
114 ppbv were reported, indicating its ubiquitous presence worldwide and a broad atmospheric impacts  
115 over various regions. During the CalNex-LA campaign 2010, ClNO<sub>2</sub> was measured at ground site,

116 the Research Vessel and aircraft platform, which depicted a full picture of the abundance of ClNO<sub>2</sub>  
117 and confirmed its large impacts on atmospheric chemistry in both urban and coastal regions in  
118 California (Riedel et al., 2012; Young et al., 2012; Mielke et al., 2013). Recently, Wang et al. (2016)  
119 used a box model simulated the chemical evolution of the plume after leaving the observation site in  
120 Hongkong and showed ClNO<sub>2</sub> chemistry had a following-day enhancement of ozone peak and  
121 daytime ozone production rate by 5–16% and 11–41%, along with a large increasing of OH, HO<sub>2</sub> and  
122 RO<sub>2</sub> concentration especially in the morning. While Xia et al. (2021) and Lou et al. (2022) reported  
123 winter measurements of ClNO<sub>2</sub> in north and east China, respectively, they both showed moderate  
124 ClNO<sub>2</sub> level and a relative small contributions of ClNO<sub>2</sub> chemistry to radical source and ozone  
125 enhancement on campaign average. These results is quite different with that happened during the  
126 summertime in China (Tham et al., 2016; Wang et al., 2016; Tan et al., 2017), and highlight the large  
127 variation of ClNO<sub>2</sub> chemistry influenced by temporal spatial distribution.

128 Despite its likely importance to the regional atmospheric oxidation and air quality, investigations  
129 of ClNO<sub>2</sub> chemistry in China remain relatively sparse. There are several field measurements of  
130 ClNO<sub>2</sub> conducted in the China in recent years, while considering the large diversities of air mass in  
131 inland and coastal regions in China, more field and model works are need to gain more insights to  
132 the ClNO<sub>2</sub> chemistry in various atmospheric environments and assess its atmospheric impacts. Until  
133 now, only several field measurement of ClNO<sub>2</sub> were reported in Pearl River Delta (PRD) region  
134 (Tham et al., 2014; Wang et al., 2016; Yun et al., 2018a), and only Wang et al. (2016) reported a  
135 comprehensive analysis of the impact of ClNO<sub>2</sub> chemistry on radical and ozone formation in 2013 as  
136 mentioned before. To understanding the increasing O<sub>3</sub> problem in recent years (Wang et al., 2019a)  
137 and examining the role of ClNO<sub>2</sub> chemistry in O<sub>3</sub> formation in PRD, we measured ClNO<sub>2</sub>, N<sub>2</sub>O<sub>5</sub>, and  
138 other related parameters at a regional site in PRD during a severe photochemical pollution season in  
139 2019. The abundance, formation, and variation during different air masses patterns are well  
140 characterized. The factors impact its formation are diagnosed. Finally, the contribution of chlorine  
141 radicals liberated by ClNO<sub>2</sub> photolysis on the daytime radical chemistry, as well as ozone formation  
142 are comprehensively assessed by a box model coupled with detailed chlorine chemistry.

## 143 **2. Method**

### 144 **2.1 Measurement site**

145 This campaign was conducted at the Guangdong Atmospheric Supersite of China, which is located  
146 on the top of a mountain (~ 60 m high, a.s.l.) in Heshan (22.728°N, 112.929°E), Jiangmen city,  
147 Guangdong Province (Yang et al., 2022a) . This site was in the western Peral River Delta where no  
148 major industry in the surroundings, but with some farmland and a few residents live at the hill foot.

149 The traffic is far away from this site and believed to have little influence on the sampling. The  
150 anthropogenic activity is much lower than the urban regions like Guangzhou City, but the air quality  
151 is often influenced by neighbor cities, especially the outflow of air masses from the regions on the  
152 north and northeast. Therefore, the air masses sampled at this site are sometimes representative of the  
153 urban pollution from the center PRD. There were many atmospheric intensive studies once  
154 conducted in the site to study the air pollutions in PRD (Tan et al., 2019; Yun et al., 2018b). In this  
155 study, the instruments were located on the top floor of the measurement building with inlets  
156 approximately 15 m above the ground. The data presented in the study were collected from 27<sup>th</sup>  
157 September to 17<sup>th</sup> November 2019, during which photochemical pollution occurred frequently (Yang  
158 et al., 2022a). Time is given as CNST (Chinese National Standard Time = UTC+8 h). During the  
159 campaign, sunrise was approximately at 06:00 and sunset was approximately at 18:00 CNST.

## 160 **2.2 Instrument setup**

161 A comprehensive suite of instrumentation was overviewed and listed in Table 1. An iodide-adduct  
162 Time-of-Flight Chemical Ionization Mass Spectrometer (ToF-CIMS) with the Filter Inlet for Gas and  
163 AEROSols (FIGAERO) was applied to measure ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> along with other oxygenated  
164 organic species (Ye et al., 2021; Wang et al., 2020b). In brief, the gas phase species were measured  
165 via a 2-m-long, 6-mm-outer-diameter PFA inlet while the particles were simultaneously collected on  
166 a Teflon filter via a separate 2-m-long, 10-mm-outer-diameter copper tubing inlet; both had flow  
167 rates of 2 L min<sup>-1</sup> with a drainage flow of 20 L min<sup>-1</sup>. The gas phase was measured for 25 minutes at  
168 1 Hz, and the FIGAERO instrument was then switched to place the filter in front of the ion molecule  
169 region; it was then heated incrementally to 200 °C to desorb all the mass from the filter to be  
170 measured in the gas phase, which resulted in high-resolution thermograms. ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> are  
171 measured as the iodide adduct ions at m/z 207.867 (IClNO<sub>2</sub><sup>-</sup>) and m/z 234.886 (IN<sub>2</sub>O<sub>5</sub><sup>-</sup>) in the ToF-  
172 CIMS, respectively. The measurement background and sensitivities for detecting ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub>  
173 with the dependence of water content were quantified (see Appendix). The limit of detection (LOD)  
174 for ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> were 4.3 and 6.0 pptv in 1-minute time-resolution, respectively, with an  
175 uncertainty of ~30%.

176 Sub-micron aerosol composition (PM<sub>1</sub>) were measured by a High-Resolution Time of Flight  
177 Aerosol Mass Spectrometer (HR-ToF-AMS) (DeCarlo et al., 2006). The soluble ions of sodium and  
178 potassium was measured by a commercial instrument (GAC-IC) equipped with an aerosol collector  
179 and detected by ion chromatography (Dong et al., 2012). The particle number size distribution  
180 (PNSD) was measured by a scanning mobility particle sizer (SMPS, TSI 3938). The aerosol surfaces  
181 area was calculated based on the size distribution measurement and corrected to wet particle-state by

182 a hygroscopicity growth factor, with a total uncertainty of determining wet aerosol surface areas by  
 183 ~30% (Liu et al., 2013). VOCs were measured by Proton Transfer Reaction Time-of-Flight Mass  
 184 Spectrometry (PTR-MS)(Wu et al., 2020; He et al., 2022) and an automated gas chromatograph  
 185 equipped with mass spectrometry or flame ionization detectors (GC-MS). A commercial instrument  
 186 (Thermo Electron model 42i) was used to monitor NO<sub>x</sub>. O<sub>3</sub> was measured by a commercial  
 187 instrument using ultraviolet (UV) absorption (Thermo Electron 49i). PM<sub>2.5</sub> was measured by a  
 188 Tapered Element Oscillating Microbalance (TEOM, 1400A analyzer). SO<sub>2</sub> and CO were measured  
 189 by commercial instruments (Thermo Electron 43i and 48i). In addition, the meteorological  
 190 parameters were available during the measurement. Photolysis frequencies were determined by a  
 191 spectroradiometer (Bohn et al., 2008). The aerosol liquid water content (ALWC) is calculated from  
 192 the ISORROPIA-II thermodynamic equilibrium model (Clegg et al., 1998). We used the reverse  
 193 mode in ISORROPIA-II with the input of water-soluble ions along with ambient temperature (*T*) and  
 194 relative humidity (RH). Given the high RH in this campaign, we ran the model by assuming aerosol  
 195 phase were metastable.

196 **Table 1.** Summary of the information about observed gas and particle parameters during the  
 197 campaign.

Species	Limit of detection	Methods	Accuracy
N <sub>2</sub> O <sub>5</sub>	6.0 pptv (3σ, 1 min)	FIGAERO-ToF-CIMS	± 30%
ClNO <sub>2</sub>	4.3 pptv (3σ, 1 min)	FIGAERO-ToF-CIMS	± 30%
NO	60 pptv (2σ, 1 min)	Chemiluminescence	± 20%
NO <sub>2</sub>	0.3 ppbv (2σ, 1 min)	Mo convert	± 20%
O <sub>3</sub>	0.5 ppbv (2σ, 1 min)	UV photometry	± 5%
VOCs	0.1 ppbv (5 min)	PTR-ToF-MS	± 30%
VOCs	20-300 pptv (1 h)	GC-FID/MS	± 20%
PM <sub>2.5</sub>	0.1 μg m <sup>-3</sup> (1 min)	TEOM	± 5%
CO	4 ppbv (5 min)	IR photometry	± 5%
SO <sub>2</sub>	0.1 ppbv (1 min)	Pulsed UV fluorescence	± 10%
HCHO	25 pptv (2 min)	Hantzsch fluorimetry	± 5%
PNSD	14 nm -700 nm (4 min)	SMPS	± 20%
Aerosol composition	<0.16 μg m <sup>-3</sup> (30 min)	GAC-IC	± 30%
PM <sub>1</sub> components	0.15 μg m <sup>-3</sup> (4 min)	HR-ToF-AMS	± 30%
Photolysis frequencies	Varies with species (20 s)	Spectroradiometer	± 10%

198

### 199 2.3 Box model setup

200 A zero-dimensional chemical box model constrained by the field campaign data was applied to  
 201 simulate the ClNO<sub>2</sub> chemistry. The box model was based on the Regional Atmospheric Chemical  
 202 Mechanism version 2 (RACM2) described in Goliff et al. (2013), and chlorine-related chemical

203 mechanism was added (Wang et al., 2017b; Tan et al., 2017). Briefly, chlorine chemistry was adapted  
204 to RACM2 from the modifications to Master Chemical Mechanism (Xue et al., 2015), and the  
205 oxidation products from reactions between lumped VOC species and chlorine radicals were adapted  
206 from those of OH oxidation from RACM2.  $j(\text{ClNO}_2)$  was calculated according to the NASA-JPL  
207 recommendation based on the work by Ghosh et al. (2012). The impact of  $\text{O}_3$  by  $\text{ClNO}_2$  chemistry  
208 was assessed by differing the results of two scenarios with and without the constrains of the observed  
209  $\text{ClNO}_2$  in the model simulation. For the reaction rate constant of the lumped species with Cl, the  
210 fastest value from different species was used to represent the upper limit of the impact of chlorine  
211 chemistry. It should be note that the setting will lead to overestimation on the contributions from  
212  $\text{ClNO}_2$  chemistry. The model was constrained by the observed  $\text{ClNO}_2$ ,  $\text{NO}_x$ ,  $\text{O}_3$ , CO, VOCs  
213 (assignment to RACM2), photolysis frequencies, ambient temperature, and pressure. The model runs  
214 were from 29 September to 17 November, 2019 with most of the measurement data taken accounted  
215 for, and with a two-days spin-up. The constant lifetime corresponds to a deposition velocity of 1.2  
216  $\text{cm s}^{-1}$  with an assumed boundary layer height of 1000 m was used for the input trace gases, and the  
217 model-generated species were set to 24 hours lifetime due to the loss caused by the dry deposition  
218 (Lu et al., 2012). The input data were averaged and interpolated to 1 hour of resolution.

### 219 **3. Results and discussions**

#### 220 **3.1 Overview of measurement**

221 Figure 1 shows time series of  $\text{ClNO}_2$  and relevant trace gases, particles, and meteorological  
222 parameters during the measurements. In this campaign, the meteorological condition featured high  
223 temperature ( $24.7 \pm 3.8$  °C) and high humidity ( $62.1\% \pm 15.6\%$ ), low wind speed ( $1.5 \pm 0.8$   $\text{m s}^{-1}$ ),  
224 and the dominant air flow were from north and northwest. Compared to those with previously  
225 measurements at the same site in January 2017 (Yun et al., 2018b), the temperature was higher and  
226 relative humidity was lower during the measurements. The average and maximum concentration of  
227 particulate matter ( $\text{PM}_{2.5}$ ) was  $47.6 \pm 19.3$   $\mu\text{g m}^{-3}$  and  $138$   $\mu\text{g m}^{-3}$ , respectively, which is significantly  
228 lower than that observed in January 2017, with a maximum up to  $400$   $\mu\text{g m}^{-3}$ . The dominant air  
229 pollutant was  $\text{O}_3$  with hourly campaign maximum and the average mean daily maximum 8-hour  $\text{O}_3$   
230 (MDA8  $\text{O}_3$ ) of  $152.8$  ppbv and  $75.2 \pm 20.9$  ppbv, respectively. There were 27 days out of 53 days  
231 with the hourly maximum of  $\text{O}_3$  exceeded the Chinese national air quality standard ( $200$   $\mu\text{g m}^{-3}$ ,  
232 equivalent to 93 ppbv), suggesting severe ozone pollution during the measurement period in PRD

233 region. NO<sub>2</sub> concentration was also elevated with  $21.0 \pm 10.4$  ppbv on campaign average. The  
 234 concurrent high O<sub>3</sub> and NO<sub>2</sub> made large nitrate radical production rate occurred with a daily average  
 235 of  $2.5 \pm 2.1$  ppbv h<sup>-1</sup> (median, 1.8 ppbv h<sup>-1</sup>). The campaign maximum NO<sub>3</sub> production rate was  
 236 observed up to 18.6 ppbv h<sup>-1</sup> in the afternoon at 11<sup>th</sup> November, 2019. At night, the nitrate radical  
 237 production rate was  $1.8 \pm 1.5$  ppbv h<sup>-1</sup> on campaign average (median, 1.4 ppbv h<sup>-1</sup>). However, high  
 238 NO<sub>3</sub> production rate did not mean high concentrations of NO<sub>3</sub>, N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> in the atmosphere,  
 239 as the concentration affected by both their sources and sinks.

240  
 241 **Figure 1.** Time series of N<sub>2</sub>O<sub>5</sub>, ClNO<sub>2</sub> and relevant parameters. The grey dotted line in the O<sub>3</sub> panel  
 242 denotes Chinese national air quality standard for hourly maximum O<sub>3</sub> ( $200 \mu\text{g m}^{-3}$ , equivalent to 93  
 243 ppbv). NO<sub>3</sub> radical is calculated based on a thermal equilibrium with measured NO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub>.

244 N<sub>2</sub>O<sub>5</sub> existed at a moderate concentration at most nights, with the daily nocturnal peaks range from  
 245 <100 pptv to 1180 pptv and nocturnal average of  $64 \pm 145$  pptv. During the nights from 27<sup>th</sup> – 30<sup>th</sup>  
 246 September, 2019, the N<sub>2</sub>O<sub>5</sub> concentration was significantly higher than other nights. The NO<sub>3</sub>  
 247 lifetime, calculated by steady state method (Brown et al., 2003), was much longer in the four nights  
 248 than other nights, implied relative weak sink of NO<sub>3</sub>-N<sub>2</sub>O<sub>5</sub> for the first four nights. The lifetime of  
 249 NO<sub>3</sub> was < 1 minute in general (except the first four nights), indicating active NO<sub>3</sub> chemistry at this  
 250 site. The NO<sub>3</sub> concentration was calculated assuming the thermal equilibrium of NO<sub>2</sub>-NO<sub>3</sub>-N<sub>2</sub>O<sub>5</sub>,  
 251 with a possible lower bias caused by the equilibrium coefficient for reversible reactions of NO<sub>3</sub> and

252  $\text{N}_2\text{O}_5$  ( $K_{eq}$ ) (Chen et al., 2022). Figure 1 shows the variation of calculated  $\text{NO}_3$  coincided with  $\text{N}_2\text{O}_5$ .  
 253 Elevated  $\text{NO}_3$  occurred at the first four nights with a maximum of 90 pptv (1 h time resolution),  
 254 which is comparable with the reported  $\text{NO}_3$  level at other sites in Pearl River Delta (Wang and Lu,  
 255 2019; Brown et al., 2016).  $\text{ClNO}_2$  showed a clear diurnal variation with high level during the night.  
 256 The nocturnal average and hourly maximum were  $198 \pm 232$  pptv and 1497 pptv, respectively. The  
 257 abundance of  $\text{ClNO}_2$  and  $\text{N}_2\text{O}_5$  are lower than those observed at the same site in 2017, with high  
 258  $\text{N}_2\text{O}_5$  and the highest value ever observed  $\text{ClNO}_2$  of 3358 pptv and 8324 pptv (1-minute time  
 259 resolution), respectively (Yun et al., 2018b). The difference of  $\text{ClNO}_2$  level between the two  
 260 campaigns conducted in 2017 and 2019 may be caused by the aerosol loading. High particulate  
 261 chloride ion was observed in the site with  $0.74 \pm 1.33 \mu\text{g m}^{-3}$  on nocturnal average, which was higher  
 262 at night with a peak in the second half of night and decrease at daytime.

### 263 3. 2 Characterization of pollutants in different air masses.

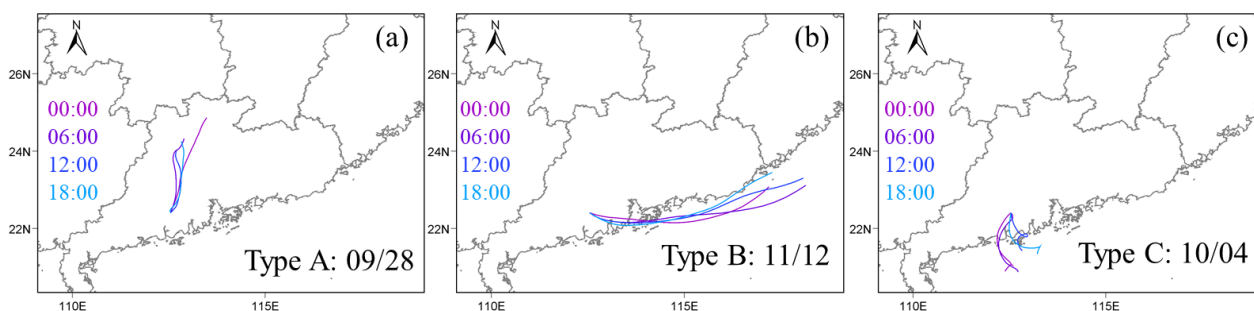

264 We noticed the air mass is highly varied during the measurements. For example, during the period of  
 265 10/02 - 10/05, the observed ozone and  $\text{ClNO}_2$  were much lower than other days; while during the  
 266 period of 11/11 - 11/13, the air masses were much polluted with high  $\text{O}_3$ ,  $\text{PM}_{2.5}$  and  $\text{ClNO}_2$ . We  
 267 therefore plotted the backward trajectories of 24 h history of air masses arriving at the measurement  
 268 site at 500 m AMSL height at 00:00, 06:00, 12:00, 18:00 day by day. The measurement period was  
 269 separated into three patterns meteorologically according to the analysis of backward trajectories.  
 270 Table 2 listed the detailed information about the air mass classification. The air masses from  
 271 northeast (and north) were the dominant with a total of 37 days, which was characterized with the  
 272 outflow of the center city clusters of PRD and those from inland through long distance transport. We  
 273 checked the pollutants of the air masses from PRD and the north out of PRD (e.g., Hunan or Jiangxi  
 274 Province), while no significant difference was found. Therefore, we merged the two inland air  
 275 masses as Type A. The second type was from the coastal or offshore from east and southeast (Type  
 276 B), which features the outflow of coastal cities like Shenzhen and Hong Kong, which occurred on 12  
 277 days in total. The third type was the clean air masses from the South China Sea (4 days, Type C).  
 278 Figure 2 shows three cases of each air masses mentioned above.

279 **Table 2.** The detailed information of three air mass types.

Air mass type	Periods	Days
Type A: inland air from northeast	09/26-10/01;10/08;10/11-10/20;10/24- 11/10;11/14-15	37 (69.8%)
Type B: coast air from east	10/06-07; 10/09-10; 10/21-23; 11/11-13; 11/16-17	12 (22.6%)

Type C: marine air from south	10/02-05	4 (7.5%)
----------------------------------	----------	----------

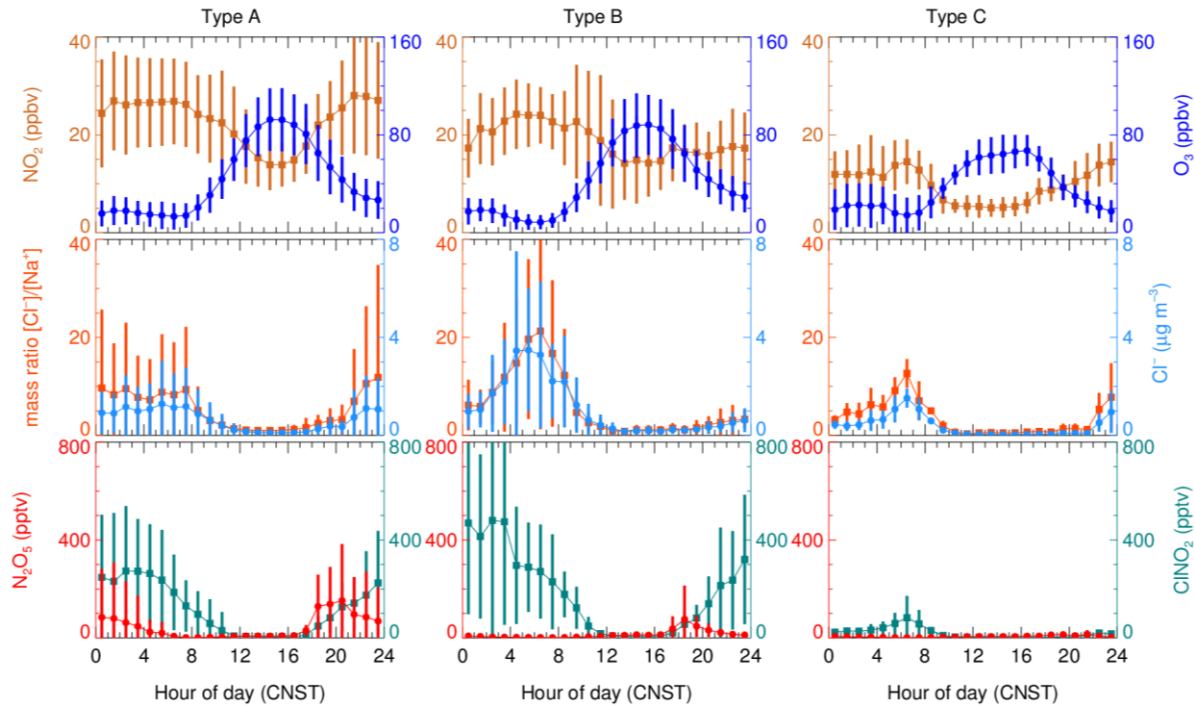

280 The mean diurnal profiles of measured  $\text{NO}_2$ ,  $\text{O}_3$ ,  $\text{N}_2\text{O}_5$ ,  $\text{ClNO}_2$ , the particle chloride content and  
 281 the ratio of chloride to sodium in the three types of air masses are shown in Figure 3, with a detailed  
 282 summary of related parameters in nocturnal medians listed in Table 3. High levels of  $\text{NO}_2$  and  $\text{O}_3$   
 283 were observed in Type A and B air masses, with small difference of  $\text{NO}_2$  diurnal variation during the  
 284 second half of night. In comparison, the two pollutants in Type C were much lower. If we focus on  
 285 the abundance at night, we found a large difference in  $\text{NO}_2$  level with a sequence Type A > Type B >  
 286 Type C, which results in the same sequence of  $\text{NO}_3$  productions in different air masses. The  
 287 nocturnal  $\text{NO}_2$  seems to be a good indicator of the level of pollution, that nocturnal  $\text{CO}$ ,  $\text{PM}_{2.5}$  and  
 288  $\text{SO}_2$  also followed this order with highest concentration in Type A. These results indicate that the  
 289 most polluted air mass came from the inland urban regions of PRD.

290  
 291 **Figure 2.** Three typical cases with air mass from different regions at 29<sup>th</sup> Sept., 12<sup>th</sup> Nov. and 4<sup>th</sup> Oct.,  
 292 respectively. Backward trajectory of 24 h history of air masses arriving at the measurement site with  
 293 500 m height at 00:00, 06:00, 12:00, 18:00.

294 Given the particulate chloride a precursor of  $\text{ClNO}_2$ , we examined its diurnal variations in the  
 295 three air mass types. The highest level of  $\text{Cl}^-$  was found in Type B, and then followed by Type A and  
 296 Type C (also at night). Although the diurnal profile of  $\text{Cl}^-$  in the three types is similar, the increasing  
 297 rate of  $\text{Cl}^-$  during the second half of night in Type A is much slower than those in coastal and offshore  
 298 air masses. This imply a difference source of chloride, which will be further discussed in the Section  
 299 3.4.  $\text{N}_2\text{O}_5$  was observed with moderate concentration in the Type A air mass throughout the night,  
 300 with a nocturnal peak of 152.4 pptv between 20:00-21:00, while little  $\text{N}_2\text{O}_5$  only occurred in the first  
 301 half of night in Type B and C with a peak of 75.9 pptv and 13.6 pptv, respectively. The concentration  
 302 difference may be attribute to two aspects. Firstly, the difference of  $\text{P}(\text{NO}_3)$  results in more  $\text{N}_2\text{O}_5$   
 303 produced in Type A. Secondly, compared with the air mass from coastal or offshore regions, the  
 304 nocturnal temperature and RH condition from Type A is much lower, and the loss of  $\text{N}_2\text{O}_5$  may be

305 faster in Type B and C than that in Type A. The nocturnal median RH in Type A reached up to 67%,  
 306 while 78% and 79% in Type B and Type C, suggesting a favorable condition for heterogeneous  
 307 hydrolysis of  $\text{N}_2\text{O}_5$  for all the three air mass types. The elevated  $\text{ClNO}_2$  was observed in Type A and  
 308 B with a nocturnal peak of 273.6 pptv and 479.8 pptv, respectively. Significantly less  $\text{ClNO}_2$  was  
 309 observed in Type C air mass with a peak of 82.6 pptv. The reason of the different levels of  $\text{ClNO}_2$   
 310 observed in the three air masses types are discussed in Section. 3.4.

311  
 312 **Figure 3.** Mean diurnal profiles of  $\text{N}_2\text{O}_5$ ,  $\text{ClNO}_2$  and relevant parameters in the three types of air  
 313 masses.

314 **Table 3.** Statistics results (median  $\pm$  standard deviation) of the related parameters in the three types  
 315 of air masses (from 18:00 to 06:00 CNST).

Air mass	Type-A	Type-B	Type-C
RH (%)	67.0 $\pm$ 11.9	78.0 $\pm$ 10.9	79.0 $\pm$ 9.1
T ( $^{\circ}\text{C}$ )	22.8 $\pm$ 3.0	23.3 $\pm$ 2.2	25.6 $\pm$ 1.9
$\text{ClNO}_2$ (pptv)	131.0 $\pm$ 202.8	162.0 $\pm$ 310.1	16.7 $\pm$ 21.2
$\text{N}_2\text{O}_5$ (pptv)	17.8 $\pm$ 164.9	6.3 $\pm$ 64.6	2.8 $\pm$ 9.3
$\text{Cl}^-$ ( $\mu\text{g m}^{-3}$ )	0.41 $\pm$ 1.11	0.56 $\pm$ 1.85	0.33 $\pm$ 0.51

$\text{CO}$ (ppbv)	540.3 $\pm$ 122.3	448.4 $\pm$ 130.7	367.5 $\pm$ 89.8

### 316 3.3 N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> yield

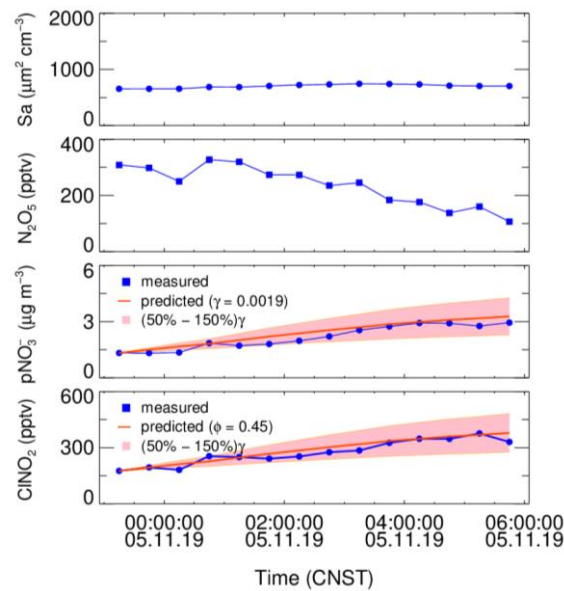

317 In line with previous studies, we estimate N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> yield using the  
318 measurements of N<sub>2</sub>O<sub>5</sub>, ClNO<sub>2</sub> and particulate nitrate (Phillips et al., 2016; Wang et al., 2018; Tham  
319 et al., 2018). By assuming both the nocturnal enhancement of nitrate and ClNO<sub>2</sub> are mainly  
320 attributed to N<sub>2</sub>O<sub>5</sub> uptake processes, ClNO<sub>2</sub> yield can be solely derived by the regression analysis of  
321 ClNO<sub>2</sub> versus particulate nitrate (Wagner et al., 2012; Riedel et al., 2013). The  $\phi_{\text{ClNO}_2}$  can then be  
322 obtained by the fitted regression slope (S, Eq. 1) and named as regression method.

$$323 \phi = 2S/(S+1) \quad (\text{Eq. 1})$$

324 Combining with the data of N<sub>2</sub>O<sub>5</sub> and aerosol surface area, the increase in ClNO<sub>2</sub> and nitrate  
325 can be simulated simultaneously by setting the input of N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> yield  
326 (named as simulation method). The optimal N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> yield are obtained  
327 simultaneously by adjusting the two parameters until the simulation reproduces the observed increase  
328 ClNO<sub>2</sub> and nitrate (Phillips et al., 2016; Xia et al., 2020; Tham et al., 2018). This analysis assumes  
329 only N<sub>2</sub>O<sub>5</sub> uptake process dominates the increase of ClNO<sub>2</sub> and nitrate, and other physicochemical  
330 processes like vertical transportation, depositions are less important. This method requests the air  
331 mass in the analysis duration time is relative stable and less affected by emission and transportation.  
332 In addition, it is not valid in the case with negative changes of ClNO<sub>2</sub> and nitrate. The following  
333 selection criteria is set to pick out the suitable plumes to meet the assumptions. Firstly, the consistent  
334 increase trends of ClNO<sub>2</sub> and the NO<sub>3</sub><sup>-</sup> and clear correlation between them during the analysis  
335 duration should be observed with a regression coefficient threshold of 0.5, which indicates the two  
336 products have the same source. Secondary, an equivalent or faster increase of ammonium  
337 accompanied with nitrate, to ensure insignificant degas of HNO<sub>3</sub> to the atmosphere. The  
338 observational data were averaged to 30 min for the following analysis, the time-period of each  
339 derivation ranges from 2.5 to 10 hours. Figure 4 depicts an example of the derivation on 5<sup>th</sup>  
340 November, 2019, the stable Sa indicates stable air mass during the analysis period. And the  
341 prediction is well reproduced the observed increase in ClNO<sub>2</sub> and NO<sub>3</sub><sup>-</sup>.

342 During this campaign, we carefully identified 20 plumes with clear correlations between ClNO<sub>2</sub>  
343 and particulate nitrate by the slope method ( $R^2 \geq 0.5$ ). As shown in Table 4, the derived ClNO<sub>2</sub> yield  
344 varied from 0.13 to 1.00 with a median of  $0.45 \pm 0.22$  (mean value of 0.44). In the 20 plumes, we  
345 derived N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> for 12 cases in total. The results in other 8 night were not  
346 valid due to the lack of Sa data (four nights) or producing unreasonably high results due to the  
347 observed low N<sub>2</sub>O<sub>5</sub> concentration near the detection limit biased the simulations. We show good  
348 consistent of derived ClNO<sub>2</sub> yields by the two different methods. The estimated N<sub>2</sub>O<sub>5</sub> uptake  
349 coefficient showed a large variation and ranged from 0.0019 to 0.077 with a median of  $0.0195 \pm$

350 0.0288 (mean value of 0.0317). The estimated  $\gamma_{\text{N}_2\text{O}_5}$  is within the range determined by previous  
 351 field studies (Tham et al., 2018). Specifically in China, the average level of  $\gamma_{\text{N}_2\text{O}_5}$  is comparable  
 352 with those reported in urban Beijing (Wang et al., 2017a; Wang et al., 2018), Wangdu (Tham et al.,  
 353 2018), and Jinan (Wang et al., 2017c) during the summertime, but systematically higher than those  
 354 determined in China in wintertime (Xia et al., 2021; Wang et al., 2020a; Brown et al., 2016), except  
 355 the case reported on the urban canopy of Beijing (Chen et al., 2020). McDuffie et al. (2018a)  
 356 summarized the reported  $\phi_{\text{ClNO}_2}$  based on the observations, and we showed that the estimated  
 357 average  $\phi_{\text{ClNO}_2}$  in this study is in the middle to upper end of the values reported globally (Xia et al.,  
 358 2021; McDuffie et al., 2018a). Due to the limited data points, we cannot distinguish the difference of  
 359  $\gamma_{\text{N}_2\text{O}_5}$  between the three air mass patterns. The  $\text{ClNO}_2$  yields in Type A are slightly lower than those  
 360 in Type B with an average of 0.41 and 0.47, respectively.

361  
 362 **Figure 4.** An example of the derivation of  $\text{N}_2\text{O}_5$  uptake coefficient and  $\text{ClNO}_2$  yield constrained by  
 363 observation of aerosol surface area,  $\text{N}_2\text{O}_5$  and the enhancement of particulate nitrate and  $\text{ClNO}_2$  on  
 364 5<sup>th</sup> November, 2019. The pink region presents  $\pm 50\%$  uncertainty of  $\text{N}_2\text{O}_5$  uptake coefficient.

365 **Table 4.** The derived  $\text{N}_2\text{O}_5$  uptake coefficient and  $\text{ClNO}_2$  yields at each night.

NO.	Period	$\gamma_{\text{N}_2\text{O}_5}$ <sup>a</sup>	$\phi_{\text{ClNO}_2}$ <sup>a</sup>	$\phi_{\text{ClNO}_2}$ <sup>b</sup>	$r^{2\text{b}}$	Type
1	10/02 01:00-06:00	NaN	NaN	0.13	0.90	C
2	10/02 23:00-06:00	NaN	NaN	0.25	0.90	C

20	11/13 21:00-00:00	0.0070	0.70	0.75	0.92	B

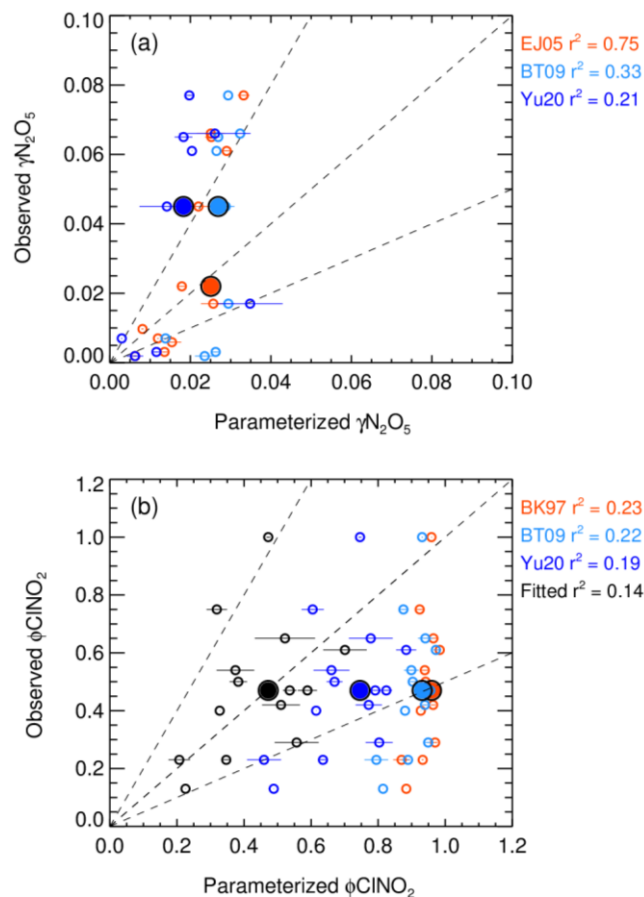

366 Note: <sup>a</sup> the values of  $\gamma\text{N}_2\text{O}_5$  and  $\phi\text{ClNO}_2$  are derived by simulation method; <sup>b</sup> the  $\phi\text{ClNO}_2$  and the  
367 correlation coefficient ( $R^2$ ) between  $\text{ClNO}_2$  and particulate nitrate are derived by regression method,  
368 the data was filtered with a correlation coefficient obtained from linear fitting threshold of 0.5.

369 To gain insight into the factors governing the  $\text{N}_2\text{O}_5$  uptake and  $\text{ClNO}_2$  formation processes, the  
370 estimated  $\gamma\text{N}_2\text{O}_5$  and  $\phi\text{ClNO}_2$  were compared with those predicted from complex laboratory-derived  
371 and field-derived parameterizations. An aqueous inorganic ionic reaction mechanism once raised by  
372 Bertram and Thornton (2009) and established a volume-limited parameterization by considering the  
373 aerosol volume, surface area, nitrate content, ALWC, and chloride content (named BT09, Eq. 8).

$$374 \quad \gamma_{BT09} = \frac{4H_{aq}Vk}{cSa} \left( 1 - \frac{1}{1 + \frac{k_3[\text{H}_2\text{O}]}{k_{2b}[\text{NO}_3^-]} + \frac{k_4[\text{Cl}^-]}{k_{2b}[\text{NO}_3^-]}} \right) \quad (8)$$

375 Where  $H_{aq}$  is Henry's law coefficient of  $\text{N}_2\text{O}_5$ ,  $V$  is the aerosol volume;  $k$  is equal to  $1.15 \times 10^6 - (1.15$   
376  $\times 10^6)^{\exp(-0.13[\text{H}_2\text{O}])}$ ;  $k_3/k_{2b}$  is the ratio of reaction rate of  $\text{H}_2\text{O}$  versus  $\text{NO}_3^-$  to  $\text{H}_2\text{ONO}_2^+$  that was set to  
377 0.06, and  $k_4/k_{2b}$  is the ratio of reaction rate of  $\text{Cl}^-$  versus  $\text{NO}_3^-$  to  $\text{H}_2\text{ONO}_2^+$  that was set to 29  
378 (Bertram and Thornton, 2009). The mean values of particulate volume to surface ratio ( $V/Sa$ ) was  
379 measured. A simple parameterization (EJ05) considered the effect of enhanced RH and temperature  
380 on  $\text{N}_2\text{O}_5$  uptake was also included (Evans and Jacob, 2005). In addition, the recently established  
381 empirical parameterization based on the same framework (Eq. 8, named Yu20), optimized some  
382 parameters according to the meta-analysis of five field measurements in China by Yu et al. (2020),  
383 also assessed in the study. Figure 5(a) shows the correlation of estimated  $\gamma\text{N}_2\text{O}_5$  versus the  
384 parameterization. All the three parameterizations fail to predict the high values. The simple  
385 parameterization of EJ05 had the best performance with a high correlation and a consistent

386 prediction of the median value. While other two parameterizations, BT09 and Yu20, underestimated  
 387 the observed  $\gamma_{\text{N}_2\text{O}_5}$ . Figure 6(a-h) show the dependence of the observed  $\gamma_{\text{N}_2\text{O}_5}$  on the factors  
 388 reported in previous literatures that possibly alert the processes of  $\text{N}_2\text{O}_5$  uptake and  $\text{ClNO}_2$  formation.  
 389 We show that  $\gamma_{\text{N}_2\text{O}_5}$  highly correlated with the ambient RH as well as liquid water content,  
 390 confirming the critical role of water content in  $\text{N}_2\text{O}_5$  uptake and explained the reason why EJ05 had a  
 391 good performance. The dependence of  $\gamma_{\text{N}_2\text{O}_5}$  on nitrate mass concentration does not follows the rule  
 392 of nitrate suppressing effect (Wahner et al., 1998), which may be due to the covariance of nitrate and  
 393 liquid water content. With respect to other factors, insignificant impacts on the  $\text{N}_2\text{O}_5$  uptake are  
 394 obtained.

395  
 396 **Figure 5.** The inter-comparison of observation and parameterization of  $\text{N}_2\text{O}_5$  uptake coefficient (a)  
 397 and  $\text{ClNO}_2$  yield (b). The larger size of solid dots represents the median results. The parameterizations  
 398 of EJ05, BT09, Yu20 and BK97 cited from Evans and Jacob (2005), Bertram and Thornton (2009),  
 399 Yu et al. (2020), Behnke et al. (1997), respectively. The fitted  $\text{ClNO}_2$  yield (colored by black) in  
 400 panel (b) shows the best fitting result in the study by adopting the  $k_4/k_3$  of 32.0.

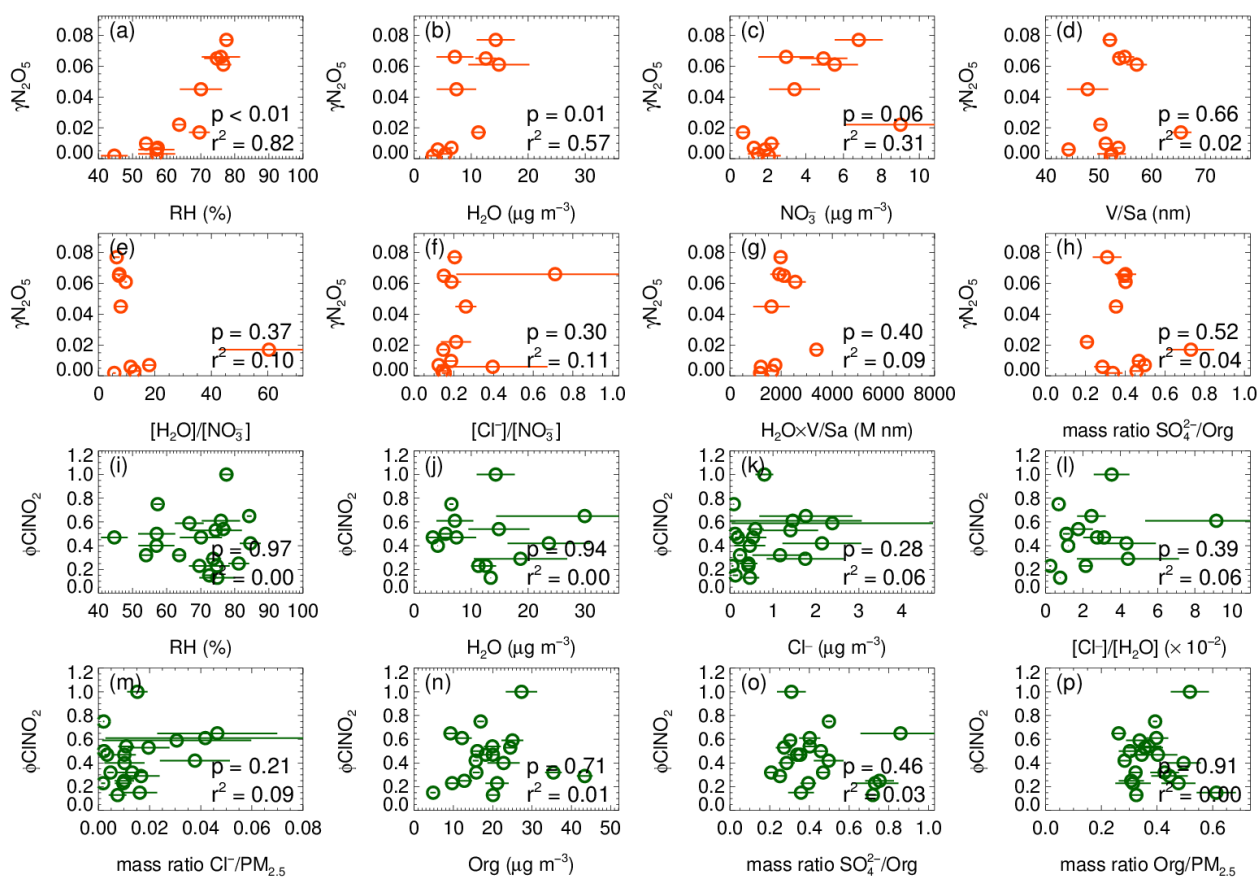

401 Bertram and Thornton (2009) also proposed a  $\text{ClNO}_2$  yield parameterization method that  
 402 considering the ratio of ALWC and chloride content (Eq. 9), here the  $k_4/k_3$  was the ratio of reaction

403 rate of  $\text{H}_2\text{ONO}_2^+$  versus  $\text{Cl}^-$  to  $\text{H}_2\text{O}$  and adopted as  $483 \pm 175$ . Behnke et al. (1997) determined this  
404 ratio of  $836 \pm 32$ , while it is estimated to be  $105 \pm 37$  in Yu et al. (2020).

$$405 \quad \varphi_{BT09} = \left( \frac{[\text{H}_2\text{O}]}{1+k_4/k_3[\text{Cl}^-]} \right)^{-1} \quad (9)$$

406 Figure 5(b) shows that all the predicting  $\text{ClNO}_2$  yield based on the abovementioned  
407 parameterizations overestimated the observations. The performance of the parameterization schemes  
408 of BK97 and BT09 based on the model aerosol conditions with an overestimation up to ~100% are  
409 expected and consistent with previous studies, which may be caused by the unaccounted potentially  
410 competitive effect of other species like organics, sulfate for the  $\text{NO}_2^+$  intermediate (McDuffie et al.,  
411 2018a; Staudt et al., 2019; Xia et al., 2021; Wang et al., 2017d). Although the empirical  
412 parameterization (Yu20) based on field observations improved the prediction and narrowed the gap  
413 effectively, the overestimation is still large with an average of ~50%, which indicated that the yield  
414 are more strongly suppressed in this study than those observed in the campaigns of Yu et al. (2020).  
415 The factor 32.0 ( $k_4/k_3$  in Eq. 9) was derived by iterative algorithms to achieve the best consistent  
416 between the observed and parameterized  $\text{ClNO}_2$  yield, which is smaller than the Yu20 parameters by  
417 factors of 3.3. We examined the relationships of  $\text{ClNO}_2$  yields with aerosol water content and other  
418 aerosol compositions as shown in Figure 6(i-p). We show that  $\varphi_{\text{ClNO}_2}$  only weakly correlated with  
419 the content of chloride (including the mass ratio and fraction in  $\text{PM}_{2.5}$ ) and the molar ratio of chloride  
420 to water, confirmed the dependence found in laboratory studies. However, we did not find the  
421 dependence of the yields with aerosol organic or sulfate, as well as the RH and water alone in the  
422 campaign, implying the  $\text{ClNO}_2$  yield mechanism is much more complicated than the laboratory  
423 conditions.

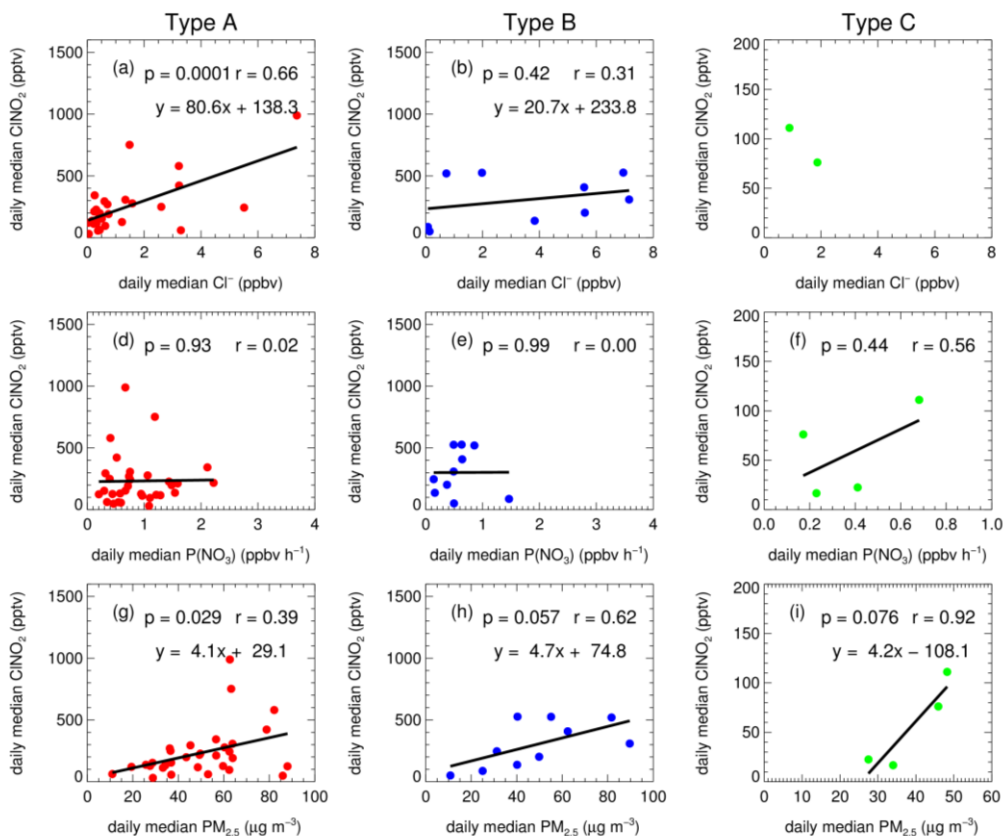

424

425 **Figure 6.** The estimated  $\text{N}_2\text{O}_5$  uptake coefficient and  $\text{ClNO}_2$  yield versus related parameters.

426 **3.4 The factors influence  $\text{ClNO}_2$  formation**

427 The  $\text{ClNO}_2$  formation can be largely affected by the budget of  $\text{NO}_3$ - $\text{N}_2\text{O}_5$  and  $\text{N}_2\text{O}_5$  uptake processes.  
 428 The variation of  $\text{NO}_3$  loss by VOC and NO alert the  $\text{NO}_3$  loss distribution by  $\text{N}_2\text{O}_5$  uptake and  
 429  $\text{ClNO}_2$  formation indirectly. Figure 7 shows the correlation between daily median  $\text{ClNO}_2$  and mass  
 430 concentration of chloride,  $\text{PM}_{2.5}$  and  $\text{NO}_3$  production rate for the three types of air masses. Due to the  
 431 limited dataset of type C, the correlation analysis may not make sense, therefore, we did not take  
 432 type C into consideration in detailed discussion. We show that the mass concentration of chloride  
 433 also showed a correlation coefficient with  $\text{ClNO}_2$  by 0.66 and 0.31 for type A and B, respectively.  
 434 Furthermore, the mass concentration of  $\text{PM}_{2.5}$  correlated reasonably with the  $\text{ClNO}_2$  formation with  
 435 the correlation coefficient of 0.39 and 0.62 for type A and B, respectively. But, the levels of  $\text{ClNO}_2$   
 436 demonstrate little relationship with the nitrate production rate. This is quite different from the results  
 437 observed in United Kingdom, where the  $\text{ClNO}_2$  levels are mainly controlled by  $\text{NO}_2$  and  $\text{O}_3$ , rather  
 438 than by the  $\text{N}_2\text{O}_5$  uptake processes (Sommariva et al., 2018).

439

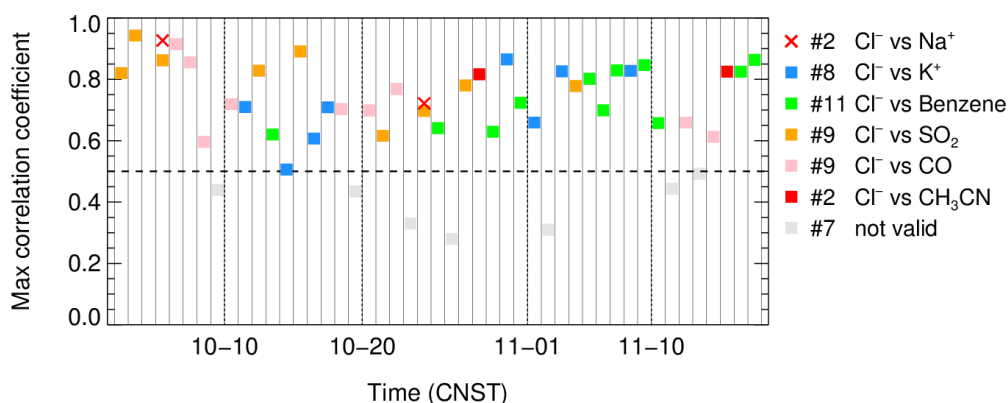

440 **Figure 7.** The functional dependence of daily median of ClNO<sub>2</sub> on particulate chloride, nitrate  
 441 radical production rate and PM<sub>2.5</sub> in the air mass of Type A (a, d, g), Type B (b, e, h) and Type C (c, f,  
 442 i).

443 The low correlation between ClNO<sub>2</sub> and NO<sub>3</sub> production rate is within expectations. In general,  
 444 the production of nitrate radical controls the total budget of N<sub>2</sub>O<sub>5</sub>, if N<sub>2</sub>O<sub>5</sub> uptake dominated the sink  
 445 of NO<sub>3</sub>, as the result the N<sub>2</sub>O<sub>5</sub> uptake and its products would show good correlation with NO<sub>3</sub>  
 446 production rate. But in fact, NO<sub>3</sub> loss can also be affected by other loss pathways, like the reactions  
 447 with NO and VOCs. In many cases, the NO<sub>3</sub> loss is dominated by VOC or NO, that means the  
 448 ClNO<sub>2</sub> formation is suppressed. If the two loss pathways are highly varied due to irregular emissions,  
 449 then the relationship between ClNO<sub>2</sub> and NO<sub>3</sub> production rate would be less correlated. We  
 450 confirmed large variations of NO and VOC (not shown) in hourly and daily scales, which means the  
 451 proportion of N<sub>2</sub>O<sub>5</sub> uptake to the total loss of NO<sub>3</sub> is highly varied correspondingly. In addition, the  
 452 variation of N<sub>2</sub>O<sub>5</sub> uptake coefficient and ClNO<sub>2</sub> yield also result in the weak correlation between  
 453 NO<sub>3</sub> production rate and ClNO<sub>2</sub> concentration. The weak correlation reflects the highly variable  
 454 chemical processes from NO<sub>3</sub> production to ClNO<sub>2</sub> production in this region.

455 As the precursor of ClNO<sub>2</sub>, higher concentrations of particulate chloride result in high ClNO<sub>2</sub>  
 456 yield from N<sub>2</sub>O<sub>5</sub> uptake to some extent, as evidenced by our field observation (Figure 6) and

457 previous laboratory studies (Bertram and Thornton, 2009; Roberts et al., 2009; Ryder et al., 2015).  
458 High  $PM_{2.5}$  concentrations usually provide more aerosol surface area to promote  $N_2O_5$  uptake. The  
459 close relationship between  $ClNO_2$  and  $PM_{2.5}$  indicate that aerosol surface area, most likely, is a  
460 critical factor that limited  $ClNO_2$  formation. The proportion of nitrate in the total  $PM_{1.0}$  was small  
461 with an average of 10.4%, therefore the correlation of  $ClNO_2$  and  $PM_{2.5}$  cannot attribute to the  
462 covariance between nitrate and  $PM_{2.5}$ . In addition, the  $ClNO_2$  level in the air mass of Type B show  
463 higher correlation to both  $Cl^-$  and  $PM_{2.5}$  than type A, suggesting that the  $ClNO_2$  formation in Type B  
464 is more effectively affected by the levels of chloride and  $PM_{2.5}$ .

465 Recently model simulation indicated that the  $ClNO_2$  chemistry level is sensitive to the emission of  
466 chloride in PRD (Li et al., 2021). In this study, a question raised that where is the source of chloride?  
467 The mass ratio of  $Cl^-/Na^+$  is often used as an indicator of sea salt or anthropogenic sources to  
468 chloride with a threshold of 1.81 (Yang et al., 2018; Wang et al., 2016). High ratio means the  
469 particulate chloride affected by anthropogenic emission rather than sea salt. We determine that the  
470 mean mass ratios of  $Cl^-$  to  $Na^+$  are 5.3, 6.3 and 3.1 in Type A, B and C, respectively (Figure 3). This  
471 indicated that  $PM_{2.5}$  sampled during the campaign was not strongly influenced by fresh sea salt  
472 aerosols. In the three types, the Type C air mass had a lowest ratio and may be influenced by both sea  
473 salt and anthropogenic emissions, which seems reasonable since it come from South China Sea. If  
474 we assume that Type A air mass is free of sea salt and only influenced by anthropogenic activities,  
475 the higher ratio implies more intensive chloride source in Type B. The correlation between  
476 particulate chloride and some possible indicators, including  $K^+$ , benzene,  $SO_2$ , CO, acetonitrile  
477 ( $CH_3CN$ ), were examined day by day. Figure 8 shows the max correlation coefficient ( $R^2$ ) in each  
478 day with a threshold of 0.5. We filtered out 39 out of 46 days during this campaign with a fraction of  
479 85%. Among the 39 days, a total of 11 days is associated with strongest correlation between  $Cl^-$  and  
480 benzene, which is typically come from industrial emissions.  $Cl^-$  also correlated with  $K^+$ , CO and  
481  $CH_3CN$  in 19 day in total, implies potential contributions from biomass burning emissions. In total of  
482 9 days for highest correlations of  $Cl^-$  with  $SO_2$  indicated coal-fired power plants emissions may also  
483 contributed to  $Cl^-$  emission. We summarized that the source of chloride may be highly varied from  
484 different anthropogenic activities including biomass burning, industrial processes as well as coal-  
485 fired power plants. The statistic results in Table 5 suggest that the  $Cl^-$  in air mass of Type A were  
486 affected by various sources, especially related to the sources associated with  $K^+$ , benzene and  
487  $CH_3CN$ ; the  $Cl^-$  in Type B was mainly contributed by the similar source of CO, and Type C was only  
488 affected by coal-fired power plants emissions. In addition, Figure 8 showed that there are 2 days that  
489 the correlations between  $Cl^-$  and  $Na^+$  exceeded the max of the selected anthropogenic factor matrix,  
490 indicated that the aerosol still also impacted by sea salt to some extent.

491

492 **Figure 8.** The max correlation coefficient between particulate chloride and a selected parameter  
 493 matrix (including  $K^+$ , benzene,  $SO_2$ , CO, acetonitrile ( $CH_3CN$ )) in each day. The labelled number in  
 494 each legend indicates the days be the maximum, the dashed line denotes the threshold of 0.5 (39  
 495 valid days out of 46 in total). The cross means the correlation coefficient between  $Cl^-$  and  $Na^+$  is  
 496 larger than the max.

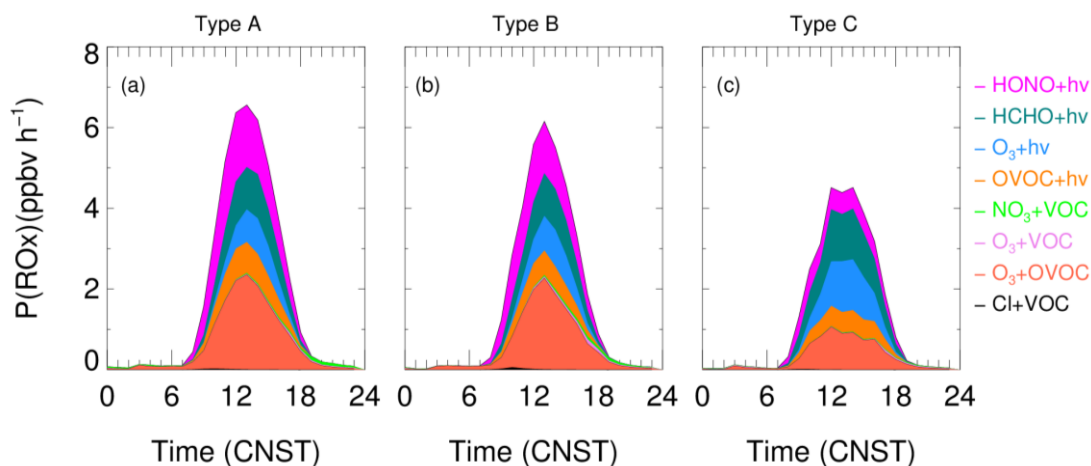

497 **Table 5.** The statistic of the days for highest factors correlated with particulate chloride in different  
 498 air mass pattern.

Factors	Type A	Type B	Type C
$K^+$	8	0	0
Benzene	9	2	0
$SO_2$	5	1	3
CO	4	5	0
$CH_3CN$	2	0	0

### 499 3.5 The impacts of $ClNO_2$ on atmospheric oxidation

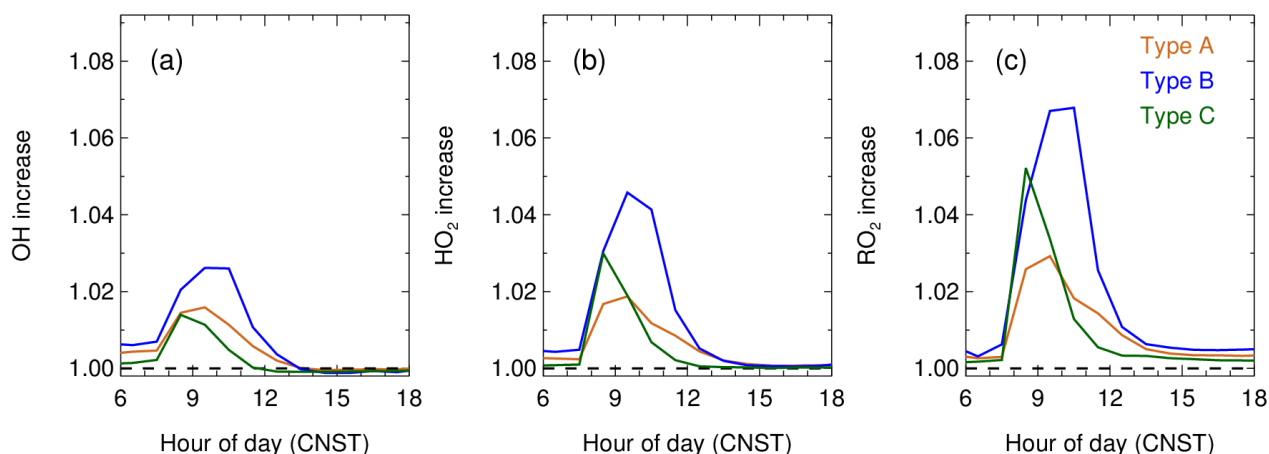

500 In this section, we focus on the assessment of the impact of  $ClNO_2$  photolysis on the source of  
 501 radicals and the contribution to the atmospheric oxidation. Figure 9 shows the diurnal accumulation  
 502 of  $RO_x$  production rate from model simulations with  $ClNO_2$  chemistry in the three types of air mass.  
 503 The total  $RO_x$  production rate was higher in Type A and then followed by Type B and C, in which  
 504 photolysis of HONO, HCHO,  $O_3$  and OVOCs had large contributions. In addition, we noticed that  
 505 the significant role of OVOCs (including photolysis and react with  $O_3$ ) in producing  $RO_x$  at this site,  
 506 especially in the Type A and B air mass. This result is consistent with that constrained by observed  
 507 OVOCs in Guangzhou City (Wang et al., 2022c). Cl radical, liberated by  $ClNO_2$ , enhanced little  $RO_x$   
 508 production, with a morning peak contribution of 1.3%, 2.2% and 1.8% for Type A, B, C, respectively  
 509 (08:00-09:00). The contribution of  $ClNO_2$  photolysis to the production of  $RO_x$  is less than 1% on  
 510 daytime average, similar to the results obtained in winter Shanghai (Lou et al., 2022) as well as  
 511 North China (Xia et al., 2021), and much lower compared to previous studies reported in summer

512 time in China (Tan et al., 2017; Tham et al., 2016). However, another winter campaign conducted in  
 513 Hongkong in winter showed much more significant impacts compared with our observation (Wang et  
 514 al., 2016), indicated that the ClNO<sub>2</sub> chemistry can also had a large influence on the radical formation  
 515 in wintertime.

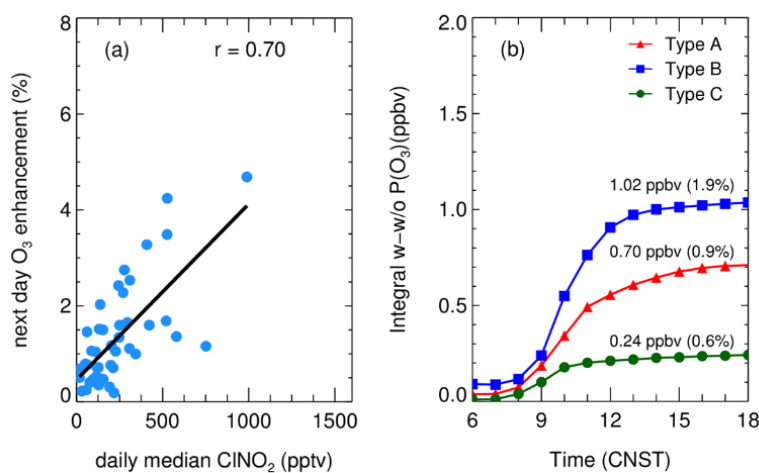

516  
 517 **Figure 9.** The diurnal cycle and distribution of ROx production rate in the three types air masses.

518 Figure 10 shows the enhancement of OH, HO<sub>2</sub> and RO<sub>2</sub> radicals with the consideration of ClNO<sub>2</sub>  
 519 chemistry. The enhancement of the three radicals peaked in the morning. On average, OH  
 520 concentration was enhanced by 1.5% to 2.6% in different air masses. The percentage of enhancement  
 521 for HO<sub>2</sub> radical was 1.9% to 4.6%, whereas the enhancement for RO<sub>2</sub> was a little bit higher (3.0% to  
 522 6.8%). In general, the enhancement of radicals was more significant in Type B than other two types  
 523 of air masses, which is related to elevated ClNO<sub>2</sub> concentrations for these air masses. Low ClNO<sub>2</sub>  
 524 and other radical precursors led to an earlier enhancement peak (08:00-09:00) in Type C and lasted a  
 525 short time period. Although the increase peak occurred later at 09:00-10:00 for the air mass of Type  
 526 A and Type B, the increase lasted for a longer time and had a longer effect. Overall, daytime OH,  
 527 HO<sub>2</sub> and RO<sub>2</sub> enhanced by 1.0%, 2.0%, and 3.0% on campaign average.

528  
 529 **Figure 10.** The diurnal cycle on the enhancement of OH (a), HO<sub>2</sub> (b), RO<sub>2</sub> (c) by CINO<sub>2</sub> chemistry  
 530 in the three air mass patterns.

531 Figure 11 depicts the integral enhancement of O<sub>3</sub> production by CINO<sub>2</sub> photolysis varied from less  
 532 than 0.1 ppb to 4 ppb day by day, with a percentage of <1% to 4.9% with a median of 0.8%. Our  
 533 results are comparable with the winter case in North China (Xia et al., 2021). The next day O<sub>3</sub>  
 534 enhancement was highly correlated with the level of CINO<sub>2</sub> with the correlation coefficient of 0.7  
 535 (Fig. 11(a)). The daily net O<sub>3</sub> production enhanced by 0.70 ppbv (0.9%), 1.02 ppbv (1.9%), 0.24  
 536 ppbv (0.6%) on daytime accumulation in Type A, B, C, respectively, which is consistent with the  
 537 nocturnal level of CINO<sub>2</sub> in the three air masses presented in Table 3.

538  
 539 **Figure 11.** (a) The correlation of daily median CINO<sub>2</sub> (18:00-06:00) and its impact on next day net  
 540 O<sub>3</sub> production enhancement during the campaign; (b) the average contribution of daytime integral O<sub>3</sub>  
 541 by CINO<sub>2</sub> mechanism in the three types of air masses.

542 Table 6 summarized the observation-constrained box model simulation results about the impacts  
 543 of CINO<sub>2</sub> chemistry. The average CINO<sub>2</sub> concentration in the observation is moderate compared with

544 previous observations, other radical precursors (e.g., HCHO) also elevated at the same time. This  
 545 leads to a large total radical and ozone production rate and relative minor contribution by ClNO<sub>2</sub>  
 546 chemistry. Which indicates that the contribution of ClNO<sub>2</sub> chemistry is affected by the budget of  
 547 other radical precursors. In addition, significant contribution by ClNO<sub>2</sub> chemistry to photochemical  
 548 pollution also frequently observed in different campaigns (Tham et al., 2016; Wang et al., 2016), in  
 549 which the receptor site may have aging plumes with higher ClNO<sub>2</sub> and thus larger contributions  
 550 (Wang et al., 2016), suggests the large variability of ClNO<sub>2</sub> and its environmental impacts at various  
 551 air masses. Here, our observations should be representative of the local condition and reflects the  
 552 chemistry and impacts of ClNO<sub>2</sub> on the air pollutions in PRD region.

553 **Table 6.** The summary of impacts of ClNO<sub>2</sub> on the next-day enhancement of ozone and radical  
 554 production based on box model that constrained by field observations in previous literatures.

Location	Duration	ClNO <sub>2</sub> peak (ppb)	Daytime average Enhancement P(O <sub>3</sub> )	Daytime average Enhancement P(RO <sub>x</sub> )	References

555 Note: <sup>a</sup> used box model to estimate the following evolution after the plume passing measurement site  
 556 and the impacts on the next day air quality; <sup>b</sup> not constrained the observed ClNO<sub>2</sub> concentration but  
 557 simulated the observed maximum ClNO<sub>2</sub> case (1.5 ppbv ClNO<sub>2</sub>) to predict the corresponding upper  
 558 contribution.

559 Previous studies suggest that chlorine radicals from ClNO<sub>2</sub> photolysis may contribute significantly  
 560 to the oxidation of some VOCs species, especially for long-chain alkanes (Shi et al., 2020; Wang et  
 561 al., 2022b). The oxidation of long-chain alkanes (C<sub>10</sub>~14 n-alkanes) by chlorine and OH radicals  
 562 during the morning hour (09:00-10:00) were also evaluated based on modeled oxidants concentration.  
 563 We observe small contributions of chlorine radical with a percentage of 4.3%, 4.3% and 3.8% for n-  
 564 decane, n-dodecane, and n-tetradecane, respectively, during the period (Oct. 16<sup>th</sup> to Nov. 17<sup>th</sup>, 2019)  
 565 when the long-chain alkanes measurement was valid. We also checked the role of chlorine radicals in  
 566 short-chain alkanes oxidation, obtaining a slightly larger contribution than the long-chain alkanes,  
 567 which is attributed to a relatively larger reaction rate constants between Cl with OH with respect to

568 the short-chain alkanes. The daytime average contributions of Cl ranged from 1.4% - 1.6% varied by  
569 the chain length of the alkanes. Therefore, we concluded that chlorine radicals liberated by ClNO<sub>2</sub>  
570 photolysis play a role in the oxidation of alkanes in the morning time, but are not critical compared  
571 with OH oxidation on the daytime average. We note that several studies reported other sources  
572 produced a large number of halogen radicals like Cl<sub>2</sub> (Liu et al., 2017; Xia et al., 2020), BrCl (Peng  
573 et al., 2021), the daytime reaction of HCl with OH (Riedel et al., 2012; Eger et al., 2019; Li et al.,  
574 2019). These may cause more alkanes oxidized by halogen radicals. However, it is not possible to  
575 assess the overall impacts by constraining all precursors of chlorine radical in this work, which may  
576 warrant further investigation by more comprehensive field studies equipped with the instruments for  
577 detecting these species.

#### 578 **4. Conclusion**

579 An intensive field study in Pearl River Delta took place during a photochemical pollution season  
580 from Sept. 26<sup>th</sup> to Nov. 17<sup>th</sup>, 2019, providing a comprehensive observation dataset to understand the  
581 ClNO<sub>2</sub> chemistry and its impacts on the air quality. We observed a wide variation for determining  
582 factors of ClNO<sub>2</sub> formation in different kinds of air masses. Two types of air mass from northern and  
583 northeastern inland cities and the eastern coastal regions, features polluted with elevated O<sub>3</sub> and  
584 related trace gases like NO<sub>x</sub> and CO. Correlation analysis showed that ClNO<sub>2</sub> formation is limited by  
585 chloride availability and PM<sub>2.5</sub> concentrations (mostly due to aerosol surface area) at this site.

586 We estimated the N<sub>2</sub>O<sub>5</sub> uptake coefficients and ClNO<sub>2</sub> yield during this campaign and assessed the  
587 performance of previous parameterizations schemes. The newly developed observation-based  
588 empirical parameterization was also checked and showed an overall underestimation. We showed the  
589  $\gamma$ N<sub>2</sub>O<sub>5</sub> only strongly correlated with RH, and the parameterization proposed by Evans and Jacob  
590 (2005) showed a considerable consistent with the observation. The ClNO<sub>2</sub> yield only showed weak  
591 correlation with the content of particle chloride, and the exist parameterizations systematically  
592 overestimated the yield. The particulate chloride mainly originated from anthropogenic emissions  
593 rather than sea salt. However, the specific contributing source of chloride in this region cannot be  
594 determined, due to the varying correlation relationship with different kinds of anthropogenic  
595 emission indicators day by day. This result highlights the ClNO<sub>2</sub> chemistry may be triggered by  
596 many kinds of anthropogenic activities in the PRD regions (Wang et al., 2016; Yang et al., 2018).

597 Observation-constrained box model revealed chlorine radicals liberated by ClNO<sub>2</sub> chemistry had a  
598 relatively small contribution to the following daytime level of RO<sub>x</sub> radicals and O<sub>3</sub> in this region. The  
599 small contribution of ClNO<sub>2</sub> chemistry in PRD region may be due to the limited ClNO<sub>2</sub> produced by  
600 N<sub>2</sub>O<sub>5</sub> uptake processes, and other strong primary sources of radicals weakened its contribution

601 indirectly. Given complex source of particulate chloride, we call for more field investigations to  
602 address the chlorine chemistry and its roles in air pollutions in China.

603 **Data availability.** The datasets and code used in this study are available from the corresponding  
604 author upon request (byuan@jnu.edu.cn).

605 **Author contributions.** H.C.W. and B.Y. designed the study. E.Z, X.X.Z. and H.C.W. operated and  
606 calibrated the CIMS, H.C.W. analyzed the data, H.C.W. and B.Y. wrote the manuscript with inputs  
607 from all coauthors.

617 Laboratory for providing the HYSPLIT model.

## 618 **Appendix**

### 619 **A1. The measurement background and calibration of CIMS**

620 The background measurement of ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> was performed during the campaign. Figure 1A  
621 showed an example of the background check at the beginning of the campaign, which confirmed the  
622 negligible background signal in the measurement of ClNO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub> in the ambient condition. The  
623 calibration of ClNO<sub>2</sub> measurement sensitivity has been introduced in Wang et al. (2022a). In brief, a  
624 nitrogen flow (6 mL min<sup>-1</sup>) containing 10 ppmv Cl<sub>2</sub> was passed over a slurry containing NaNO<sub>2</sub> and  
625 NaCl to produce ClNO<sub>2</sub> (Thaler et al., 2011), and NaCl was included in the slurry in order to  
626 minimize the formation of NO<sub>2</sub> as a byproduct. The mixed flow containing ClNO<sub>2</sub> was then

627 conditioned to a given RH and sampled into the CIMS instrument. To quantify ClNO<sub>2</sub>, the mixed  
628 flow was delivered directly into a cavity attenuated phase shift spectroscopy instrument (CAPS,  
629 Model N500, Teledyne API) to measure background NO<sub>2</sub> concentrations or through a thermal  
630 dissociation tube at 365 °C to fully decompose ClNO<sub>2</sub> to NO<sub>2</sub>, and the total NO<sub>2</sub> concentrations were  
631 then determined using CAPS. The differences in the measured NO<sub>2</sub> concentrations with and without  
632 thermal dissociation was equivalent to ClNO<sub>2</sub> concentrations. The CAPS instrument had a detection  
633 limit of 0.2 ppbv in 1 min for NO<sub>2</sub> and an uncertainty of ~10%. To calibrate CIMS measurements of  
634 N<sub>2</sub>O<sub>5</sub>, a humidity adjustable mixed flow containing stable N<sub>2</sub>O<sub>5</sub>, which was produced via O<sub>3</sub>  
635 oxidation of NO<sub>2</sub>, was sampled into the CIMS instrument to obtain a normalized humidity  
636 dependence curve of N<sub>2</sub>O<sub>5</sub>. While the concentration of N<sub>2</sub>O<sub>5</sub> source is not quantified due to the  
637 absence of a N<sub>2</sub>O<sub>5</sub> detector, so we delivered the N<sub>2</sub>O<sub>5</sub> source flow through a supersaturated sodium  
638 chloride solution to convert N<sub>2</sub>O<sub>5</sub> to ClNO<sub>2</sub> with a unit efficiency at 50% RH, which is a widely used  
639 method for the calibration of ClNO<sub>2</sub> by CIMS technique. The absolute N<sub>2</sub>O<sub>5</sub> sensitivity at 50% RH  
640 can be realized and then scaled to other humidity condition by the normalized N<sub>2</sub>O<sub>5</sub> sensitivity curve  
641 determined before. The sensitivity curves for N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> to water content were shown in  
642 Figure A2. In this study, the sensitivity of the instrument was calibrated after the campaign. The main  
643 parameters (pressure: voltages, etc.) of the CIMS were checked every day and were relatively stable,  
644 indicating that the CIMS is operating stably during the campaign.

645 Figure A3 shows the high-resolution peak fitting results of typical mass spectra at m/z 235 and m/z  
646 208 for N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> in three air mass patterns, respectively. The peaks of N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> were  
647 clearly resolved in the mass spectra. The peak of IN<sub>2</sub>O<sub>5</sub><sup>-</sup> can be well retrieved by separating a large  
648 adjacent peak of C<sub>2</sub>H<sub>4</sub>IO<sub>3</sub>S<sup>-</sup> in the air masses affected by marine emissions (Type B and C), which  
649 might be hydroperoxymethyl thioformate (HPMTF) from dimethyl sulfide oxidation (Veres et al.,  
650 2020). The interference signals including H<sub>3</sub>INO<sub>2</sub>S<sup>-</sup> for ClNO<sub>2</sub> measurements can also be well  
651 separated in all the three air mass patterns. These results underline the necessity and feasibility in the  
652 application of ToF analyzer in detecting N<sub>2</sub>O<sub>5</sub> and ClNO<sub>2</sub> with iodide CIMS.

653
